The effects of ortho, meta, and para structural arrangements on the antiknock performance of phenyl alkyl ethers are illustrated in figure V-4 (d). The basic ether for this particular example is methyl phenyl ether (anisole), which is shown on the left side of the figure. The addition of a carbon atom to the benzene ring to form *o*-methylanisole caused a decrease in performance. Adding a carbon atom in the meta or para position to form *m*-methylanisole and *p*-methylanisole slightly increased the antiknock performance. In each engine, *m*-methylanisole and *p*-methylanisole were about equal in performance number and both were considerably better than *o*-methylanisole. This result was similar to that obtained for the aromatics (figs. V-3 (e) to V-3 (g)).

Several ethers containing olefinic radicals are shown in figure V-4 (e). Isopropyl methallyl ether and *tert*-butyl methallyl ether blends had the highest performance numbers of this group of compounds and phenyl methallyl ether the lowest. At A. S. T. M. Aviation and A. S. T. M. Supercharge conditions, phenyl methallyl ether was the poorest of the 22 ethers examined.

Hydrogenating the benzene nucleus of anisole to give methyl cyclohexyl ether is shown in figure V-4 (f) to produce a large drop in performance number. Of the three methyl cycloalkyl ethers shown, all of which were relatively low, methyl cyclopropyl ether was the highest at A. S. T. M. Supercharge conditions and methyl cyclopentyl ether was highest at A. S. T. M. Aviation conditions.

The relative antiknock characteristics of all the ethers investigated are presented in figure V-4 (g) at A. S. T. M. Aviation (lean) conditions. Under these conditions only the three *tert*-butyl alkyl ethers raised the knock limit of the base fuels. The maximum improvement in performance number was 29 and was obtained with isopropyl *tert*-butyl ether.

The antiknock characteristics of all the ethers investigated are compared in figure V-4 (h) at A. S. T. M. Supercharge (rich) conditions. Twelve of the ethers improved the performance of the base fuel; the greatest increase in knock-limited performance, about 63 performance numbers, was obtained with methyl *tert*-butyl ether. Comparison of figures V-4 (g) and V-4 (h) clearly shows that nine of the phenyl alkyl ethers have much better antiknock characteristics at rich mixtures than at lean mixtures. It is also apparent that the methyl cycloalkyl ethers show little promise as antiknock blending agents at the A. S. T. M. Aviation and A. S. T. M. Supercharge conditions.

Comparison of classes of compounds.—As a matter of interest, the isomers having the highest antiknock ratings in figures V-1, V-3 (i), V-3 (j), V-4 (g), and V-4 (h) have been plotted in figure V-5. The performance numbers have been plotted against boiling points in order to illustrate the most promising antiknock compounds in the boiling range of commercial gasolines. Comparison of the curves in figure V-5 is not strictly valid, inasmuch as all the isomers in a given group of compounds have not been studied. Within the limitations of the investigation, however, these two figures do illustrate how the antiknock characteristics of the better paraffins, aromatics, and ethers compare.

When the boiling range of aviation gasoline is assumed to be 100° to 338° F, it is seen (fig. V-5 (a)) that for A. S. T. M. Aviation lean conditions the C₅ and C₆ paraffins have the highest performance numbers in the boiling range from 80° to 120° F. In the boiling range between 130° and about 300° F, the ethers have the highest performance numbers. Above 300° F the highest performance numbers were obtained with the aromatic blends.

At A. S. T. M. Supercharge conditions (fig. V-5 (b)), the paraffin blends had the highest performance numbers in the range of boiling temperatures from 80° to 120° F. Above 120° F the ethers had the highest antiknock ratings up to a boiling temperature of 220° F. At higher boiling temperatures the aromatics exhibited superior antiknock characteristics.

FIGURE V-5.—Comparison of isomers having highest antiknock values in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

BLENDING CHARACTERISTICS

In the preceding section, the discussion of structural trends was based on studies in which 25 percent of a given compound was blended with a selected base fuel. On the basis of such studies, it can be concluded that one compound is better than another or that all compounds align themselves in an order of antiknock performance that is influenced by engine operating conditions. This situation is complicated, however, in that the relative order of antiknock value of a series of compounds at a fixed engine condition is influenced by the concentration of the compound in the blends upon which such an investigation is based. In other words, one compound could be better than another if both were compared in 25-percent blends but the reverse could be true if both were compared in 50-percent blends.

Blending characteristics of various potential aviation-fuel blending agents have been the subject of considerable investigation. A portion of the more recent findings in such studies is reported in references 17 to 20. The results of these investigations show conclusively that compounds differ radically in their blending behavior as regards antiknock performance.

Paraffins.—The blending characteristics of paraffinic fuels at rich fuel-air ratios may be expressed by the following equation (see chapter VIII):

$$\frac{1}{P_b} = \frac{N_1}{P_1} + \frac{N_2}{P_2} + \frac{N_3}{P_3} + \dots \quad (1)$$

where

$N_1, N_2, N_3, \dots$ mass fractions of components 1, 2, 3, $\dots$, respectively, in blend

P_b knock-limited indicated mean effective pressure of blend

$P_1, P_2, P_3, \dots$ knock-limited indicated mean effective pressures of components 1, 2, 3, $\dots$, respectively

The application of this equation to data in the present investigation is illustrated in figure V-6 (a) for the A. S. T. M. Supercharge engine. The ordinate of this figure is a reciprocal scale and the abscissa is linear. For the fuels shown, 2,2,3,4-tetramethylpentane, 2,3,3,4-tetramethylpentane, and 2,2,3-trimethylbutane, the blending relation with the base fuel is linear up to a concentration of 50 percent added paraffin. Knock-limited indicated mean effective pressures (fig. V-6 (a)) for 2,2,3,4-tetramethylpentane and 2,3,3,4-tetramethylpentane are from reference 12. Similar data for 2,2,3-trimethylbutane are from reference 11.

Although data for these fuels at lean fuel-air ratios are not shown herein, an examination of such data indicated that the blending relation is nonlinear. The authors of reference 17 attribute this fact to the variation of the end-gas temperature from one blend to another. That is, for a system in which a paraffinic blending agent is blended with a paraffinic base stock, the relation between the reciprocal of the knock-limited performance and the composition will be linear if the end-gas temperature, or a wall temperature closely related to the end-gas temperature, is held constant for each blend tested.

Olefins.—Blending data for two olefins (reference 12) are shown in figure V-6 (b) for the A. S. T. M. Supercharge engine operating at a rich fuel-air ratio. In this case, olefinic

FIGURE V-5.—Concluded. Comparison of isomers having highest antiknock values in blend with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-6.—Knock-limited performance of blends with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

blending agents are blended with a paraffinic base fuel and the resulting relation between the reciprocal of the knock-limited performance and composition is nonlinear. The blending equation (1) is based upon one assumption, that for the equation to apply the blends should be tested at a constant percentage of excess of fuel or air. The differences between stoichiometric fuel-air ratios for olefins and paraffins, however, do not appear sufficiently great to explain the non-linearity of this blending curve.

Aromatics.—The blending relations for the aromatic hydrocarbons (fig. V-6 (c)), like those of the olefins (fig. V-6 (b)), were found to be nonlinear in the A. S. T. M. Supercharge engine at rich mixtures. With the exception of 1,2-dimethylbenzene and 1,2,4-trimethylbenzene, all the aromatics increased the knock-limited performance of the base fuel at the concentration investigated.

It has previously been mentioned that the concentration level at which compounds are examined may have considerable effect on the relative order of antiknock rating, as shown

in figure V-6 (c) for isopropylbenzene. For example, a blend of 50 percent by volume of isopropylbenzene has the second highest antiknock rating of the aromatics investigated; at concentrations below 35 percent by volume, however, the performance of isopropylbenzene is exceeded by that of 1,3-dimethylbenzene, 1,3-diethylbenzene, 1-ethyl-4-methylbenzene, and *n*-propylbenzene.

This result can perhaps be seen a little more clearly in figure V-7 (b), in which the blending data for the A. S. T. M. Supercharge engine are illustrated by a bar chart. The hydrocarbons are listed on this chart in order of decreasing antiknock rating, as determined by the 50-percent blends. At lower concentrations, however, the bars indicate a different order of rating.

At A. S. T. M. Aviation conditions (fig. V-7 (a)), the variation of knock-limited performance with composition was found to be different from that obtained at A. S. T. M. Supercharge conditions (figs. V-6 (c) and V-7 (b)). For example, the data presented in figure V-7 (a) indicate that the knock-limited performance of the base fuel is decreased as the concentration of aromatic is increased. Moreover, in figure V-7 (a) the aromatics do not rate in the same order at all concentrations.

Ethers.—Blending data for six ethers determined at A. S. T. M. Supercharge conditions are shown in figure V-8 (b). Methyl *tert*-butyl ether and ethyl *tert*-butyl ether have the highest antiknock characteristics of the six ethers at all concentrations. Isopropyl *tert*-butyl ether is also better than the three aromatic ethers at a concentration of 50 percent; however, at concentrations below about 20 percent, isopropyl *tert*-butyl ether is lower than any of the other ethers.

The ethers shown in figure V-8 (b), like the olefins and aromatics, do not follow the reciprocal blending relation defined by equation (1).

FIGURE V-6.—Continued. Knock-limited performance of blends with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

FIGURE V-8.—Concluded. Comparison of knock-limited performance of ether blends with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon.

The blending relations for the ethers in figure V-8 (b) were investigated at A. S. T. M. Aviation conditions and the results obtained are presented in figure V-8 (a). At these conditions, the three *tert*-butyl alkyl ethers all improved the knock-limited performance of the base fuel; the improvement became greater as concentration was increased. On the other hand, the three aromatic ethers decreased the performance of the base fuel; the decrease became greater as the concentration was increased.

TEMPERATURE SENSITIVITY

In order to determine the effects of changes of inlet-air temperature on knock-limited performance, most of the hydrocarbons and ethers were evaluated in the 17.6 engine at inlet-air temperatures of 100° and 250° F. These tests were made with each compound in 20-percent-by-volume blends with isooctane. The final blends were evaluated at both temperatures in the unleaded state and with 4 ml TEL per gallon. (See appendix A, tables A-3 and A-4, respectively.) The greatest portion of the temperature-sensitivity studies of this investigation was conducted on blends with

FIGURE V-9.—Temperature sensitivity of blends with isooctane. Compression ratio, 7.0; engine speed, 1800 rpm; coolant temperature, 212° F; spark advance, 30° B. T. C.

isooctane. A few experiments, however, were made in which the compounds were blended with the mixed base fuel. (See appendix A, table A-5.)

The term "temperature sensitivity" has been given several definitions by investigators in the field of fuel research; however, none of these definitions has been wholly satisfactory. Perhaps the data offering the most scientific approach to such a definition are reported in references 21 to 24, but the emphasis in these references is placed upon engine severity rather than the more restricted idea of temperature sensitivity; that is, engine severity is a more inclusive term that considers other factors of engine performance such as compression ratio, spark advance, engine speed, and cooling, as well as inlet-air temperature.

Considerable experimental data are required in order to evaluate fully the engine severity as described in references 21 to 24 and in most cases during the present investigation the available quantities of the pure fuels were too small for

(b) Paraffins; leaded to 4 ml TEL per gallon.

FIGURE V-9.—Continued. Temperature sensitivity of blends with isooctane. Compression ratio, 7.0; engine speed, 1800 rpm; coolant temperature, 212° F; spark advance, 30° B. T. C.

extensive studies. For this reason, the sensitivity studies of these fuels to changes of engine conditions were restricted merely to measurements of the effect of inlet-air temperature on knock-limited performance. In so doing it was necessary to establish arbitrarily a definition for temperature sensitivity. This term is defined by the following equation:

$$\text{Relative temperature sensitivity} = \frac{\text{knock-limited imep of blend (inlet air at 100° F)}}{\text{knock-limited imep of base fuel (inlet air at 100° F)}} \div \frac{\text{knock-limited imep of blend (inlet air at 250° F)}}{\text{knock-limited imep of base fuel (inlet air at 250° F)}}$$

The term "relative" is used in this definition as the equation essentially describes the temperature sensitivity of the blend relative to that of the base fuel. This definition is the same as that used in references 5 to 11 and 13. The base fuels used in this study were paraffins and do not show high temperature sensitivity.

Temperature sensitivities computed by this equation for all the compounds in the present investigation are presented in appendix A, table A-6. In the discussion of temperature sensitivity in the following paragraphs and in the subsequent discussion of lead susceptibility, it should be remembered that the data were obtained over a long period of time and reproducibility errors therefore exist. Although no extensive reproducibility data were obtained, a few such runs indicated that relative temperature sensitivities computed by the equation and relative lead susceptibilities computed by a similar equation may be in error by ± 0.05 .

Paraffins.—The temperature sensitivities of unleaded and leaded paraffinic fuel blends in the 17.6 engine at two fuel-air ratios are compared in figures V-9 (a) and V-9 (b). Of the paraffinic blending agents investigated (references 12 and 13), the three nonanes, 2,3,3,4-tetramethylpentane, 2,2,3,4-tetramethylpentane, and 2,2,3,3-tetramethylpentane, appear to be most sensitive to changes of inlet-air temperature at the lean fuel-air ratio in unleaded blends (fig. V-9 (a)). At the rich fuel-air ratio, however, the differences in temperature sensitivities among the paraffins are small.

In figures V-9 (a) and V-9 (b), the paraffins are listed in the same order. Inspection of these plots illustrates that tetraethyl lead affects temperature sensitivity. For example, in figures V-9 (a) and V-9 (b) the order of temperature sensitivities of the various paraffins is obviously different at both fuel-air ratios.

As previously mentioned, a few of the compounds in this investigation were examined in blends with the mixed base fuel. In the investigation of reference 13, paraffinic and olefinic blending agents in blends with the mixed base fuel were subjected to variations of compression ratio. When these data are computed in the manner explained in references 23 and 24, it is possible to compare over a reasonably wide range the influence of engine severity on knock-limited performance. This effect is determined by computation of compression-air densities and compression temperatures at the knock limit; the main assumption is that these factors are related in some manner to end-gas densities and temperatures that cannot be directly measured (reference 21). compression-air densities and temperatures are calculated by the following equations:

$$\rho_c = \frac{W_0 (r-1)}{i V_d} \quad (2)$$

$$T_c = T_0 r^{\gamma-1} \quad (3)$$

where

ρ_c compression-air density, pounds per cubic inch

W_0 intake-air flow, pounds per minute

r compression ratio

i intake cycles per minute

V_d engine displacement volume, cubic inches

T_c compression-air temperature, °R

T_0 intake-air temperature, °R

γ ratio of specific heat of charge at constant pressure to that at constant volume (assumed to be 1.4)

Although the data in reference 13 were determined by varying the compression ratio, it is apparent from the equation of compression temperature that the effect of varying the compression ratio is equivalent to that of varying the intake-air temperature.

The sensitivities of two paraffinic fuels (reference 13) are shown in figures V-10 (a) and V-10 (b) at two fuel-air ratios in a modified A. S. T. M. Supercharge engine. The two paraffin blends are more sensitive than the base fuel to changes of compression ratio or intake-air temperature, as indicated by the slopes of the curves in figures V-10 (a) and V-10 (b). The two paraffin blends had lower knock limits than the base fuel at severe conditions (high compression temperatures), but higher limits at mild conditions (low compression temperatures).

Olefins.—Plots similar to those in figures V-10 (a) and V-10 (b) are shown in figures V-10 (c) and V-10 (d) for

(a) Paraffins; lean conditions.

FIGURE V-10.—Effect of compression temperature on compression-air density for blends with mixed base fuel consisting of 87.5 percent isooctane and 12.5 percent *n*-heptane+4 ml TEL per gallon. three olefins in blends with the mixed base fuel (reference 13). At both fuel-air ratios, the three olefin blends were more sensitive to a change of engine severity than the base fuel. At the severe conditions the three olefin blends had lower knock limits than did the base fuel, but at milder conditions the olefin blends had higher knock limits.

Aromatics.—The temperature sensitivities of aromatic blends determined in the 17.6 engine are shown in figures V-9 (c) and V-9 (d). The aromatics are listed in figure V-9 (c) in the order of decreasing sensitivity at the rich fuel-air ratio. As in the case of paraffins (figs. V-9 (a) and V-9 (b)), the sensitivities were inconsistent from one fuel-air ratio to another. Moreover, the sensitivities were influenced by tetraethyl lead.

The most sensitive aromatics at the rich fuel-air ratio (fig. V-9 (c)) were 1,3-dimethylbenzene, 1-methyl-4-isopropylbenzene, and *tert*-butylbenzene; whereas at the lean fuel-air ratio, a number of aromatics had high sensitivities. In leaded blends (fig. V-9 (d)), the differences in relative temperature sensitivity among the aromatics were not great at the rich fuel-air ratio, but at a lean fuel-air ratio appreciable differences occurred. At the lean fuel-air ratio, a number of the aromatics had sensitivities 20 to 25 percent greater than the sensitivity of the base fuel.

It has been shown herein that 1,3,5-trimethylbenzene and *tert*-butylbenzene had higher performance numbers than the other aromatics investigated at the lean condition of the A. S. T. M. Aviation method (fig. V-3 (i)). For this reason the temperature sensitivities of these two aromatics are of particular interest. These two aromatics in unleaded blends have temperature sensitivities equal to or greater than sensitivities of the other aromatics investigated at the lean fuel-

air ratio (fig. V-9 (c)). On the other hand, the leaded blends shown in figure V-9 (d) indicate that the temperature sensitivity of *tert*-butylbenzene is reduced considerably, whereas 1,3,5-trimethylbenzene is still quite sensitive.

Similarly, among the better aromatics at A. S. T. M. Supercharge conditions (fig. V-3 (j)) were 1,3-dimethyl-5-ethylbenzene, 1-methyl-3,5-diethylbenzene, 1-methyl-4-*tert*-

butylbenzene, and 1,3,5-triethylbenzene. As indicated in figure V-9 (c) for unleaded blends at a rich fuel-air ratio, these four aromatics show only moderate temperature sensitivity varying between 1.0 and 1.05. In leaded blends (fig. V-9 (d)) and at a rich fuel-air ratio, the four aromatics still exhibited only moderate temperature sensitivity varying between 1.0 and 1.05.

FIGURE V-11.—Comparison of isomers having highest temperature sensitivities in blend with isooctane. Compression ratio, 7.0; engine speed, 1800 rpm; coolant temperature, 212° F; spark advance, 30° B. T. C.

Compression-air density-temperature relations were determined for several aromatics and are reported in reference 10. The relation obtained for three of the aromatics is presented in figures V-10 (e) and V-10 (f) in order to illustrate the nature of the results. As indicated by the slopes of the curves in these figures, the sensitivities of the aromatic blends are somewhat greater than the sensitivity of the base fuel.

Ethers.—Temperature sensitivities determined for six ethers are shown in figures V-9 (e) and V-9 (f). The ethers (unleaded blends) are listed in figure V-9 (e) in the order of decreasing sensitivity at the rich fuel-air ratio (0.11); at this fuel-air ratio the three aromatic ethers appear to be more

sensitive to temperature changes than do the *tert*-butyl alkyl ethers, with the possible exception of methyl *tert*-butyl ether. At the lean fuel-air ratio (0.065), anisole appears to be the most sensitive of the ethers; however, with consideration for the estimated reproducibility of these data there may be little real difference in the sensitivities of the six ethers shown.

In leaded blends (fig. V-9 (f)), the aromatic ethers are perhaps more temperature-sensitive than the *tert*-butyl alkyl ethers with the possible exception of methyl *tert*-butyl ether at the lean fuel-air ratio. At the rich fuel-air ratio, anisole and *p*-methylanisole show the highest sensitivities; however, the experimental accuracy may minimize the apparent differences shown on the figures.

Comparison of classes of compounds.—The temperature sensitivities of the various classes of compounds are compared in figure V-11. The procedure used in preparing these plots was the same as that used for figure V-5.

In figure V-11 at two fuel-air ratios, the low-boiling ethers have the greatest temperature sensitivities in the boiling range of 100° to 175° F. Above 175° F the aromatics are more sensitive than the other classes examined. In the boiling range from 300° to 350° F, however, the ethers have temperature sensitivities comparable to those of the aromatics.

LEAD SUSCEPTIBILITY

Lead susceptibilities of the various organic compounds investigated were determined in the 17.6 engine by comparing unleaded blends (20 percent by volume) with blends containing 4 ml TEL per gallon. Data were obtained at two inlet-air temperatures, 100° and 250° F. (See appendix A, table A-7.)

Lead susceptibility, or lead response, is usually defined as the increase in octane number or power output resulting from the addition of a given quantity of tetraethyl lead to a fuel. For the present investigation, however, lead susceptibility is

(a) Paraffins; inlet-air temperature, 100° F.

FIGURE V-13.—Comparison of isomers having highest lead susceptibility in blends with isooctane. Compression ratio, 7.0; engine speed, 1800 rpm; inlet-air temperature, 100° F; coolant temperature, 212° F; spark advance, 30° B. T. C.

expressed in a manner similar to that used for temperature sensitivity:

$$\text{Relative lead susceptibility} = \frac{\left\{ \begin{array}{l} \text{knock-limited imep of blend} + 4 \text{ ml TEL/gal} \\ \text{knock-limited imep of base fuel} + 4 \text{ ml TEL/gal} \end{array} \right\}}{\left\{ \begin{array}{l} \text{knock-limited imep of blend} + 0 \text{ ml TEL/gal} \\ \text{knock-limited imep of base fuel} + 0 \text{ ml TEL/gal} \end{array} \right\}}$$

As in the foregoing discussion of temperature sensitivity, the estimated accuracy of these ratios is about ± 0.05 .

Paraffins.—The lead susceptibilities of six paraffinic blends are shown in figures V-12 (a) and V-12 (b). In figure V-12 (a) (inlet-air temperature, 100° F), the fuels are arranged in order of decreasing response at the rich mixture. At this condition, 2,4-dimethyl-3-ethylpentane exhibits the greatest susceptibility to tetraethyl lead, but at the lean fuel-air ratio, 2,3-dimethylpentane, 2,2,3-trimethylbutane, and 2,2,3,4-tetramethylpentane have the best response. The lead susceptibility is appreciably influenced by fuel-air ratio.

In figure V-12 (b) (inlet-air temperature, 250° F), the fuels are listed in the same order as that of figure V-12 (a), but little or no difference in lead susceptibility is apparent at the rich fuel-air ratio except in the case of 2,2,3-trimethylbutane. At the lean fuel-air ratio, 2,2,3,4-tetramethylpentane and 2,3,3,4-tetramethylpentane had the highest lead susceptibilities.

Olefins.—A limited amount of data was obtained in the 17.6 engine to show the lead susceptibility of olefins in 20-

percent-by-volume blends with isooctane. (See appendix A, table A-7 (a).) For convenience, a portion of these data is summarized in the following table:

Olefin	Lead susceptibility of 20-per- cent olefinic blends relative to isooctane			
	Inlet-air temperature (°F)			
	250		100	
	Fuel-air ratio			
	0.065	0.11	0.065	0.11
	2,3-dimethyl-2-pentene.....	0.95	1.00	1.00
2,3,4-trimethyl-2-pentene.....	1.05	1.05	1.05	1.05
3,4,4-trimethyl-2-pentene.....	1.00	1.00	1.05	1.00

Aromatics.—In figures V-12 (c) and V-12 (d), the lead susceptibilities of aromatic blends are shown. The blends in figure V-12 (c) are listed in order of decreasing response at the rich fuel-air ratio. At this ratio, the data indicate that 1-methyl-4-ethylbenzene is the aromatic most susceptible to additions of tetraethyl lead. This particular aromatic also had the greatest response at the lean fuel-air ratio. From figures V-12 (c) and V-12 (d), lead susceptibility is obviously affected by fuel-air ratio.

At the higher inlet-air temperature (fig. V-12 (d)), the trend in lead susceptibility differs from that observed at 100° F (fig. V-12 (c)) for the aromatics. For the rich fuel-air ratio (fig. V-12 (d)), three of the aromatics, 1-methyl-4-ethylbenzene, 1,3-dimethylbenzene, and 1-methyl-4-isopropylbenzene, appear to be the most susceptible. At the lean fuel-air ratio, however, *tert*-butylbenzene is considerably more susceptible than the other aromatics.

Ethers.—Lead susceptibilities of the ether blends are presented in figures V-12 (e) and V-12 (f). At an inlet-air temperature of 100° F (fig. V-12 (e)), methyl *tert*-butyl ether and *p*-methylanisole have the greatest lead susceptibilities at the lean fuel-air ratio. At the rich fuel-air ratio, methyl *tert*-butyl ether has the highest susceptibility with anisole and *p*-methylanisole next.

At an inlet-air temperature of 250° F (fig. V-12 (f)), the three *tert*-butyl alkyl ethers have the highest susceptibilities at the lean fuel-air ratio. The three aromatic ethers and methyl *tert*-butyl ether exhibit the highest susceptibilities at the rich fuel-air ratio.

Comparison of classes of compounds.—In figure V-13, the lead susceptibilities are plotted against boiling points for the isomers having highest lead susceptibilities in each class of compounds. At both lean (fig. V-13 (a)) and rich (fig. V-13 (b)) fuel-air ratios, the low-boiling ethers appear to be most susceptible to tetraethyl lead in the boiling range from 125° to 160° F. Above 160° F, the aromatics show the greatest lead response.

CONCLUDING REMARKS

On the basis of an investigation of the type reported herein, it is difficult to draw any specific conclusions, inasmuch as antiknock characteristics are influenced by many

factors. The relative order of antiknock ratings of a series of compounds is influenced by engine conditions, by the tetraethyl lead content, and by the concentration of blending agent in the base fuel with which a comparison is made. With consideration for these factors, *tert*-butylbenzene, methyl and ethyl *tert*-butyl ethers, 2,2,3-trimethylbutane, and several nonanes were among the best compounds in their respective organic classes. This selection was based upon temperature sensitivity and lead susceptibility as well as antiknock value.

In an effort to generalize the data obtained in this investigation, the subsequent conclusions are expressed in terms of the relation of various performance factors to the gasoline boiling range as influenced by the classes of organic compounds investigated. Furthermore, these conclusions must necessarily be restricted to the limitations of this investigation and therefore cannot be applied without exception.

Antiknock ratings.—In the low-boiling gasoline range, the highest antiknock ratings are among the more volatile paraffins and ethers. In the intermediate gasoline range, the ethers excel; in the high-boiling range the aromatics have the highest antiknock ratings.

Temperature sensitivity.—In the low-boiling gasoline range, the data are incomplete as regards temperature sensitivity, but there are indications that the volatile ethers are more sensitive to temperature changes than are the paraffins or aromatics. In the intermediate and high-boiling ranges of gasoline, the aromatics are more sensitive to temperature than the paraffins and the ethers. Moreover, the aromatics that have the highest antiknock ratings are also sensitive to temperature.

Lead susceptibility.—In the low-boiling gasoline range, the data are incomplete as regards lead susceptibility, but there are indications that the more volatile ethers are more susceptible to additions of tetraethyl lead than are the paraffins and the aromatics. In the intermediate and high-boiling ranges of gasoline, the aromatics show greater lead susceptibility than either the paraffins or the ethers.

CHAPTER VI

AROMATIC AMINES AS FUEL ADDITIVES

In addition to those fuel components that may be classified in the broad category of blending agents, there are other compounds known as fuel additives. These compounds are generally distinguished by their chemical dissimilarity to the constituents normally found in petroleum and by their pronounced effect, when present in even small concentrations, on certain fuel characteristics. An optimum concentration of additive for over-all fuel performance can usually be found that best satisfies all requirements of the fuel; that is, the concentration of additive that will yield maximum improvement in a given fuel characteristic may have a deleterious effect on another equally important characteristic so that a compromise must be made.

By far the most important of the fuel additives are the so-called antiknock *dopes*. Tetraethyl lead (ch. VII), one of the most widely publicized additives in use today, is known primarily for its knock-suppressing qualities. The critical shortages of tetraethyl lead and the high-antiknock blending agents during World War II stimulated the search for other compounds that might be of value as antiknock agents. The NACA participated in this search for new antiknock additives, and a summarization of that survey of the aromatic amines is presented in this chapter.

Although the studies of the NACA placed greatest emphasis on the antiknock qualities of the aromatic amines, other properties were investigated to determine the useful concentrations that could be employed. These properties included low-temperature solubility measurements and determinations of the gasoline-water distribution coefficients. In addition, new methods of analysis were devised to determine the quantities of amines present in prepared fuels. Such analytical methods are necessary for purposes of fuel inspection because the use of additives is controlled by specifications.

ANTIKNOCK EVALUATION OF AROMATIC AMINES

Engines and test conditions.—Two small-scale engines and one full-scale single-cylinder test engine were used in the evaluation of the antiknock characteristics of aromatic amines. One small-scale engine was a CFR engine that conformed to the A. S. T. M. Supercharge method for knock rating except for the fuel system and the method of knock detection. The fuel system was arranged so that fuel was circulated through a primary pump, a fuel cooler, and back into the injection pump gallery. Knock was detected by a magnetostriction pickup unit in conjunction with a cathode-ray oscilloscope. Incipient detonation was taken as the criterion of knock.

As pointed out in chapter II, antiknock behavior at one condition of engine operation does not afford a satisfactory basis for estimation of performance at another condition or in another engine. For this reason, the following three sets of conditions were chosen for the small-scale engine evaluation of the aromatic amines.

	Inlet-air temperature (° F)	Spark advance (° B. T. C.)	Coolant temperature (° F)
A. S. T. M. Supercharge standard conditions	225	45	375
Condition A	250	30	250
Condition B	150	30	250

The engine speed of 1800 rpm and compression ratio of 7.0 were held constant throughout the investigation.

Of these three sets of conditions, the A. S. T. M. Supercharge condition is considered to be the most severe by virtue of the advanced spark and high coolant temperature; condition A is somewhat milder; and condition B is the mildest of the three. Additional runs were made in the second CFR engine, which was equipped to conform to specifications of the A. S. T. M. Aviation method for knock rating.

At each of these conditions, 2-percent (by weight) blends of the aromatic amines were examined with AN-F-28 (28-R) fuel as the base fuel. In order to eliminate reproducibility errors, the straight base fuel and the base fuel containing amine were compared on the same day. The selection of 2 percent amine as the only concentration to be investigated was determined primarily by the quantities of amines available.

The full-scale engine investigation was conducted in an air-cooled aircraft cylinder mounted on a Cooperative Universal Engine (CUE) crankcase. The auxiliary apparatus used in these tests was similar to that described in reference 1 except that a heat exchanger was installed in the cooling-air line to control the cooling-air temperature; the exhaust system was so modified that the engine could be operated either at atmospheric or reduced exhaust pressure.

The cooling-air flow was determined for each run by operating the engine at a brake mean effective pressure of 140 pounds per square inch and a fuel-air ratio of 0.10 and by adjusting the damper valve in the cooling-air line until a rear-spark-plug-bushing temperature of 365° F was reached. The cooling-air pressure drop across the cylinder was maintained constant for each run.

Mixture-response curves were determined at two operating conditions: (1) simulated cruise conditions recommended by the Coordinating Research Council (CRC), which specify an engine speed of 2000 rpm, an inlet-air temperature of 210° F, a spark advance of 20° B. T. C., and atmospheric exhaust pressure; and (2) a modification of these CRC conditions that consisted of an advance spark setting of 30° B. T. C. and a reduced exhaust pressure of 15 inches of mercury absolute. The exhaust pressure of 15 inches of mercury was chosen in view of earlier test results (reference 2) in which a critical relation was shown to exist between manifold and exhaust pressures and knock-limited power in the lean region where the manifold pressure is within 10 and -5 inches

^b Performance numbers.^c 1.76 percent amine added.

mercury of the exhaust pressure. The spark advance of 30° B. T. C. was chosen because of the interest in aircraft-engine operation at advanced spark under cruise conditions.

In the full-scale engine studies, 2-percent (by weight) amine blends with AN-F-28 fuel were also used.

Knock-limited performance.—In order to present the most reliable comparison of the many amines examined, the anti-knock ratings of all blends are expressed as power ratios (references 3 to 7). The small-scale engine results shown in table VI-1 (except for A. S. T. M. Aviation results) are therefore expressed as the quotient of the knock-limited indicated mean effective pressure (imep) of the amine blend divided by the knock-limited indicated mean effective pressure of the base fuel (AN-F-28). By this method the

influence of day-to-day variations in engine reproducibility is reduced to a minimum because each blend was examined on the same day as the base fuel.

The data from table VI-1 have been plotted in figure VI-1 to illustrate the relations that exist between antiknock effectiveness and molecular structure. Because the A. S. T. M. Supercharge method is a rich-mixture rating method, only the data at a fuel-air ratio of 0.11 have been considered in this analysis.

Fuel sensitivity (ch. II) is an obstacle to the development of any rigid generalizations between chemical structure and performance. For example, in figure VI-1 (a) at A. S. T. M. Supercharge conditions, it is seen that 15 aromatic amines have antiknock values equal to or greater than aniline. At condition A (fig. VI-1 (b)), 17 aromatic amines are equal to

(a) A. S. T. M. Supercharge standard conditions.

FIGURE VI-1.—Antiknock effectiveness of 2-percent aromatic amine blends with AN-F-28 (28-R) fuel. Fuel-air ratio, 0.11.

or greater than aniline, but at condition B (fig. VI-1 (c)), only 5 compounds are equal to or greater than aniline. Purely from consideration of nominal engine operating conditions it will be recalled that the A. S. T. M. Supercharge condition is probably the most severe, with condition B the mildest, and condition A intermediate. It is obvious, then, that some risk is involved in a statement that any single amine is always better than aniline. In fact, N-methyl-*p*-toluidine is the only compound that did exceed aniline in antiknock value at all three conditions, and at condition B the margin of superiority was, for all practical purposes, negligible.

On the basis of the data contained in figures VI-1, however, two generalizations can be made with regard to

(b) A. S. T. M. Supercharge modified A conditions.

FIGURE VI-1.—Continued. Antiknock effectiveness of 2-percent aromatic amine blends with AN-F-28 (28-R) fuel. Fuel-air ratio, 0.11.

structural trends. The first of these is as follows: When one hydrogen atom in the $-NH_2$ group of any given primary aromatic amine is replaced by an alkyl group, the greatest increase or least decrease in antiknock value from that of the primary amine will result when the alkyl substituent is a methyl radical ($-CH_3$). This statement is supported by the following data:

Aromatic amine	Relative Power		
	A. S. T. M. Supercharge	Condition A	Condition B
Aniline.....	1.09	1.11	1.14
N-Methylaniline.....	1.14	1.12	1.10
N-Ethylaniline.....	1.01	1.04	1.04
N-Propylaniline.....	1.02	1.02	1.06
N-Butylaniline.....	1.01	1.01	1.01
N-Isopropylaniline.....	1.01	1.04	1.01
N-tert-Butylaniline.....	1.02	.99	1.02
<i>p</i> -Toluidine.....	1.11	1.14	1.11

(c) A. S. T. M. Supercharge modified B conditions.

FIGURE VI-1.—Concluded. Antiknock effectiveness of 2-percent aromatic amine blends with AN-F-28 (28-R) fuel. Fuel-air ratio, 0.11.

For each of these three series of compounds, the antiknock values of the three primary amines considered as bases (aniline, *p*-toluidine, and *p*-isopropylaniline) were increased more by the substitution of a methyl radical for one of the hydrogen atoms attached to the nitrogen than by substitution of any other radical. For the two cases where the performance decreased (N-methylaniline at condition B and N-methyl-*p*-isopropylaniline at condition A), the decrease in performance was less with the methyl radical than with any of the other radicals examined.

The influence of replacing a hydrogen atom attached to the nitrogen with an aromatic radical was investigated for only one compound; however, in this one case the aromatic radical appeared approximately equal in effectiveness to a methyl radical, as shown by the following table:

Aromatic amine	Relative Power		
	A. S. T. M. Supercharge	Condition A	Condition B
Aniline.....	1.09	1.11	1.14
N-Methylaniline.....	1.14	1.12	1.10
Diphenylamine.....	1.11	1.15	1.10

The second generalization of the data can be made with reference to hydrogen substitutions on the aromatic ring: *The addition of an alkyl radical to the aromatic ring of an aromatic amine is more effective insofar as antiknock value is concerned when the addition is made in the para position rather*

FIGURE VI-2.—Apparatus for determination of cloud point. (Fig. 1 of reference 9.)

TABLE VI-2.—ANTIKNOCK EFFECTIVENESS OF AROMATIC-AMINE ADDITIONS TO AN-F-28 (28-R) FUEL IN A FULL-SCALE AIR-COOLED AIRCRAFT ENGINE CYLINDER *

For each compound there are two rows of values. The first row is imep, lb/sq in.; the second is imep ratio, which is the ratio of the imep of 98 percent 28-R fuel plus 2 percent aromatic amine to the imep of 28-R.]

N-Methyl- <i>p</i> -toluidine.....	1.19	1.18	1.15
Aniline.....	1.09	1.11	1.14
<i>o</i> -Ethylaniline.....	1.00	1.04	2.07
<i>p</i> -Ethylaniline.....	1.09	1.13	1.12
Aniline.....	1.09	1.11	1.14
<i>o</i> -Isopropylaniline.....	.97	1.01	1.95
<i>p</i> -Isopropylaniline.....	1.11	1.16	1.12

The small number of A. S. T. M. Aviation ratings (table VI-1) does not justify inclusion as supporting data for the foregoing generalizations. It is interesting to note, however, that the addition of diphenylamine improved the performance of the base fuel by 15 performance numbers more than any of the other aromatic amines for which A. S. T. M. Aviation ratings were obtained.

One additional observation to be made from the data of table VI-1 concerns the replacement by alkyl radicals of both hydrogen atoms attached to the nitrogen, that is,

As shown by the following comparisons, the replacement of one hydrogen atom by an alkyl radical is more effective for maintaining or improving the antiknock value of the starting compound than replacement of both hydrogen atoms:

Aromatic amine	Relative Power		
	A. S. T. M. Supercharge	Condition A	Condition B
Aniline.....	1.09	1.11	1.14
N-Methylaniline.....	1.14	1.12	1.10
N,N-Dimethylaniline.....	---	.99	1.00
Aniline.....	1.09	1.11	1.14
N-Ethylaniline.....	1.01	1.04	1.04
N,N-Diethylaniline.....	1.00	1.03	1.01

Suitable quantities of the pure aromatic amines used in the small-scale engine studies were not available for the full-scale engine investigation (reference 8); therefore, a few isomeric mixtures were examined. The results of these tests are presented in table VI-2.

The data show that all the aromatic amines increased the knock-limited performance of the base fuel at both full-scale engine conditions throughout the fuel-air ratio range. At both sets of engine conditions and lean and rich fuel-air ratios, the blends of N-methylcumidines, N-methyltoluidines, and N-methylaniline were about equal in knock-limited performance, and all three were superior to the other blends tested.

When the severity of the test conditions was changed by advancing the spark and reducing the exhaust pressure, contrary effects were noted for the several blends. In every case the rich-mixture (fuel-air ratio, 0.10) knock-limited performance of the several fuels was decreased by the change of conditions. The lean-mixture (fuel-air ratio, 0.065) performance of 28-R fuel and the blend containing N-methylxylidines was increased, whereas the blend containing xylidines remained about the same. The percentage improvement in the knock-limited performance of the base fuel resulting from addition of the amines was less at the condition of advanced spark and reduced exhaust pressure than at the other condition.

PHYSICAL PROPERTIES OF AROMATIC AMINES

Of the physical properties examined in the NACA investigation of aromatic amines, low-temperature solubility and gasoline-water distribution coefficients received the greatest attention. The low-temperature solubility characteristics are of primary importance because of specification requirements that the additives must remain in solution at the lowest temperatures encountered in service. Current fuel specifications limit the freezing point to a maximum of -76°F (-60°C). Gasoline-water distribution coefficients are of interest because of the wide usage of water-distribution storage systems. In such systems the additive may be extracted from the fuel by diffusion when fuel and water are in intimate contact.

Physical properties, other than low-temperature solubility and gasoline-water distribution coefficients, were determined for the amines examined and are presented in table VI-3.

Low-temperature solubility.—Solubilities of 42 aromatic amines in blends with gasoline were measured at temperatures as low as -85°F (-65°C) and at concentrations as high as 10 percent by weight (reference 9). The solubilities of aromatic amines are appreciably affected by the compo-

sition of gasoline to which the addition is made; therefore, three different base gasolines were used:

1. Grade 65 gasoline from which aromatic hydrocarbons were successively extracted with 10-percent fuming sulfuric acid and silica gel.

2. Extracted grade 65 gasoline to which was added 15 percent by volume of an aromatic mixture of 5 parts xylene, 2 parts cumene, and 1 part toluene.

3. Different batches of typical current aviation gasoline, AN-F-28 (Amendment 2) fuel containing 12 to 20 percent aromatic hydrocarbons by volume.

The apparatus for determination of low-temperature solubilities of the amines is shown in figure VI-2. Briefly, the procedure used in reference 9 to determine the solubility consisted in slowly cooling and stirring the gasoline-amine sample in the sample tube until the amine separated as a cloud from the gasoline; the temperature at which the cloud formed was recorded. The sample was then slowly warmed until the amine went into solution and the cloud disappeared; the temperature was again recorded. These two temperatures were averaged to give the incipient-separation temperature or cloud point. Cloud points were reproducible to within $\pm 1.5^{\circ}\text{C}$.

^a Table II of reference 9.^b Aromatic mixture consisted of five parts xylene, two parts cumene, and one part toluene.^c Solubility at room temperature.

FIGURE VI-5.—Solubility of aromatic amines in AN-F-28, Amendment-2, fuel. (Fig. 4 of reference 9.)

The solubilities of the amines in the aromatic-free gasoline, in the gasoline of 15-percent aromatic content, and in the AN-F-28 fuel are presented in figures VI-3, VI-4, and VI-5, respectively. The amines that were soluble to at least 10 percent by weight at -76°F (-60°C) in each of the gasolines are

- N-Ethylaniline
- N-Propylaniline
- N-Isopropylaniline
- N-tert-Butylaniline
- N,N-Diethylaniline
- N-Methyl-p-toluidine
- N-Methyl-o-toluidine
- N-Methyltoluidines (from chlorotoluenes)
- N-Ethyl-p-toluidine
- N-Isopropyl-p-toluidine
- N-Methyl-p-ethylaniline
- N-Methylethylaniline, mixed isomers (from chloroethylbenzenes)
- o-Isopropylaniline
- p-Isopropylaniline
- N-Methyl-p-isopropylaniline
- N-Isopropyl-p-isopropylaniline
- Cumidines (from synthetic cumenes)
- Cumidines (from refinery cumenes)
- N-Methylcumidines (from bromocumenes)
- N-Methyl-p-tert-butylaniline
- N-Methyl-2,4-xylidine
- N-Methylxylidines (from bromoxylenes)
- 2,4-Diethylaniline
- 2-Methyl-5-isopropylaniline
- N,N-Dimethyl-2-methyl-5-isopropylaniline
- N,N-Diethyl-2,4,6-trimethylaniline
- Pseudocumidine (technical)

FIGURE VI-4.—Solubility of aromatic amines in blend of 85 percent extracted grade 65 base stock and 15 percent (by volume) of aromatic mixture consisting of 5 parts xylene, 2 parts cumene, and 1 part toluene. (Fig. 3 of reference 9.)

At room temperature, *N*-methyl-*p*-phenylenediamine and *p*-phenylenediamine were less than 0.5 percent (by weight) soluble in the test gasoline; no additional solubility data were taken for these compounds. At room temperature, *N,N'*-dimethyl-*p*-phenylenediamine was soluble to the extent of 1 to 2 percent by weight but was too unstable to permit accurate measurement of solubility by the method employed. *N,N*-Diethyl-*p*-phenylenediamine was tested only in the aromatic-free gasoline.

When figures VI-3 and VI-4 are compared, it is seen that composition of the base fuel greatly influenced the solubilities of the amines. The addition of 15 percent aromatics to the aromatic-free gasoline approximately doubled or tripled the amine solubility. Solubilities in AN-F-28 fuel (fig. VI-5) were about the same as those in the gasoline containing 15 percent aromatics. Representative samples of AN-F-28 fuel contained 12 to 20 percent (by volume) aromatics.

A summary of the solubilities of the amines at -76°F (-60°C) in the different test gasolines is presented in table VI-4. The results were obtained by interpolating or extrapolating the experimental data. The data obtained for commercial xylydines (reference 10) are included for comparison.

The solubility of an aromatic amine in the aromatic-free gasoline at -76°F (-60°C) may be taken as an indication of the maximum concentration in which the amine could be added to current aviation fuels on the basis of solubility alone. The aromatic hydrocarbons present in most of the wartime aviation fuels provided a margin of safety in preventing this concentration of amine from separating at -76°F (-60°C).

Gasoline-water distribution coefficients.—If a fuel containing an additive such as an aromatic amine is stored in contact with water for an extended period of time, a certain amount of the additive will be extracted by the water. An analysis of a fuel-storage system in which this extraction might occur was made by Olson and Tischler (reference 11) in order to develop an expression from which the loss of amine to water could be approximated. Storage systems of this type have been variously termed "overwater storage systems, water-displacement storage systems, and aqua storage systems."

As pointed out in reference 11, it is unlikely that a single expression can be written for use under all conditions encountered in practice, but certain assumptions permit a mathematical derivation of an equation that covers a wide range of situations. In the operation of a tank utilizing the water-displacement principle, fuel is removed from the tank by adding water at the bottom of the tank. Fuel is added to the tank by removal of storage water from the tank. Two phases, one of gasoline and one of water, exist in the tank, which is full of liquid at all times.

The following assumptions are made in reference 11 in determining the expressions for concentration of additive in fuel stored over water at any volume of fuel:

1. When equilibrium conditions are reached, the distribution law applies to the additive; namely, the ratio between the concentrations of the additive in the two phases of the gasoline-water system is constant at constant temperature.

The ratio is described as the distribution coefficient and defined as

$$K = \frac{\text{additive concentration in gasoline phase}}{\text{additive concentration in water phase}}$$

This constant must be experimentally determined for each additive. It varies with temperature of the fuel and water and with the nature of the fuel. Any variation in the distribution coefficient caused by additive concentration may be assumed negligible in the range of concentrations produced by the distribution process.

2. The volume of the additive itself, when present to the extent of 2 or 3 percent or less, is negligible by comparison with the volumes of gasoline and water. The equilibrium concentration is the minimum concentration of additive in the fuel at the volume in question.

The following symbols are used in the analysis of reference 11:

K	gasoline-water distribution coefficient (experimentally determined)
X	concentration of additive in gasoline before addition or removal of portion of fuel
X'	concentration of additive in gasoline after addition or removal of portion of fuel (at equilibrium)
V	volume of storage tank
V_g	volume of fuel in tank before addition or removal of portion of fuel
V_g'	volume of fuel in tank after addition or removal of portion of fuel
V_w	volume of water in tank before addition or removal of portion of fuel
V_w'	volume of water in tank after addition or removal of portion of fuel
V_f	volume of fuel added or withdrawn ($V_f = V_g' - V_g$)
Y	concentration of additive in water added or withdrawn
Z	concentration of additive in fuel added or withdrawn

Because the manner in which an overwater-storage system is operated is one of the most important variables influencing the additive concentration in the stored fuel, two cases representing two very different operating procedures have been studied:

Case 1.—The first case applies to successive additions or withdrawals of fuel stored in contact with water when an appreciable period of time has elapsed between each addition or withdrawal.

In order to approximate this situation it is assumed that during the actual addition or withdrawal of fuel, no additive is transferred between the gasoline and water phases but that equilibrium distribution of additive between the two phases is attained during the period between successive additions or withdrawals of fuel. This assumption is based on the slowness of the rate of diffusion of additive between the two phases. The following equation will agree more closely with the actual situation the longer the period between additions or withdrawals of fuel:

$$(X V_g + Z V_f) + \left(\frac{X V_w}{K} - Y V_f \right) = X' (V_g + V_f) + \frac{X'}{K} (V_w - V_f) \quad (1)$$

This equation may be expressed in words as follows:

(Quantity of additive in gasoline after addition or withdrawal of fuel but before equilibrium) + (quantity of additive in water after addition or withdrawal of fuel but before equilibrium) = (quantity of additive in gasoline after equilibrium) + (quantity of additive in water after equilibrium).

Expanding and collecting terms gives

$$X' = \frac{KXV_g + KZV_f + XV_w - KYV_f}{KV_g + KV_f + V_w - V_f} \quad (2)$$

If fuel is displaced from the tank by fresh water, $Z=X$, $Y=0$, $V_g' = V_g + V_f$ and $V_w' = V_w - V_f$. Then

$$X' = X \left(\frac{V_w + KV_g'}{V_w' + KV_g'} \right) \quad (3)$$

Case 2.—The second case applies to successive small withdrawals of fuel over an appreciable length of time. For this approximation, equilibrium distribution of additive is assumed to exist between gasoline and water at all times. An equation of this sort permits evaluation of additive concentration under circumstances where withdrawals of fuel have been small, compared with the tank capacity, but very numerous. Equation (4) may thus be considered as the result of applying the equations of case 1 to an infinite number of steps, with equilibrium established between each step.

Let $\Delta X = X' - X$, $\Delta V_g = V_g' - V_g$, and $\Delta V_w = V_w' - V_w$. Then,

$$X'V_g' + \frac{X'V_w'}{K} = X' - \Delta X(V_g' - \Delta V_g) + \left(\frac{X' - \Delta X}{K} \right) (V_w' - \Delta V_w) + (X' - \Delta X)\Delta V_g \quad (4)$$

or, in words,

(Quantity of additive in fuel stored over water) + (quantity of additive in water) = (quantity of additive in stored fuel before removal of small increment) + (quantity of additive in water before addition of increment of fresh water) + (quantity of additive removed in small increment of fuel).

By removing second-order differentials, equation (4) can be expanded and simplified:

$$-X'\Delta V_w = (KV_g' + V_w')\Delta X \quad (5)$$

But $-\Delta V_w = \Delta V_g$ and $V_w' = V - V_g'$; therefore,

$$\frac{\Delta X}{X'} = \frac{\Delta V_g}{V_g'(K-1) + V} \quad (6)$$

By integration from any concentration X and volume V_g to X' and V_g' ,

$$X' = X \left[\frac{V_g'(K-1) + V}{V_g(K-1) + V} \right]^{\frac{1}{K-1}} \quad (7)$$

TABLE VI-5.—STORAGE-SYSTEM INVESTIGATION

Sample taken *	May 27	June 7	June 19	July 3	July 13 1943
Fuel in tank before removal of batch, gal.	8105	8105	6105	2105	1105
Water in tank before removal of batch, gal.	16,895	16,895	18,895	22,895	23,895
Fuel removed, gal.-----	(fuel placed in storage system)	2000	4000	1000	1105
Xylidines, grams/100 ml (electrometrically)	1.05 .98 Mean 1.01	(b)	{ 0.94 .826 .826 .82	0.825 .83	0.815 .82 (c)
Equilibrium concentration, X' (equation (2))		^d 0.900	^e 0.886	0.825	0.806

* Analysis indicated under each date is prior to removal from the storage tank of the quantity of fuel indicated under that date.

^b Sample was inadvertently mixed with some xylidine-free fuel.

^c The fuel stored over water gave a negligible decrease in knock rating when compared with the original batch of fuel.

^d Sample calculation for run on June 7: Because the tank contained no fuel prior to the addition of the 8105 gallons on May 27, $V_g=0$, $X=0$, and $Y=0$; therefore, from equation (2)

$$X' = \frac{(17)(1.01)(8105)}{(17)(8105) + 25,000 - 8105}$$

$$= 0.900 \text{ (equilibrium concentration attained on standing).}$$

^e Sample calculation for run on June 19: In this case, $Z=X$ and $Y=0$. Equation (2) therefore becomes equation (3) and

$$X' = 0.900 \left(\frac{(16,895 + (17)(6105))}{(18,895 + (17)(6105))} \right) = 0.886$$

FIGURE VI-6.—Additive concentration in gasoline stored over water for distribution coefficient of 20. (Fig. 1 of reference 11.)

In full-scale, overwater-storage tests of xylidine-blended fuel, 8105 gallons of aviation fuel were stored in a tank of 25,000-gallon capacity and immediately sampled and analyzed. The stored fuel (containing xylidines) was sampled and analyzed periodically, and part of the fuel was removed. This process is a batch process; therefore, equation (2) is applicable. This test provides an evaluation of the equation for the particular conditions.

With the assumption of an average temperature of 65° F for the tank contents and fuel displacement with fresh water,

a volume distribution coefficient of 17 was selected for xylidines (reference 12). The results of the full-scale, water-system test and the equilibrium concentration calculated from equation (2) are compared in table VI-5. The calculated results agree well with the experimental data for this particular test.

Normally anticipated additive concentration in fuel stored over water is shown in figure VI-6 for three different types of tank operation. A volume distribution coefficient of 20 is assumed, inasmuch as experimental values range from 13 to 26 for xylidines (reference 12).

The topmost curve of figure VI-6 represents fuel displaced

from a full tank in successive small increments over a period of time sufficiently long for equilibrium to exist continuously. Equation (7) applies for this case. The second curve illustrates the variation in concentration to be expected if fuel is displaced from a full tank in successive quantities with equilibrium existing between withdrawals. Equation (2) applies for this case. The lower curve illustrates the concentration to be expected if fuel is displaced from a full tank in a single, fairly rapid operation with equilibrium established only after the withdrawal; it also illustrates the change in concentration resulting from the addition of a batch of fuel to a tank containing additive-free water.

FIGURE VI-7.—Maximum possible loss of additive from fuel stored over water. A value for distribution coefficient is required for particular system, but plot is independent of original concentration of additive, nature of fluids, or temperature. (Fig. 2 of reference 13.)

Generally speaking, the loss of an additive, such as xylidines, with a distribution coefficient of about 20 will not be severe. The greatest loss will occur when the tank contains a ratio of xylidine-free water to fuel greater than about 4:1 (reference 11).

It is emphasized that the equations presented in the foregoing paragraphs apply only to the extent that the assumptions hold for a particular application. In practice, factors such as temperature, varying gasoline-water interface area, and frequency and quantity of additions or withdrawals will influence the results.

As previously stated, the evaluation of loss of additive to water in a water-displacement fuel-storage system is dependent on the distribution coefficient K for the particular additive under consideration. Olson, Tischler, and Goodman (reference 13), and Goodman and Howard (reference 14) have determined distribution coefficients for 45 aromatic amines.

The base gasoline used in determining the distribution coefficients was an aromatic-extracted grade 65 gasoline to which was added 15 percent (by volume) of an aromatic-hydrocarbon mixture consisting of five parts xylene, two parts cumene, and one part toluene. Blends of 1, 3, and 6 percent (by weight) aromatic amine in this base fuel were examined. Earlier data on xylidines (reference 12) show that temperature is the most significant variable affecting the distribution coefficient; consequently, measurements were made at 40° and 100° F. The distribution coefficients for the amines are shown in table VI-6.

The effect of the distribution coefficient in loss of additive to water in a water-displacement system is illustrated in figure VI-7 (reference 13). This figure was prepared by use of the previously discussed equations (reference 11) and is independent of the original additive concentration, the nature of the two fluids, or the temperature. Figure VI-7 shows the minimum possible additive concentration in the fuel remaining in the tank after part of the fuel is displaced from a full tank with amine-free water. The greatest amine loss will occur if the fuel is removed in a single batch; however, this seldom occurs in practice. A lower loss of additive than indicated in figure VI-7 will result if removal of the stored fuel is stepwise.

Methods of analysis for aromatic amines.—For a period of about 2 years the NACA used spectrophotometric measurements of the ultraviolet absorption of aromatic amines in the analysis for presence of amines in gasoline and water. This method of analysis has been reported in detail by

Tischler and Howard (references 15 and 16). The spectrophotometric method is more accurate than titration methods and has proved to be applicable to quantitative determination in hydrocarbon solutions of all monoaryl amines tested in the NACA laboratories.

Standard water solutions of the following amines could not be prepared because of the very low water solubility of the amine:

N-Methyl-*p*-*tert*-butylaniline
N-Isopropyl-*p*-isopropylaniline
N, N-Dimethyl-2-methyl-5-isopropylaniline
N, N-Dimethyl-2,4,6-trimethylaniline
Diphenylamine
N-Methyl-diphenylamine.

^a Data from references 13 and 14.

^b Density of gasoline solution at 40° F, 0.732 gram/ml.

^c Values for K_{v1} were computed by multiplying corresponding K_{w1} values by density of gasoline solution.

^d Density of gasoline solution at 100° F, 0.704 gram/ml.

CHAPTER VII

TETRAETHYL LEAD AS A FUEL ADDITIVE

For years tetraethyl lead $\text{Pb}(\text{C}_2\text{H}_5)_4$ has been considered the most effective practical additive for suppressing knock in conventional spark-ignition engines. In comparison with the additive-type compounds discussed in chapter VI, tetraethyl lead is considerably more effective. An investigation reported by Calingaert (reference 1) indicates that the knock-suppressing tendency of tetraethyl lead is 118 times greater than that of aniline.

On the basis of cost and antiknock effectiveness alone, tetraethyl lead is far more desirable than any known blending agent, because so little is required in a fuel to equal the antiknock effectiveness of a much larger volume of blending agent. Deleterious effects may, however, occur in engines when fuels containing high concentrations of tetraethyl lead are used. These harmful effects have necessitated strict regulations on the quantity that can be tolerated in fuels for various types of service.

In general, fuels used in commercial aviation contain smaller quantities of tetraethyl lead than those used in military aircraft. At the outbreak of World War II, Army-Navy aviation-fuel specifications permitted tetraethyl lead in quantities less than 3.0 ml per gallon. This limit was later raised to 4.0 ml per gallon; as critical shortages of more desirable blending agents occurred, the limit was again raised to 4.6 ml per gallon. Upon one occasion during the war, continued shortages of fuel stocks and the need for much higher performance fuels resulted in considerable experimentation with fuels containing 6.0 ml per gallon.

PROCESS OF LEAD-DEPOSIT ACCUMULATIONS ON AIRCRAFT-ENGINE SPARK PLUGS

As noted in reference 2, one of the disadvantages of tetraethyl lead as an antiknock agent for aircraft fuels is its characteristic of depositing, either as metallic lead or as a compound, on combustion-chamber surfaces during engine operation. Such deposits on spark plugs cause ignition failures both by bridging the electrode gaps and by forming conducting paths across the insulator surfaces and are suspected of lowering preignition ratings of spark plugs (ch. IV) and contributing to erosion of spark-plug electrodes. For these reasons lead deposition on spark plugs constitutes a flying hazard, increases time and cost of engine maintenance, and limits the use of tetraethyl lead in fuels.

The investigation described in reference 2 illustrates the characteristics of the progressive build-up of spark-plug deposits. In order to determine the progressive accumulation of deposit on spark plugs, each spark plug was weighed periodically throughout a series of test runs in a CFR engine at constant operating conditions. Additional runs were made in a single cylinder of a full-scale liquid-cooled aircraft engine. Three different types of spark plug, designated A, B, and C, were used.

Variation of deposition with time.—The results of a deposit test in the CFR engine for a type A spark plug are shown in figure VII-1. The condition of large total deposit was simulated without the necessity of excessive operating periods by increasing the tetraethyl lead content of the fuel to 34 ml per gallon.

The accumulation of deposit increases with operating time (fig. VII-1), but the rate of deposition decreases. After completion of this test, an effort was made to operate the engine with the coated spark plug, but the test was unsuccessful because of short circuiting.

Effect of power level on deposition.—Operating conditions affect the accumulation of deposits on spark plugs, as illustrated in figure VII-2. Failure of the spark plug during the low-power run occurred shortly after 14 hours of operation because of the formation of a small bead of lead deposit

FIGURE VII-1.—Lead deposition for type A spark plug in CFR engine with AN-F-28 fuel leaded to 34 ml TEL per gallon. Compression ratio, 6.65; engine speed, 1800 rpm; imep, 82 pounds per square inch; fuel-air ratio, 0.10; inlet-air temperature, 85° F; coolant temperature, 212° F; spark advance, 45° B. T. C. (Fig. 1 of reference 2.)

on an electrode gap. A photograph of the spark plug in this case is shown in figure VII-3.

Accumulation of deposit masses.—Spark-plug deposition for a type B spark plug in the full-scale single-cylinder test engine is shown in figure VII-4 (reference 2). The spark plug was located in the exhaust position and the engine was operated under simulated cruise conditions. The fuel contained 18 ml TEL per gallon. During this test the condition of the plug was photographically recorded at various time intervals (fig. VII-5). As shown in these photographs, the deposit existed during operation in the form of molten globules, which changed position. The changes in position are attributed to the influence of gravitation and molecular forces and forces arising from gas flow in the combustion chamber (reference 2). The concentration of deposit near the lowest point of the spark-plug cavity became more pronounced as the deposit increased.

FIGURE VII-2.—Effect of power level on lead deposition for type C spark plug in CFR engine with AN-F-28 fuel leaded to 4.6 ml TEL per gallon. Compression ratio, 6.65; fuel-air ratio, 0.10; inlet-air temperature, 90° F; coolant temperature, 212° F; spark advance, 45° B. T. C. (Fig. 2 of reference 2.)

FIGURE VII-3.—Type C spark plug with lead in left gap. Failure of plug occurred after 14 hours operation at low power in CFR engine. (Fig. 3 of reference 2.)

As pointed out in reference 2, observation of deposits on many spark plugs indicates that these deposits may vary considerably in characteristics and appearance under different conditions. Consequently, no particular deposit can be considered typical. Deposits similar to those in figure VII-5 have been observed on badly fouled spark plugs from service engines.

Deposit losses.—From the data discussed in the foregoing paragraphs, it was concluded (reference 2) that the manner in which the rate of deposition varies (figs. VII-1, VII-2, and VII-4) suggests that the net rate is the result of deposition (possibly at constant rate) and loss of deposit at a rate

FIGURE VII-4.—Lead deposition for type B spark plug in exhaust position of liquid-cooled aircraft cylinder with AN-F-28 fuel leaded to 18 ml TEL per gallon. Engine speed, 2000 rpm; inlet-air pressure, 30 inches of mercury absolute; fuel-air ratio, 0.10; inlet-air temperature, 85° F; coolant temperature, 250° F. (Fig. 4 of reference 2.)

FIGURE VII-5.—Accumulation of lead deposits on type B spark plug in exhaust position of liquid-cooled aircraft cylinder. (Fig. 5 of reference 2.)

that increases as the total deposit increases. In order to test this conclusion, a spark plug was operated in the CFR engine on S reference fuel containing 6 ml TEL per gallon.

After $7\frac{1}{2}$ hours of operation, the deposit weight was found to be 159 milligrams. The spark plug was then replaced without cleaning and operated for 1 hour under the same conditions but with unleaded S reference fuel. At the end of 1 hour the deposit weight had decreased to 112 milligrams, a decrease of 30 percent. A similar test on another spark plug resulted in a 35-percent weight loss.

Significance of deposit weights.—A spark plug may fail electrically when a deposit of sufficient electric conductance to prevent sparking is formed between the spark-plug shell, or a ground electrode, and the center electrode. A very small quantity of deposit may cause failure if the deposit directly bridges the electrode gap. (See fig. VII-3.) There is evidence, however, that gap bridging is not the most common type of failure of spark plugs incorporating large nickel or tungsten electrodes. In the more usual case of failure by conduction along deposits on the insulator, relatively large quantities of deposit are necessary before short circuiting occurs. The amount, distribution, and conductivity of the deposit determine the path of short circuiting. From the photographic evidence in figure VII-5 it was concluded (reference 2) that, aside from certain concentrating influences such as the force of gravity and large temperature differences, the deposit distribution is primarily a matter of chance. The amount of deposit and the chemical or physical properties of the deposit can then be considered as factors determining the probability of failure. The actual failure, however, is dependent upon the distribution of deposit.

ETHYLENE DIBROMIDE IN TETRAETHYL LEAD FLUID

One of the principal causes of exhaust-valve failure in reciprocating engines has been found to be corrosion and collapse of the valve crown at excessively high operating temperatures (reference 3). Analysis of deposits on exhaust valves has shown conclusively that all the lead present in the fuel has not been properly scavenged from the cylinder. This fact supports the conclusion of Banks (reference 4) and Hives and Smith (reference 5) that hot corrosion of exhaust valves is a result of the action of lead oxide deposited on the valve head during operation with leaded fuel.

In order to minimize the undesirable lead deposits, ethylene dibromide is added to the tetraethyl lead before addition to the fuel. The ethylene dibromide reacts with lead in the cylinder during combustion to form volatile compounds that may be easily scavenged with the exhaust gases. The mixture of ethylene dibromide and tetraethyl lead (and small quantities of dye and kerosene) prior to addition to the fuel is called tetraethyl lead fluid. The fluid currently used in aircraft fuels contains 0.96 gram of ethylene dibromide per ml TEL. This quantity of ethylene dibromide is the amount theoretically required to combine with all the lead in the

mixture. Such a mixture of the dibromide and tetraethyl lead is popularly known as a 1-T (one-theory) mix.

An investigation (reference 6) was conducted to determine the influence of excess ethylene dibromide on the degree of valve-crown corrosion occurring during engine operation. The effects resulting from use of 1-T and 2-T mixes were compared. Because the use of excess ethylene dibromide could conceivably reduce the knock-limited performance of the leaded fuel, studies of knock-limited performance were included.

Effect on exhaust-valve corrosion.—Results of valve-corrosion tests in a full-scale air-cooled aircraft cylinder are summarized in the following table (reference 6):

Fuel *		Length of run (hr)	Weight loss of valve		
TEL (ml/gal)	Mix		Total (grams)	Rate (gram/hr)	Rate (percentage of loss with 1-T mix)
4.53	1-T	22	5.18	0.235	100
	2-T	16½	1.97	.119	51
6.0	1-T	18	3.17	0.176	100
	2-T	18	.53	.029	16

*AN-F-28 (28-R) was used as base fuel. This fuel contained about 4.53 ml TEL/gal.

For the tests in which the concentration of tetraethyl lead was 4.53 ml per gallon, the exhaust-valve temperature was held at approximately 1200° F. When the concentration was increased to 6.0 ml per gallon, however, the combustion-air inlet temperature was reduced to 95° F as compared with 150° F for the test with the fuel of lower tetraethyl lead concentration. This change caused a lower exhaust-valve temperature and probably accounts for the reduction in amount of valve corrosion in the test of fuel with 6.0 ml TEL per gallon.

Comparative photographs of the valves from the tests just described are shown in figures VII-6 and VII-7.

Effect on lead deposition.—Because of corrosion of the valve crown it was difficult to determine quantitatively the effect of ethylene dibromide on deposits. (See reference 6.) For this reason, the measurement of deposits was confined to the piston crown and the spark plugs. In the test with the fuel containing 4.53 ml TEL per gallon, the rate of lead deposition on the piston crown with the 2-T mix was about 73 percent of the rate during the test with the 1-T mix.

The effect of ethylene dibromide on spark-plug deposits was also determined for fuel containing 6.0 ml TEL per gallon; these results are shown in the following table:

Spark plug	Mix	Weight of deposit (gram)	Reduction in deposit (percent)
Front.....	1-T 2-T	0.083 .021	0 75
Rear.....	1-T 2-T	0.109 .014	0 87

(a) Valve after 22 hours of operation with 1-T mix.

(b) Valve after 16½ hours of operation with 2-T mix.

FIGURE VII-6.—Effect of excess ethylene dibromide on exhaust valves in air-cooled aircraft cylinder with fuel leaded to 4.53 ml TEL per gallon. (Fig. 1 of reference 6.)

Effect on knock-limited power.—When the ethylene dibromide concentration was increased to the equivalent of a 2-T mix, there was apparently no effect on the knock limit over the range of conditions investigated in the full-scale air-cooled cylinder (fig. VII-8). (See references 6 and 7.)

Other tests were made to evaluate the effects of ethylene dibromide on knock-limited power in a CFR test engine operating at conditions specified for the A. S. T. M. Supercharge method; the results are presented in table VII-1.

(a) Valve after 18 hours operation with 1-T mix.

(b) Valve after 18 hours operation with 2-T mix.

FIGURE VII-8.—Effect of excess ethylene dibromide on knock-limited performance in air-cooled aircraft cylinder. Engine speed, 2200 rpm; inlet-air temperature, 250° F; spark advance, 20° B. T. C. (Fig. 3 of reference 6.)

Increasing the ethylene dibromide concentration from 0 to 5.34 ml per gallon decreased the knock-limited power of the leaded and unleaded S reference fuel about the same amount, 6 to 9 percent depending upon the fuel-air ratio. Changing the concentration of ethylene dibromide from 0 to 2.67 to 4.01 ml per gallon had no effect on the knock-limited performance of the leaded fuel; however, a change of 0 to 2.67 ml per gallon decreased the knock-limited power of the unleaded fuel a maximum of about 6 percent.

LEAD SUSCEPTIBILITY

The lead susceptibility or lead response of a fuel is defined as the increase in knock-limited performance of the fuel resulting from the addition of a given quantity of tetraethyl lead. In 1943 the NACA conducted an analysis of existing data on pure hydrocarbon fuels to determine the manner in which the lead susceptibility is influenced by fuel type, engine type, and engine operating conditions. This analysis (references 8 and 9) was based on data obtained from the American Petroleum Institute (API) Hydrocarbon Research Project.

DATA FROM SUPERCHARGED ENGINES

In cooperation with the API, the Ethyl Corporation investigated the lead susceptibility of many pure compounds. These data were determined in a small-scale engine having a displacement of 17.6 cubic inches.

Paraffins.—Examination of the Ethyl Corp. data demonstrated that the lead susceptibility could be represented as a straight line by plotting the knock-limited indicated mean effective pressures of the pure fuels against the knock-limited indicated mean effective pressures of the leaded fuels (reference 8). By this method, data for paraffinic fuels were plotted as shown in figure VII-9 (a). It is obvious in this figure that the fuel which has the highest permissible indicated mean effective pressure in the pure state has the greatest lead response. The percentage increase in indicated mean effective pressure for 1.0 ml TEL, however, is constant regardless of the permissible indicated mean effective pressure. Heron and Beatty (reference 10) found this fact to be true for 6.0-ml additions of tetraethyl lead.

The susceptibility of isooctane to various quantities of tetraethyl lead is shown in figure VII-9 (b). Because it was believed that the lead susceptibility of all paraffins might be represented by a chart similar to figure VII-9 (b), a later investigation (reference 9) was made with blends of two paraffinic fuels (S and M reference fuels) containing up to 8.0 ml TEL per gallon. This study was made in a supercharged CFR engine modified as described in reference 11.

Data from reference 9 are plotted in figure VII-10. These plots are based on results reported by Heron and Beatty (reference 10) which indicate that for supercharged tests a linear relation exists between the reciprocal of the knock-limited indicated mean effective pressures and blend composition. (See chapter VIII.)

(a) Paraffins. (Fig. 10 of reference 8.)
(b) Isooctane (2,2,4-trimethylpentane). (Fig. 11 of reference 8.)

FIGURE VII-9.—Lead susceptibility of various fuels in 17.6 engine. Compression ratio, 5.6; engine speed, 900 rpm; approximate fuel-air ratio, 0.07; inlet-air temperature, 225° F; coolant temperature, 300° F.

The lines of constant tetraethyl lead concentration in these figures can be represented by the equation of an equilateral hyperbola:

$$P(A-N)=B \quad (1)$$

where

N volume percentage of S reference fuel in M reference fuel
 B slope

The asymptotes of the hyperbola represented by equation (1) are zero and A . The constant A is independent of tetraethyl lead concentration and fuel-air ratio and is equal to 145 (the intersection of the curves with the abscissa).

In figures VII-11, the data from figure VII-10 have been converted to plots of the knock-limited indicated mean effective pressure of the clear fuel against the knock-limited indicated mean effective pressure of the leaded fuel. This type of plot has an advantage over that of figure VII-10 in that the lead susceptibility can be represented by a linear relation without the use of a reciprocal scale.

A scale representing antiknock ratings in terms of octane numbers and leaded isooctane has been added to figure VII-11. This scale corresponds to the ordinate values of knock-limited indicated mean effective pressure; that is, a 90-octane fuel whether clear or leaded (fig. VII-11(a)) has a knock-limited indicated mean effective pressure of 85 pounds per square inch under the conditions presented. With the addition of this scale, the chart may be used to obtain either the knock-limited indicated mean effective pressure or the octane rating of a paraffinic fuel containing various quantities of tetraethyl lead. Only the unleaded fuel need be tested in order to estimate the lead response for any concentration of tetraethyl lead.

The estimation of lead susceptibility according to the foregoing procedure is of value in the study of paraffinic fuels in which the quantity of fuel available for testing is limited. In such cases the rating of the clear fuel can be determined by a standard rating method such as the A. S. T. M. Supercharge rating method, and the rating of the test fuel plus various amounts of tetraethyl lead can be approximated from a chart previously established for the selected rating method.

Cycloparaffins and olefins.—Insufficient data exist to establish definitely the susceptibilities of the cycloparaffins (fig. VII-12 (a)) and olefins (fig. VII-12 (b)). When figures VII-9, VII-12 (a), and VII-12 (b) are compared, the order of lead response for the paraffins, cycloparaffins, and olefins is found to be as follows:

Hydrocarbons	Percentage increase imep					
	(ml TEL/gal)					
	1.0	2.0	3.0	4.0	5.0	6.0
Paraffins.....	26	36	46	51	57	61
Cycloparaffins.....	23					
Olefins.....	14					

* Percentage increase in imep for olefins was estimated from diisobutylene.

DATA FROM NONSUPERCHARGED ENGINES

The relation between critical compression ratio and A. S. T. M. Motor method octane number can be represented by the equation for a hyperbola. (See fig. VII-13.) The curve in this figure was calculated from figure 1 of reference 12, which shows the relation between height of compression chamber and A. S. T. M. Motor method octane number.

FIGURE VII-12.—Lead susceptibility of various fuels in 17.6 engine. Compression ratio, 5.6; engine speed, 900 rpm; approximate fuel-air ratio, 0.07; inlet-air temperature, 225° F; coolant temperature, 300° F. (Fig. 13 of reference 8.)

The equation for the curve in figure VII-13 is

$$(R-3.3)(125-N_1)=125 \quad (2)$$

where

R critical compression ratio

N_1 A. S. T. M. Motor method octane number

The asymptotes for the curve are critical compression ratio, 3.3 and A. S. T. M. Motor method octane number, 125. As

FIGURE VII-13.—Variation of critical compression ratio with octane number for A. S. T. M. Motor method. (Fig. 3 of reference 8.)

FIGURE VII-14.—Lead susceptibility of various fuels based on A. S. T. M. Motor ratings.

pointed out in reference 8, these asymptotes will vary with engine operating conditions.

The curve just discussed is related to a linear method used by Heron and Beatty (reference 10) to express lead susceptibility (gain of octane number per ml TEL). The method is illustrated in figure VII-14 (a) for data obtained by the API. The relation between figures VII-13 and VII-14 (a) may be shown by extending the lines in figure VII-14 (a) until they intersect. This intersection occurs at an octane number of 125. If both scales of figure VII-14 (a) were converted to critical compression ratios, the point of intersection of the curves would be at a compression ratio of 3.3. These two points of intersection are the asymptotes of figure VII-13.

Figure VII-14.—Concluded. Lead susceptibility of various fuels based on A. S. T. M. Motor method ratings.

FIGURE VII-15.—Variation of K with tetraethyl lead concentration. (Fig. 25 of reference 8.)

FIGURE VII-16.—Variation of compression ratio with tetraethyl lead concentration. (Fig. 26 of reference 8.)

FIGURE VII-17.—Variation of power increase with tetraethyl lead concentration for reference fuel as determined by A. S. T. M. Supercharge method. (Fig. 10 of reference 9.)

By the use of critical compression ratios, an analysis similar to that used for supercharged test engine data has been made (reference 8). As shown in figures VII-14 (b) and VII-14 (c), the lead response of the paraffins may be represented by single straight lines for 1.0 and 3.0 ml TEL, respectively. The equation for these straight lines of constant tetraethyl lead concentration is

$$R_1 = KR - 3.3 (K - 1) \quad (3)$$

where

R_1 critical compression ratio of leaded fuel

R critical compression ratio of pure fuel

K slope of line of constant tetraethyl lead concentration

The cycloparaffins (figs. VII-14 (d) and VII-14 (e)) may also be represented by single straight lines. The lead susceptibility of the olefins (figs. VII-14 (f) and VII-14 (g)) is apparently affected by the position of the double bond and therefore a single line cannot be used to represent the class as a whole.

For each class of hydrocarbons a different value of K will be obtained (equation (3)). The values of K determined for the data presented in this analysis are as follows:

Hydrocarbon	Slopes of lead susceptibility curves	
	For 1.0 ml	For 3.0 ml
Paraffins.....	1.34	1.57
Cycloparaffins.....	1.24	1.41
Octene-2.....	1.22	1.33
Octene-1.....	1.13	1.30

FIGURE VII-18.—Effect of inlet-air temperature on lead susceptibility of S reference fuel in CFR engine. Compression ratio, 7.0; engine speed, 2000 rpm; coolant temperature, 250° F; spark advance, 35° B. T. C. (Fig. 11 of reference 9.)

FIGURE VII-19.—Effect of spark advance on lead susceptibility of S reference fuel in CFR engine. Compression ratio, 7.0; engine speed, 2000 rpm; inlet-air temperature, 250° F; coolant temperature, 250° F. (Fig. 12 of reference 9.)

Because K is the slope of the line of constant tetraethyl lead concentration, it is necessary to determine the lead response of only one compound in a particular hydrocarbon classification in order to estimate the lead response of other compounds of the same type from their pure ratings. The variation of K with tetraethyl lead concentration is shown in figure VII-15.

Unlike supercharged data in which the percentage increase in power is constant for a given quantity of tetraethyl lead regardless of the pure fuel rating, the percentage increase in critical compression ratio for a given quantity of tetraethyl lead varies with the pure fuel ratings. This variation is illustrated for the paraffins by the curves in figure VII-16.

EFFECTS OF ENGINE CONDITIONS ON LEAD SUSCEPTIBILITY

Fuel-air ratio.—The effects of fuel-air ratio on lead susceptibility are readily seen in figure VII-17. Curves from the standard reference fuel framework for the A. S. T. M. Supercharge rating engine were used in preparing this plot. It is emphasized that the effects shown will vary considerably from one engine or condition to another.

Inlet-air temperature.—The lead susceptibility from tests at different inlet-air temperatures is presented in figure VII-18 at two different fuel-air ratios. For the range of inlet-air temperatures examined, the lead susceptibility of S reference fuel was constant; that is, the percentage increase of knock-limited indicated mean effective pressure caused by the addition of a given amount of tetraethyl lead was the same regardless of the inlet-air temperature.

Spark advance.—Tests made on S reference fuel clear and with 2 ml TEL per gallon at spark advances of 20° and 35°

B. T. C. are shown in figure VII-19. These data indicate that the lead susceptibility of S reference fuel is independent of variations of spark advance.

CHAPTER VIII

ANTIKNOCK BLENDING CHARACTERISTICS OF FUELS

For many years it has been known that all hydrocarbons do not exhibit the same antiknock blending characteristics. Lovell and Campbell (reference 1) illustrated this fact, and Smittenberg *et al* (reference 2) likewise clearly demonstrated that the antiknock characteristics of fuel blends depend upon the nature of the components in the blend.

An investigation was initiated in 1943 by Sanders (reference 3) to ascertain the possibility of developing a method for predicting the knock limits of fuel blends under supercharged and nonsupercharged engine operating conditions. In the original phases of this analysis, results of critical-compression-ratio (nonsupercharged) rating methods rather than results of supercharged methods were emphasized because more complete data were available and the analysis required was more detailed.

SYMBOLS

The following symbols are used in this chapter:

A, B	constants characteristic of fuels
a, b, c	constants
F	$= N_1(B_1R_1 - B_2R_2) + B_2R_2$
G	$= N_1(B_1 - B_2) + B_2 = N_1B_1 + (1 - N_1)B_2$
H	height of compression chamber, inches
k	quantity of knock-producing agent generated per unit mass
N	mass fraction
P	knock-limited indicated mean effective pressure
R	compression ratio
W, X, Y	constants in hyperbolic blending relation
β	blending constant
ρ	density
Subscripts:	
a	value of subscript 1 at asymptote
b	blend
cr	critical
d	pertaining to knock agent produced under conditions at which blend will knock
i	isooctane
m	pertaining to knock-producing agent at condition of incipient knock
t	total
1, 2, 3,	pertaining to components 1, 2, 3... in fuel blend

DERIVATIONS OF BLENDING EQUATIONS

The derivations developed in reference 3 require a clear understanding of the principles of knock testing by supercharged and nonsupercharged methods. In supercharged engine tests, all conditions except inlet-air pressure and fuel-air ratio are held constant. Fuel-air ratio may or may not be constant depending upon the operating technique employed. Inlet-air pressure is increased until a predetermined

standard knock intensity is observed. The knock-limited indicated mean effective pressure or the density of air in the cylinder charge may be used as a measure of the knock limit of the fuel being tested.

In nonsupercharged engine tests, all conditions except compression ratio are held constant. The compression ratio is increased until the standard knock intensity is reached. The compression ratio at this intensity is the measure of the knock limit and is generally termed critical compression ratio. Changes of inlet-air pressure do not affect any of the cyclic temperatures; however, an increase of compression ratio increases the temperature at the end of compression, the combustion temperature, and the end-gas temperature. The primary difference between nonsupercharged and supercharged engine methods thus lies in the fact that knock limits in nonsupercharged engines are measured at varying end-gas temperatures, whereas in supercharged engines knock limits are determined at the same end-gas temperature. (See reference 4.)

In order to derive the desired blending equations, certain assumptions were made in reference 3 regarding the mechanism of knock:

(1) Knock results from the reaction of some intermediate products during combustion, and the nature of these products as well as the reaction between them is the same regardless of the fuel used. This assumption is introduced in order that the knocking properties of fuels may be treated as additive properties.

(2) Knock occurs when the mass of knock-producing agents per unit volume reaches a given value at any end-gas temperature.

(3) At any one end-gas temperature and for any one fuel component, the mass per unit volume of the knock-producing agent evolved by that component is directly proportional to the mass of the component per unit volume; or, as stated in reference 3, a unit mass of a particular component will generate a certain mass of knock-producing agent regardless of the other components in the blend.

(4) In order to consider the differences in knock limits of the blend components, it is assumed that for any one end-gas temperature, the mass per unit volume of the knock-producing agents is a function of the molecular structure of the fuel.

(5) During combustion the temperature increase for all fuels or blends under consideration is the same. On the basis of this assumption it is possible to relate fuel knock limits to engine compression density and temperature instead of end-gas density and temperature. Many hydrocarbons of interest fulfill this condition, but some classes of fuels, such as alcohols and ethers, do not (reference 3).

The initial step in the derivation of the desired equation is justified by assumptions (1) and (2).

where

$$\rho_m = \rho_1 + \rho_2 + \rho_3 + \dots \quad (1)$$

ρ_m mass per unit volume of knock-producing agent at condition of incipient knock

$\rho_1, \rho_2, \rho_3, \dots$ mass per unit volume of knock agent produced by each component under conditions at which the blend will knock

It has been stated previously that the end-gas temperatures are constant for supercharged-engine tests but vary with the critical compression ratio of the fuel in nonsupercharged-engine tests; therefore, from assumptions (3) and (4) the following relations hold for supercharged tests:

$$\rho_1 = k_1 \rho_t N_1$$

$$\rho_2 = k_2 \rho_t N_2$$

$$\rho_3 = k_3 \rho_t N_3$$

where

N_1, N_2, N_3 mass fractions of components 1, 2, 3, respectively, in fuel blend

ρ_t total mass of fuel per unit volume

k_1, k_2, k_3 quantity of knock-producing agent generated per unit mass by components 1, 2, 3, respectively

When the pure compound 1 is tested, the knock-limited density of fuel in the charge is $\rho_{t,1}$ and

$$\rho_m = \rho_1 = k_1 \rho_{t,1} \quad (2)$$

Therefore,

$$k_1 = \frac{\rho_m}{\rho_{t,1}}$$

and

$$\rho_1 = \frac{\rho_m}{\rho_{t,1}} \rho_t N_1$$

Similarly,

$$\rho_2 = \frac{\rho_m}{\rho_{t,2}} \rho_t N_2$$

and

$$\rho_3 = \frac{\rho_m}{\rho_{t,3}} \rho_t N_3$$

Substituting these values of $\rho_1, \rho_2, \rho_3, \dots$ in equation (1) yields

$$\rho_m = \frac{\rho_m}{\rho_{t,1}} \rho_t N_1 + \frac{\rho_m}{\rho_{t,2}} \rho_t N_2 + \frac{\rho_m}{\rho_{t,3}} \rho_t N_3 + \dots$$

and

$$\frac{1}{\rho_t} = \frac{N_1}{\rho_{t,1}} + \frac{N_2}{\rho_{t,2}} + \frac{N_3}{\rho_{t,3}} + \dots \quad (3)$$

As limited by the assumptions, equation (3) is a blending equation applicable to supercharged-engine data. Because the compression ratio and fuel-air ratio must be the same for the various components in a given application of this equation, knock-limited inlet-air densities may be used instead of the fuel densities for values of $\rho_t, \rho_{t,1}, \rho_{t,2}, \rho_{t,3}, \dots$. With this substitution, equation (3) may be expressed in words as

follows: The reciprocal of the knock-limited inlet-air density of a fuel blend tested by a supercharged-engine method is the weighted average of the reciprocals of the knock-limited inlet-air densities of the pure components.

Indicated mean effective pressure is proportional to inlet-air density; therefore, it can be substituted in equation (3) for density:

$$\frac{1}{P_b} = \frac{N_1}{P_1} + \frac{N_2}{P_2} + \frac{N_3}{P_3} + \dots \quad (3b)$$

where

P_b knock-limited indicated mean effective pressure of fuel blend

P_1, P_2, P_3 knock-limited indicated mean effective pressures of components 1, 2, 3, respectively, when tested individually

For nonsupercharged tests, the charge density at the end of compression is proportional to the compression ratio. By use of an equation similar to equation (2), ρ_1 was related to the compression ratio instead of the mass of fuel per unit volume (reference 3). The value of k_1 , however, varies with compression ratio because the compression temperature varies with compression ratio. In order to account for the variation of k_1 , the following relation was assumed (reference 3) between ρ_1 and compression ratio R :

$$\rho_1 = (A_1 + B_1 R) N_1 \quad (4)$$

where

A_1, B_1 constants characteristic of fuel 1

Similarly,

$$\rho_2 = (A_2 + B_2 R) N_2$$

and

$$\rho_3 = (A_3 + B_3 R) N_3$$

where

A_2, B_2, A_3, B_3 constants characteristic of fuels 2 and 3

Substituting these values in equation (1) gives

$$\rho_m = N_1 (A_1 + B_1 R) + N_2 (A_2 + B_2 R) + N_3 (A_3 + B_3 R) + \dots \quad (5)$$

The value of A_1 may be determined by letting $N_1=1, N_2=0, N_3=0$, and $R=R_{1,cr}$ where $R_{1,cr}$ is the critical compression ratio of fuel 1 when tested individually.

$$\rho_m = A_1 + B_1 R_{1,cr}$$

$$A_1 = \rho_m - B_1 R_{1,cr}$$

Likewise,

$$A_2 = \rho_m - B_2 R_{2,cr}$$

and

$$A_3 = \rho_m - B_3 R_{3,cr}$$

Substituting in equation (5) gives

$$R = \frac{N_1 B_1 R_{1,cr} + N_2 B_2 R_{2,cr} + N_3 B_3 R_{3,cr} + \dots}{N_1 B_1 + N_2 B_2 + N_3 B_3 + \dots} \quad (6)$$

As limited by the assumptions, equation (6) is the blending equation applicable to nonsupercharged-engine data.

In this equation $B_1, B_2, B_3 \dots$ are defined as blending constants and each fuel has a blending constant that is independent of the other fuels in the blend and is determined by the critical compression ratio of the fuel and the rate of change of knock limit with inlet-air temperature.

For two-component blends, $N_2 = 1 - N_1$ and equation (6) may be written as

$$R = \frac{N_1(B_1 R_{1,cr} - B_2 R_{2,cr}) + B_2 R_{2,cr}}{N_1(B_1 - B_2) + B_2} \quad (7)$$

Equation (7) is the equation of an equilateral hyperbola asymptotic to

$$N = \frac{B_2}{B_2 - B_1} = N_{a,1}$$

and

$$R = \frac{B_1 R_1 - B_2 R_2}{B_1 - B_2} = R_a$$

where

$N_{a,1}$ value of N_1 at asymptote

R_a value of R at asymptote

The asymptotic form of equation (7) is

$$(R - R_a)(N_a - N_1) = N_a(R_2 - R_a) \quad (8)$$

According to reference 3, it is unnecessary to know the absolute values of the constants in equations (6) and (7), but the relative values must be known; that is, one component may be assigned an arbitrary value of the constant, thereby fixing the values of the constants for all other components tested at the same conditions. Values of B for other components may be found by determining the critical compression ratio of the pure component and of one blend of the component with another component for which the blending constant is known. With these values the equation can be solved for the value of the unknown blending constant. When the relative values of B have been determined for all compounds, the knock limits of all blends may be computed from the blending equation.

GRAPHICAL SOLUTION OF BLENDING EQUATION FOR NONSUPERCHARGED-ENGINE DATA

A graphical method was suggested in reference 3 for determination of the blending characteristics of fuels when tested in nonsupercharged engines. Equation (7) may be put into the following form:

$$F = RG \quad (9)$$

where

$$F = N_1(B_1 R_1 - B_2 R_2) + B_2 R_2$$

and

$$G = N_1(B_1 - B_2) + B_2 = N_1 B_1 + (1 - N_1) B_2$$

If R is held constant, F is proportional to G . In figure VIII-1, the value of F has been plotted against the value of G for values of R between 2 and 15. Inasmuch as G is actually the weighted average value of B_1 and B_2 , the abscissa of

FIGURE VIII-1.—Blending chart for A. S. T. M. Motor method. (Fig. 1 of reference 3.)

figure VIII-1 has been marked G or B . All potential fuel components whose critical compression ratios and blending constants are known may be plotted on this chart.

A straight line joining the points for any two components represents all blends of the two components. This relation is true because F and G are linear functions of N_1 and, consequently, F is a linear function of G . A point representing any blend of the two components divides the line in the same ratio as that in which the components exist in the blend. For example, a blend containing 60 percent 2,2,4-trimethylpentane (isooctane) and 40 percent n -heptane will be on the line joining the points for the two components and will be 60 percent of the distance from n -heptane to 2,2,4-trimethylpentane.

EXPERIMENTAL VERIFICATION OF BLENDING EQUATIONS

Heron and Beatty (reference 5) have shown that if the reciprocal of the knock-limited indicated mean effective pressures of blends of isooctane and n -heptane is plotted against the percentage of isooctane in the blends, a straight line will result. This fact substantiates equation (3) for supercharged-engine data. The data obtained in reference 5 are shown in figure VIII-2 (a).

(a) 17.6 engine. Compression ratio, 5.6; engine speed, 900 rpm; inlet-air temperature, 225° F; coolant temperature, 300° F; spark advance, 20° B. T. C. (Fig. 2 of reference 3.)

FIGURE VIII-2.—Effect of blend composition on knock-limited performance.

Further verification of this relation is presented in figure VIII-2 (b), which shows data for S and M reference fuel blends investigated in reference 3.

Data obtained in references 2 and 6 were used in reference 3 for verification of the blending equation developed for nonsupercharged engine tests. The blending equation for *n*-heptane and isooctane under A. S. T. M. Motor method conditions is shown in reference 2 to be

$$N_i = \left(\frac{1.369 - H}{1.954 - H} \right) 179 \quad (10)$$

where

N_i isooctane in blend, percent

H height of compression chamber, inches

The value of N_i is given on a volumetric basis in reference 2 but, since the densities of the two components are about the same, N may be used as the mass fraction. The length of the engine stroke was 4.5 inches; therefore, the relation between R and H can be expressed as follows:

$$R = \frac{4.5 + H}{H} \quad (11)$$

Combining equations (10) and (11) gives

$$(R - 3.3)(125 - N_i) = 125 \quad (12)$$

The equilateral hyperbola represented by equation (12) is asymptotic to $R = 3.3$ and $N_i = 125$. The relation between R and N_i is shown in figure VIII-3(a). Inasmuch as the

(b) CFR engine. Compression ratio, 7.0; engine speed, 2000 rpm; inlet-air temperature, 250° F; coolant temperature, 250° F; spark advance, 35° B. T. C. (Fig. 3 of reference 3.)

FIGURE VIII-2.—Concluded. Effect of blend composition on knock-limited performance.

(a) A. S. T. M. Motor method. (Fig. 4 of reference 3.)

FIGURE VIII-3.—Blending characteristics of 2,2,4-trimethylpentane and *n*-heptane.

(b) A. S. T. M. Motor method; reciprocal plot. (Fig. 5 of reference 3.)

FIGURE VIII-3.—Continued. Blending characteristics of 2,2,4-trimethylpentane and *n*-heptane.

(c) A. S. T. M. Research method; reciprocal plot. (Fig. 6 of reference 3.)

components of this system are *n*-heptane and isooctane, *N* is equivalent to octane number. (See ch. III.) The curve in figure VIII-3(a) is drawn from equation (12), whereas the data points shown are taken directly from reference 2. The data from figure VIII-3(a) were replotted (reference 3)

FIGURE VIII-4.—Verification of hyperbolic blending relation for knock ratings of fuel blends by A. S. T. M. Motor method. (Fig. 7 of reference 3.) Equation of hyperbola: $(R-X)(Y-N)=W$.

as shown in figure VIII-3(b) as confirmation of the hyperbolic blending relation.

Similar data for the A. S. T. M. Research method were reported by Brooks (reference 6) and are plotted in figure VIII-3 (c). Here again the relation is linear, but the intercepts are 120 and 1.53 as compared with 125 and 1.0 for the A. S. T. M. Motor method shown in figure VIII-3 (b). The equation for the A. S. T. M. Research method data is

$$(R-4.2)(120-N)=78.3 \quad (13)$$

From the foregoing comparison of the A. S. T. M. Motor and Research methods, it was concluded (reference 3) that the asymptotes of the blending hyperbola change with changing engine conditions.

Blending relations for other two-component blending systems are shown in figure VIII-4. The data for these systems were taken from reference 2. Three two-component systems investigated in reference 2 did not follow the hyperbolic relation. These systems are shown in figure VIII-5.

FIGURE VIII-5.—Blending characteristics of diisobutylene, benzene, and toluene in *n*-heptane by A. S. T. M. Motor method. (Fig. 6 of reference 3.)

FIGURE VIII-6.—View of combustion chamber showing location of thermocouple in end zone. (Fig. 1 of reference 8.)

In connection with the system of blends of *n*-heptane and benzene (fig. VIII-5), it was found that up to a concentration of 90 percent benzene a hyperbolic relation is valid, but the value for pure benzene does not follow the relation (reference 3). In explanation of this discrepancy it should be noted that the authors of reference 2 expressed the belief that the knock rating of pure benzene might be in error.

In order to illustrate the invariance of the blending constant, a series of calculations was made involving several hydrocarbons (reference 3). The constants evolved in these calculations have been plotted on figure VIII-1. Values for cyclopentane and *n*-propylbenzene were computed from data reported in reference 7.

APPLICABILITY OF EQUATIONS TO DIFFERENT BLENDING AGENTS AND ADDITIVES

The preliminary data used in support of the derivation developed in the foregoing pages were admittedly meager; consequently, an extensive investigation was initiated to determine the general applicability of the blending equation. In the course of this investigation a number of fuels of various types were studied under different engine operating conditions in supercharged engines. The results of this investigation are reported in the succeeding paragraphs.

Paraffins.—The base fuels used in this phase of the study were an alkylate blending agent and a virgin base gasoline. The blending agents examined were:

- Triptane (2,2,3-trimethylbutane)
- Isopentane (2-methylbutane)
- Diisopropyl (2,3-dimethylbutane)
- Neohexane (2,2-dimethylbutane)
- Hot-acid octane

All blending agents and base stocks contained 4.0 ml TEL per gallon. Inspection data for these fuels are included in appendix A, table A-9. (See references 8 and 9.)

The experimental studies of these fuels were made in a single air-cooled aircraft cylinder mounted on a CUE crankcase. This apparatus is described in detail in reference 9 with the exception of a special thermocouple embedded in the cylinder head about $\frac{1}{16}$ inch from the combustion-chamber wall at a position estimated to be very near the exhaust end zone (fig. VIII-6). The temperature at this thermocouple was held constant by means of an automatic potentiometer regulator that controlled cooling-air flow across the cylinder. This instrumentation is consistent with the assumption made in reference 3 that for the blending equation to be applicable to supercharged engine data, the cyclic and end-gas temperatures must be held constant.

In figure VIII-7, a portion of the data determined in the investigation of reference 8 is shown. The ordinate scales of these figures are inverted reciprocal scales. When plotted in this manner, the data should fall on a straight line if the results are applicable to equation (3b). It is apparent in these figures that the paraffinic fuels examined, with the

FIGURE VIII-7.—Blending characteristics of paraffins in virgin base stock leaded to 4 ml TEL per gallon in full-scale air-cooled aircraft cylinder. Compression ratio, 7.7; engine speed, 2000 rpm; spark advance, 20° B. T. C.; inlet mixture temperature, 350° F; exhaust back pressure, atmospheric. (Data taken from reference 8.)

exception of neohexane at the lean fuel-air ratio, are in accord with the blending equation for supercharged-engine data.

These data were obtained at a spark advance of 20° B. T. C., a condition considered to be relatively mild; consequently, additional tests were made at a more severe condition (spark advance, 30° B. T. C.). The results of these advanced spark studies are essentially the same as those shown in figure VIII-7; that is, the relation between the reciprocal indicated mean effective pressure and composition was linear. In this case, however, data for neohexane followed the relation at both lean and rich mixtures. (See reference 8.)

Aromatics.—Experimental verification of the blending relation for aromatic fuels proved to be difficult inasmuch as pure aromatics have exceptionally high knock limits and are prone to preignite. (See reference 10.) Despite these obstacles, however, a reasonable quantity of data was obtained to determine the limitations of this class of compounds. In pursuing this phase of the investigation, no effort was made to attain the knock limit of the pure aromatics. Instead, each aromatic was blended with a paraffinic base stock and the concentration was increased until the power level was con-

(a) Aromatics in virgin base stock.

(b) Cycloparaffins in virgin base stock.

(c) Methylcyclopentane in aviation alkylate.

FIGURE VIII-8.—Blending characteristics of various fuels leaded to 4 ml TEL per gallon in full-scale air-cooled aircraft cylinder. Compression ratio, 7.3; engine speed, 2250 rpm; spark advance, 20° B. T. C.; inlet mixture temperature, 240° F; end-zone temperature, 400° F; exhaust back pressure, 15 inches of mercury absolute; fuel-air ratio, 0.10. (Data taken from reference 10.)

sidered too high to warrant further increases. Results of these tests are shown in figure VIII-8 (a). Here it is seen that the relation between composition and reciprocal indicated mean effective pressure is nonlinear.

FIGURE VIII-9.—Blending characteristics of benzene, virgin base stock, and aviation alkylate in full-scale air-cooled aircraft cylinder. Concentration of benzene in all blends, 25 percent by volume; compression ratio, 7.7; engine speed, 2000 rpm; spark advance, 20° B. T. C.; inlet mixture temperature, 240° F; end-zone temperature, 350° F. (Fig. 3 (b) of reference 11.)

A modification of equation (3b) is proposed in reference 9 in order to account for fuel components that do not follow the linear blending relations.

$$P_o = \frac{P_1 N_1 B_1 + P_2 N_2 B_2 + P_3 N_3 B_3 + \dots}{N_1 B_1 + N_2 B_2 + N_3 B_3 + \dots} \quad (14)$$

Another form of equation (14) is (reference 9)

$$\frac{N_1 \beta_1 + N_2 \beta_2 + N_3 \beta_3 + \dots}{P_o} = \frac{N_1 \beta_1}{P_1} + \frac{N_2 \beta_2}{P_2} + \frac{N_3 \beta_3}{P_3} + \dots \quad (15)$$

$\beta_1, \beta_2, \beta_3, \dots$ blending constants related to constants $B_1, B_2, B_3, \dots$ by the following equations:

$$\beta_1 = P_1 B_1$$

$$\beta_2 = P_2 B_2$$

$$\beta_3 = P_3 B_3$$

Both equations (14) and (15) are equal to equation (3b) when $\beta_1 = \beta_2 = \beta_3$ or $P_1 B_1 = P_2 B_2 = P_3 B_3$.

Performance data for aromatic fuels were employed (reference 10) to determine the validity of equation (15). From the analysis it was concluded that the equation does not apply over the entire range of composition; that is, the blending constant β for a given aromatic varies somewhat.

From a practical point of view, however, marketed aviation fuels seldom contain concentrations of aromatics in excess of 25 percent (generally much less), and for a limited range of concentration it is believed that equation (15) may be useful. Evidence to support this belief is shown in figure VIII-9.

It is seen in this figure that the blending relations are linear for a 25-percent concentration of benzene in blends of alkylate and virgin-base stock. Similar results were obtained with toluene, mixed xylenes, and cumene (reference 11). On the basis of figure V-6 (c) described in chapter V it is doubtful if the relations would be linear for concentrations much greater than 25 percent.

Cycloparaffins.—The results of tests with cycloparaffinic fuels are shown in figure VIII-8 (b). As in the case of the

aromatic fuels, the cycloparaffinic fuels examined failed to follow the blending relation in the form of either equation (3b) or equation (15).

One result of unusual interest was found in the cycloparaffinic investigation of reference 10. (See fig. VIII-8 (c).) In this figure it is seen that methylcyclopentane, when blended with alkylate, produced intermediate blends having higher knock limits than either of the pure components. This was also true for other cycloparaffins in blends with different base stocks. (See reference 10.)

Special additives.—The influence of special additives (for example, tetraethyl lead and xylydines) on the applicability of the blending equation is discussed in reference 9. In brief, the effect of such additives is essentially the same as the effect of low concentrations of aromatics mentioned in connection with figure VIII-9. That is, the blending equation applies so long as the concentration of such additives in the major blend components is constant.

PREPARATION OF BLENDING CHARTS

In the preceding sections of this chapter, a blending equation has been described and its limits of applicability have been shown by experimental data. The remainder of this chapter is devoted to an analysis that will illustrate the practical use of this equation. Specifically, the purpose of this analysis is to illustrate the preparation of performance charts from which blends of any desired lean and rich antiknock ratings can be selected. These charts are based entirely upon the A. S. T. M. Aviation (lean) and A. S. T. M. Supercharge (rich) knock rating methods. Experimental data upon which the charts are based may be found in appendix A, table A-10. (See reference 12.)

Performance numbers.—The scale of performance numbers for fuel knock rating terminates at 161. (See ch. III.) It was therefore necessary to extrapolate the scale in order to evaluate blends that would have antiknock ratings in excess of 161 by the A. S. T. M. Supercharge method. This extrapolation was made by plotting the performance numbers against knock-limited indicated mean effective pressures from a reference-fuel framework given in reference 13. The rating scale thus developed is shown in figure VIII-10. Although a definite break in this curve occurs at a performance number of 130, the curve appears to be linear between 130 and 160. On the assumption that this linear relation is true, a straight line was drawn through the points at 130 and 161 and extended to a performance number of 200.

Ternary blends.—As an example of the preparation of a performance chart, consider first that it is desired to know the A. S. T. M. Aviation and the A. S. T. M. Supercharge performance numbers of all possible ternary blends of hot-acid octane, an aviation alkylate, and a virgin base stock. A plot of composition against the reciprocal of the knock-limited indicated mean effective pressure for binary blends of any two of these fuels will result in a straight line. The three binary combinations of these materials are shown in figure VIII-11.

In the next operation, lines of constant performance number are drawn on the plot (shown as dashed lines on fig. VIII-11). These lines are established by reading values of indicated mean effective pressure at equal increments of performance number in figure VIII-10. The data as shown in figure VIII-11 comprise the basic information needed to establish A. S. T. M. Supercharge rating lines on the final chart for multicomponent blends.

For convenience in relating composition and knock-limited performance of ternary fuel blends, all performance charts in this investigation were prepared on triangular coordinate paper. The equation of a straight line on triangular coordinate paper is of the form

$$a = bN_1 + cN_2 + N_3$$

where

a, b, c constants

N_1, N_2, N_3 concentration of components 1, 2, and 3 in

FIGURE VIII-10.—Relation between performance number and knock-limited indicated mean effective pressure by A. S. T. M. Supercharge method. Fuel-air ratio, 0.11. (Fig. 1 of reference 12.)

ternary blend. Any equation relating knock-limited performance and blend composition that can be reduced to this form can be represented by a straight line of constant performance on triangular coordinate paper. Equation (3b) can be reduced to this form by multiplying through by any one of the performance values P_1, P_2 , or P_3 .

The performance chart for the system of hot-acid octane, aviation alkylate, and virgin base stock is shown in figure VIII-12 (a). Lines of constant performance number in this figure were determined by noting the intersections of the constant performance lines (fig. VIII-11) with the blending lines. For example, the 150-performance-number line in figure VIII-11 intersects the blending line of hot-acid octane and aviation alkylate at a composition of 32 percent hot-acid octane and 68 percent alkylate and intersects the blending line of hot-acid octane and virgin base stock at a composition

FIGURE VIII-11.—A. S. T. M. Supercharge blending characteristics of hot-acid octane, aviation alkylate, and virgin base stock loaded to 4 ml TEL per gallon. Fuel-air ratio, 0.11. (Fig. 2 of reference 12.)

of 67 percent hot-acid octane and 33 percent virgin base stock. These two compositions were plotted on figure VIII-12 (a) and joined by a straight line. Any point on this line represents a blend of hot-acid octane, alkylate, and virgin base stock that will give a performance number of 150 in the A. S. T. M. Supercharge engine at a fuel-air ratio of 0.11. All other lines in figure VIII-12 (a) were established in the same manner.

The lines in figure VIII-12 (a) are parallel, which is true when curves of the type shown in figure VIII-11 are linear. On the basis of data presented earlier in this chapter it appears that most paraffinic fuels do blend linearly. Even though certain constituents, such as the aromatics or ethers, do not blend linearly in combination with paraffinic base fuels, the procedure just outlined for the preparation of performance-number charts is not altered. In such cases,

(a) A. S. T. M. Supercharge method. (Fig. 3 of reference 12.)

FIGURE VIII-12.—Blending charts for hot-acid octane, aviation alkylate, and virgin base stock.

(b) A. S. T. M. Aviation method. (Fig. 5 of reference 12.)

FIGURE VIII-12.—Continued. Blending charts for hot-acid octane, aviation alkylate, and virgin base stock.

(c) A. S. T. M. Supercharge and A. S. T. M. Aviation methods. (Fig. 6 of reference 12.)

FIGURE VIII-12.—Concluded. Blending charts for hot-acid octane, aviation alkylate, and virgin base stock.

FIGURE VIII-13. A. S. T. M. Aviation blending characteristics of hot-acid octane, aviation alkylate, and virgin base stock leaded to 4 ml TEL per gallon. (Fig. 4 of reference 12.)

however, the charts prepared are subject to some error that arises from the assumption that curves of constant performance number on triangular coordinate paper are linear. Moreover, a nonlinear relation in a plot of the type shown in figure VIII-11 results in a variation of slope with performance number on the final triangular plot.

The procedure used for determining the lines of constant A. S. T. M. Aviation performance numbers for blends of the same fuels used in preparing figure VIII-12 (a) differs from that used for A. S. T. M. performance in that performance numbers are plotted directly against composition on linear coordinate paper and an estimated "best" curve is drawn through the data points to determine the binary blending relations shown in figure VIII-13. There is nothing to justify the use of this empirical method for dealing with A. S. T. M. Aviation ratings other than the fact that the end result agrees reasonably well with the experimental results. One or two exceptions to this method will be pointed out later.

The composition at the intersections of a given constant performance line with the blending lines (fig. VIII-13) were plotted on triangular coordinate paper and joined by straight lines. The resulting performance lines are shown in figure VIII-12 (b). The final chart (fig. VIII-12 (c)) was obtained by superimposing figure VIII-12 (b) on figure VIII-12 (a). Additional charts are shown in appendix B, figures B-1 and B-2 for other blending agents and base stocks. (All blends contained 4 ml TEL/gal.)

In appendix B, figure B-1 (e) represents the system of blends for cumene, virgin base, and alkylate; the lines showing A. S. T. M. Supercharge performance numbers were determined by plotting peak knock-limited-power values rather than power values at a fuel-air ratio of 0.11. This deviation from the procedure used for all other charts was necessitated by the fact that most of the mixture-response

FIGURE VIII-14.—A. S. T. M. Supercharge mixture-response curves for blends of cumene and virgin base stock leaded to 4 ml TEL per gallon. (Fig. 9 (a) of reference 12.)

curves for the cumene blends intersected at fuel-air ratios between 0.10 and 0.11. (See fig. VIII-14.) The fuel-air ratio for peak-knock-limited power varied between 0.115 and 0.132 for the cumene blends. No chart was prepared for blends of cumene, aviation alkylate, and one-pass catalytic stock because rich-mixture peaks were not obtained for a sufficient number of the binary blends of cumene and one-pass catalytic stock.

For the charts representing blends of xylenes (appendix B, figs. B-1 (f) and B-2 (g)), A. S. T. M. Aviation performance lines were omitted. This omission arises from the fact that the curve of composition against performance number for binary blends of xylenes and aviation alkylate passed through a minimum. (See fig. VIII-15.)

In general, data obtained on the A. S. T. M. Aviation engine for the aromatic blends could not be handled with complete satisfaction by the empirical procedure previously

FIGURE VIII-15.—A. S. T. M. Aviation blending characteristics of mixed xylenes and aviation alkylate. (Fig. 10 of reference 12.)

explained. For this reason the accuracy of the lines of constant A. S. T. M. Aviation performance shown for the aromatic-paraffinic systems is questionable.

Quaternary blends.—The performance charts presented in the preceding section are of interest primarily from consideration of maximum knock-limited performance attainable with various combinations of fuel blending agents and base stocks. On the other hand, producers of aviation fuel are interested in the maximum knock-free power attainable with a finished blend that meets physical-property specifications for aviation fuels. Accordingly, several charts have been prepared to illustrate how physical properties might be taken into consideration. In these examples the only physical property considered is the Reid vapor pressure. Current aviation fuel specifications preclude the use of fuels having vapor pressures in excess of 7 pounds per square inch.

In order to prepare these charts, adjustments in Reid vapor pressures of the main components were made by adding isopentane, which in the pure state has a vapor pressure of about 20 pounds per square inch. The addition of isopentane to adjust the vapor pressure of the components in a system such as that shown in figure VIII-16 will necessarily affect the maximum knock-free power attainable because of the performance rating of isopentane relative to the ratings of the other components in the system, as shown in table VIII-1.

TABLE VIII-1.—A. S. T. M. AVIATION AND A. S. T. M. SUPERCHARGE PERFORMANCE RATINGS AND REID VAPOR PRESSURES FOR VARIOUS AVIATION-FUEL COMPONENTS

Blending agent	Reid vapor pressure (lb/sq in.)	Performance number ^a

Cumene.....	.3	85	> 200

^a Performance numbers are for pure blending agent containing 4 ml TEL/gal.

^b Performance numbers over 161 are extrapolated (fig. VIII-10). Ratings are for fuel-air ratio of 0.11.

^c Extrapolated from experimental data for blends containing up to 60 percent isopentane.

^d Assumed to be the same as the rating for unleaded benzene.

FIGURE VIII-16.—Blending chart for triptane, aviation alkylate, and virgin base stock by A. S. T. M. Aviation and A. S. T. M. Supercharge methods. (Fig. 7 (a) of reference 12.) A. S. T. M. Supercharge fuel-air ratio, 0.11.

In figure VIII-16, for example, a blend of 58.5 percent triptane, 30.5 percent alkylate, and 11 percent virgin base stock has a lean-rich performance-number rating of 135/200 and a Reid vapor pressure of approximately 3.5 pounds per square inch. In order to obtain the same performance (135/200) with a blend of triptane, alkylate, and virgin base stock that has been isopentane to a Reid vapor pressure of 7 pounds per square inch (maximum permitted), a blend of 55 percent triptane, 17 percent alkylate, 7 percent virgin base stock, and 21 percent isopentane could be used. The addition of isopentane has thus effectively decreased the quantity of triptane needed to obtain the 135/200 performance rating. Isopentane has better performance characteristics than the alkylate or the virgin base stock used, as well as a higher Reid vapor pressure than the other three constituents in the blend. (See table VIII-1.)

It must be emphasized that the preceding example is given merely as an illustration of a fuel characteristic other than antiknock quality that must be considered for a finished fuel blend. This example is not intended to imply that the preparation of fuel blends with Reid vapor pressures adjusted to meet specifications will necessarily produce blends that will meet all other pertinent specifications.

Several performance charts for quaternary blends containing isopentane were prepared for comparison with the

charts previously described for ternary blends. In each of the quaternary systems the vapor pressure was adjusted to 7 pounds per square inch. Three assumptions were made in the preparation of these charts:

- (1) The relation between composition and Reid vapor pressure is linear for binary blends of isopentane with another paraffinic fuel.
- (2) The relation between composition and the reciprocal of the A. S. T. M. Supercharge (rich) knock-limited indicated mean effective pressure is linear for binary blends of isopentane with another paraffinic fuel.
- (3) The relation between composition and the A. S. T. M. Aviation performance number is linear for binary blends of isopentane with another paraffinic fuel.

On the basis of the available data, assumption (3) appears to be valid for only a few cases. For this reason the A. S. T. M. Aviation performance lines on the charts for quaternary blends may be in error.

As an example of the preparation of the performance chart for a quaternary system, assume that it is desired to isopentane the blends represented by figure VIII-16. The first step in this problem is to determine the amount of isopentane to be added to each of the pure components to obtain a Reid vapor pressure of 7 pounds per square inch and to determine the resultant lean and rich performance-

FIGURE VIII-17.—Blending charts for triptane, aviation alkylate, virgin base stock, and isopentane by A. S. T. M. Aviation and A. S. T. M. Supercharge methods. Reid vapor pressure, approximately 7 pounds per square inch; A. S. T. M. Supercharge fuel-air ratio, 0.11. (Fig. 11 of reference 12.)

FIGURE VIII-17.—Concluded. Blending charts for triptane, aviation alkylate, virgin base stock, and isopentane by A. S. T. M. Aviation and A. S. T. M. Supercharge methods. Reid vapor pressure, approximately 7 pounds per square inch; A. S. T. M. Supercharge fuel-air ratio, 0.11. (Fig. 11 of reference 12.) Percentage isopentane can be determined by subtracting sum of percentages of other components from 100.

number ratings for these blends. This information as determined from the foregoing assumptions and table VIII-1 is presented in the following table:

Fuel blend	A. S. T. M. Aviation performance number	A. S. T. M. Supercharge indicated mean effective pressure (lb/sq in.)
76 percent triptane + 24 percent isopentane + 4 ml TEL/gal	145	455
85 percent alkylate + 15 percent isopentane + 4 ml TEL/gal	121	200
92 percent virgin base + 8 percent isopentane + 4 ml TEL/gal	78	142

The triangular chart shown in figure VIII-17 (a) was obtained by treating these three blends (all of which have Reid vapor pressures of 7 lb/sq in.) as separate components by the procedure used in preparing figure VIII-16. Any point on figure VIII-17 (a) represents the A. S. T. M. Aviation and the A. S. T. M. Supercharge performance number of a quaternary blend. The actual quantity of each component in the blend, however, cannot be readily determined from the chart because the percentages given on the altitudes of the triangle show only the amounts of the binary blends at the vertexes. For this reason, the grid of the chart was so adjusted, as shown in figure VIII-17 (b), that the quantity of any one of the four components in the blend could be read directly from the chart.

As an illustration of the method for determining the com-

position of a fuel in figure VIII-17 (b), suppose that it is desired to prepare a blend of triptane, aviation alkylate, virgin base stock, and isopentane having a lean-rich rating of 130/180. The concentrations of triptane, alkylate, and virgin base in the blend having the desired rating can be read directly from the altitudes of the triangle in the manner used in previous charts. These concentrations are 48, 19, and 13 percent, respectively. The concentration of isopentane can be determined by subtracting the sum of the percentages of the other components from 100.

Performance charts for other quaternary systems are presented in figure VIII-18. The experimental value for the Reid vapor pressure of diisopropyl (table VIII-1) is 7.4; however, in preparing figures VIII-18 (b) to VIII-18 (d), a value of 7.0 was assumed for this fuel.

Accuracy of performance charts.—The accuracy of the charts was determined by selecting ternary or quaternary blends from the various charts and testing these blends by the standard A. S. T. M. Aviation and A. S. T. M. Supercharge procedures. Inasmuch as the rich ratings shown on the charts were estimated at a fuel-air ratio of 0.11, the check ratings were determined at this same fuel-air ratio.

The check blends tested are shown with their ratings in table VIII-2. These blends are also shown on the various charts (appendix B and figs. VIII-12 (c), VIII-16, and VIII-18 (a) to VIII-18 (c)) by the symbols. The fuel numbers shown adjacent to each of the symbols on the charts correspond to the fuel numbers given in this table.

Supercharge fuel-air ratio, 0.11. (Fig. 12 of reference 12.) Percentage isopentane can be determined by subtracting sum of percentages of other components from 100.

FIGURE VIII-19.—Comparison of estimated and observed knock-limited performance ratings determined by A. S. T. M. Aviation and A. S. T. M. Supercharge methods. A. S. T. M. Supercharge fuel-air ratio, 0.11. (Fig. 13 of reference 12.)

All the data in table VIII-2 are presented in figure VIII-19 to show the relation between estimated and observed performance numbers. For the 25 blends shown in figure VIII-19, the average deviation from the match line was 3.1 performance numbers for the lean ratings and 1.5 for the rich ratings.

In consideration of the accuracy of the charts it must be emphasized that the previously mentioned discrepancies noted in the lean ratings of binary blends containing aromatics are responsible for some of the large deviations in table VIII-2.

Discussion of performance charts.—The performance charts prepared in connection with this chapter can be used for certain general comparisons of paraffins, aromatics, and ethers. In figure VIII-16, for example, at the point representing a blend of 80 percent aviation alkylate, 20 percent virgin base stock, and 4 ml TEL per gallon, the lean-rich rating is 110/122. If a straight line is followed from this point toward the triptane vertex until 20 percent triptane has been added, the rating becomes 118/145. The addition of 20 percent triptane to the base blend has thus increased the lean rating of the base blend by 8 performance numbers and the rich rating by 23. If, however, the chart for benzene (appendix B, fig. B-1 (d)) with the same base stocks is examined, it is seen that a 20-percent addition of benzene changes the rating of the starting blend from 110/122 to 106/146. The addition of 20 percent benzene has therefore decreased the lean rating by 4 performance numbers, whereas

the rich rating has been increased by 24. From this comparison it follows that in this example the aromatic (benzene) and the paraffin (triptane) are equally effective for increas-

ing the A. S. T. M. Supercharge (rich) performance but that triptane is more effective than benzene for improving lean performance.

CHAPTER IX

FUEL VOLATILITY

A number of problems arise from the influence of fuel volatility on engine and aircraft performance. Among these are vapor lock, mixture distribution, ease of starting, cold weather operation, and vaporization loss. In order to permit reasonable control of these factors, fuel specifications include provisions for regulation of volatility. The particular limits established on the volatility characteristics of fuels are based on numerous laboratory investigations and considerable service experience. Some of the laboratory researches on volatility characteristics of fuel are described in this chapter.

MIXTURE DISTRIBUTION

In multicylinder engines an important requisite of good performance is uniform distribution of the fuel-air charge to the individual cylinders. However, design factors relating to engine induction systems (for example, intake manifolds, carburetors, and superchargers) tend to make the problem of distribution one of varying significance with each particular engine. Aside from the undesirable effect on general engine operation, nonuniform distribution increases fuel consumption and cooling requirements and decreases over-all knock limits. For a given engine and a fuel of given volatility, the mixture distribution is affected by over-all fuel-air ratio of the engine, engine speed, supercharger gear ratio, charge weight flow or engine power, throttle setting, and combustion-air inlet temperature. The investigation of reference 1 illustrates the degree to which these engine variables may affect mixture distribution.

Distribution of fuel-air mixture to the various cylinders was determined by exhaust-gas analysis (reference 2) by an improved sampling technique reported by Cook and Olson (reference 3). The engine used was an 18-cylinder, double-row, radial air-cooled engine installed on a test stand and fitted with a flight cowling. (See fig. IX-1.) The engine was equipped with a single-stage supercharger with low and high gear ratios of 7.6 and 9.45, respectively. Additional installation details may be found in reference 1.

The carburetor-deck pressure was maintained atmospheric and the throttle setting was varied to maintain fixed power for the tests in which the over-all fuel-air ratio, the engine speed, the power, or the intake-air temperature was varied. (See reference 1.) The results therefore show the effect of both the variable under investigation and the associated variation of throttle setting and are representative of normal sea-level performance. When the engine power and speed were varied, one of the most important influences on mixture-distribution changes was the variation in throttle angle resulting from atmospheric carburetor-deck pressure. During the tests of varying throttle setting, the carburetor-deck pressure was changed to maintain constant power; operation at altitude was thereby simulated.

FIGURE IX-1.—Installation of test engine and cowling. (Fig. 1 of reference 1.)

Effect of over-all fuel-air ratio on mixture distribution.—In figure IX-2 the influence of over-all fuel-air ratio on distribution is illustrated. It is readily seen in this figure that the distribution is best at lean fuel-air ratios. The difference between the richest and the leanest cylinders at an over-all fuel-air ratio of 0.101 is reduced from 0.032 to 0.003 at an over-all fuel-air ratio of 0.059. This general trend was found to be true at all operating conditions, although the magnitude of the differences varied. The trend is attributed to the fact that more nearly complete fuel evaporation occurs at low fuel flows where the irregularities of distribution caused by the concentration of fuel droplets are reduced. (See reference 1.)

FIGURE IX-2.—Variation of mixture distribution with over-all fuel-air ratio. Engine speed, 1600 rpm; engine power, 800 brake horsepower; low supercharger gear ratio. (Fig. 7 (a) of reference 1.)

(a) Engine power, 800 brake horsepower; over-all fuel-air ratio, 0.106.
(b) Engine power, 1000 brake horsepower; over-all fuel-air ratio, 0.110.
FIGURE IX-3.—Variation of mixture distribution with engine speed. (Fig. 9 of reference 1.)

Figure IX-4.—Variation of mixture distribution with supercharger gear ratio. Engine speed, 2000 rpm; engine power, 800 brake horsepower. (Fig. 10 (a) of reference 1.)

FIGURE IX-5.—Variation of mixture distribution with engine power. Engine speed, 2200 rpm; over-all fuel-air ratio, 0.089; low supercharger gear ratio. (Fig. 11 (b) of reference 1.)

FIGURE IX-6.—Variation of mixture distribution with throttle setting. Over-all fuel-air ratio, 0.100; low supercharger gear ratio. (Fig. 12 (a) of reference 1.)

Effect of engine speed on mixture distribution.—The results of tests at low supercharger gear ratio indicated that the variation of mixture strength between the richest and the leanest cylinders is not appreciably affected by changes of engine speed between 1600 and 2400 rpm (fig. IX-3) despite the accompanying variation in throttle angles. The general shape of the distribution patterns does vary somewhat. For example, in figure IX-3 two peaks may be seen occurring in the neighborhood of cylinders 10 and 16 at low engine speed. The peak near cylinder 16 is diminished whereas that near cylinder 10 becomes more prominent as the speed increases. At high speeds each of the maximum points tends to move to the adjacent cylinder in a direction opposite that of the impeller rotation, that is, from cylinders 10 and 16 to cylinders 8 and 14, respectively.

Effect of supercharger gear ratio on mixture distribution.—The effect of supercharger gear ratio on mixture distribution is shown in figure IX-4. At the high supercharger gear ratio, the mixture distribution was considerably improved over the distribution at low gear ratio. It was suggested in reference 1 that the more nearly uniform mixture distribution at the higher impeller speeds was due to the higher combustion-air temperature and the resulting better evaporation of the fuel passing through the supercharger as well as from the more thorough mixing at the diffuser entrance. It should be recalled, however, that in the preceding discussion no effect on mixture distribution was found when the impeller speed was increased by increasing engine speed at constant supercharger gear ratio.

FIGURE IX-7.—Variation of mixture distribution with carburetor-deck temperature. Engine speed, 2200 rpm; engine power, 1000 brake horsepower; approximate over-all fuel-air ratio, 0.100; low supercharger gear ratio. (Fig. 14 of reference 1.)

FIGURE IX-8.—Effect of fuel-air ratio on fuel consumption at various engine speeds. Engine power, 800 brake horsepower; low supercharger gear ratio. (Fig. 17 of reference 1.)

Effect of variation of power on mixture distribution.—Mixture-distribution curves for various values of brake horsepower are shown in figure IX-5 for an over-all fuel-air ratio of 0.089. The differences in mixture strength between the richest and leanest cylinder are not greatly affected by power level. Similar results were obtained at over-all fuel-air ratios leaner and richer than 0.089.

Effect of throttle setting on mixture distribution.—Tests were conducted at different throttle settings to determine the change in mixture distribution. The results obtained at one fuel-air ratio are shown in figure IX-6. The most significant differences in the distribution pattern were observed at the low power conditions. At 800 brake horsepower, for example, cylinder 14, the leanest cylinder at sea-level throttle setting, became the richest cylinder at wide-open throttle.

Although the mixture distribution patterns were different at the various power levels and throttle settings, no trend of improvement in distribution was apparent.

FIGURE IX-9.—Relation between over-all fuel-air ratio and fuel-air ratio of leanest cylinder. (Fig. 16 of reference 1.)

Effect of combustion-air temperature on mixture distribution.—Mixture distribution patterns for carburetor-deck temperatures of 45°, 90°, and 134° F are shown in figure IX-7. The general shapes of the curves in this figure are similar, but the differences between the richest and leanest cylinders decrease with increasing carburetor-deck temperature. This trend may be attributed to increased fuel evaporation at the higher temperatures and the resulting better mixing of fuel and air.

Effect of mixture distribution on fuel consumption.—In a multicylinder engine, operation with nonuniform distribution results in higher fuel consumption. The relation between brake specific fuel consumption and fuel-air ratio (fig. IX-8) is such that the over-all brake specific fuel consumption for nonuniform mixture distribution is necessarily greater than that for uniform distribution. Calculations (reference 1) indicated, however, that the difference is more pronounced when the poor distribution is obtained at a lean over-all fuel-air ratio. If mixture distribution is uniform, the brake specific fuel consumption of the entire engine is the same as that of each cylinder inasmuch as the fuel-air ratio for each cylinder is equal to that of the engine average.

If the extent to which the over-all fuel-air ratio may be reduced is (because of detonation or cooling) determined by the leanest cylinder, the effect of nonuniform mixture distribution is important. The relation between the fuel-air ratio of the leanest cylinder and the over-all fuel-air ratio is presented in figure IX-9. Also shown is the curve representing uniform distribution. At any given value of the abscissa

the difference between the two curves represents the increase in over-all fuel-air ratio required by nonuniform distribution to attain a given value of fuel-air ratio for the leanest cylinder.

Inasmuch as the mixture distribution is more nearly uniform at low over-all fuel-air ratios (fig. IX-2), the differences between the over-all fuel-air ratio and that of the leanest cylinder (fig. IX-9) decrease with decreasing mixture strength.

IMPROVEMENT OF MIXTURE DISTRIBUTION BY MECHANICAL CHANGES

One approach to the problem of elimination of nonuniform distribution is through the use of improved induction devices to permit introduction of more nearly vaporized fuel to the intake manifold. An investigation (reference 4) conducted by the NACA during World War II was concerned with the development of an injection-type impeller that would improve the uniformity of fuel-air mixture and thus promote more uniform distribution to the engine cylinders.

Injection impeller.—The variation in fuel-air ratio among the engine cylinders is influenced by centrifugal and gravitational separation of fuel droplets from the air as well as by coarse, nonuniform injection of fuel into the air stream. Consequently, an improvement in distribution can be achieved by injecting the fuel at a point where the fuel droplets are least likely to separate from the combustion air and at the same time by eliminating the coarse droplets present in the charge-air stream.

The impeller developed in reference 4 was designed to avoid the causes of nonuniform distribution by injecting fuel near the impeller outlet, where elbow and carburetor disturbances are at a minimum and where high velocity and turbulent conditions might be utilized to reduce the effect

FIGURE IX-10.—Injection impeller. (Fig. 2 of reference 5.)

of gravitational forces and to provide better mixing and fuel evaporation. The impeller (fig. IX-10) is a centrifugal impeller modified to act as a fuel distributor as well as a supercharger. The fuel passages discharge from a centrally located supply chamber into the air passages at a point sufficiently near the impeller tip to avoid fuel impingement on the stationary shroud. Fuel is discharged with a centrifugal force that exceeds the gravitational forces; consequently, a uniform peripheral fuel discharge from the impeller is attained.

Metered fuel passes from the carburetor to a stationary nozzle ring, instead of feeding to the conventional carburetor spray bar, and is delivered from the ring into a collector cup that rotates with the impeller. Between the nozzle ring and the collector cup is an air gap which eliminates surging in the system. The fuel flows by centrifugal action through the collector cup and the impeller transfer passages to the fuel-distribution annulus. From the annulus the fuel is thrown through the radial holes into the air stream.

A comparison of the mixture distribution resulting from

FIGURE IX-11.—Effect of injection impeller on mixture distribution of engine at various engine powers and speeds. (Fig. 6 of reference 4.)

FIGURE IX-12.—Effect of injection impeller on mixture distribution of engine at reduced fuel flows. (Fig. 7 of reference 4.)

a standard carburetor spray bar with that from the injection impeller is presented in figure IX-11. A summary of the data from this figure is given in table IX-1.

At 1200, 1500, and 1700 brake horsepower (table IX-1), the mixture spread was considerably less with the injection impeller than with the standard carburetor spray bar; however, at 2000 brake horsepower the improvement was less noticeable. The poorer showing at 2000 horsepower is attributed in reference 4 to the fact that the impeller does not operate as satisfactorily at the higher fuel flows, whereas

TABLE IX-1.—EFFECT OF INJECTION IMPELLER ON MIXTURE DISTRIBUTION *

Brake horsepower	Fuel-air ratio							
	1200		1500		1700		2000	
Method of fuel injection	Stand-ard spray bar	Injection impeller	Stand-ard spray bar	Injection impeller	Stand-ard spray bar	Injection impeller	Stand-ard spray bar	Injection impeller

the spray bar apparently provides better mixture distribution at the higher flows.

A comparison of the mixture distribution at reduced fuel flows for the injection impeller with the mixture distribution at higher fuel flows for the standard spray bar is shown in figure IX-12. A summary of the data from this figure is given in table IX-2.

For 1500 and 2000 brake horsepower (table IX-2), the variations in mixture distribution with the impeller at reduced fuel flows are much smaller than the variations at higher fuel flows (table IX-1). At 1700 brake horsepower the variations are greater. On the basis of these data it was suggested (reference 4) that the ability of the injection impeller to overcome the effects of gravitational and centrifugal fuel separation is inhibited at high powers and fuel flows

TABLE IX-2.—EFFECT OF INJECTION IMPELLER ON MIXTURE DISTRIBUTION AT REDUCED FUEL FLOWS *

by some design factor, the effects of which are eliminated at reduced values of fuel flow.

EFFECTS OF THREE FUEL-INJECTION METHODS ON MIXTURE DISTRIBUTION WITH LOW-VOLATILITY FUEL

In order to compare the effects of three methods of fuel injection on engine performance, an investigation (reference 5) was conducted utilizing low-volatility fuel (so-called safety fuel). Low-volatility fuel has long been considered as a substitute fuel for conventional aviation gasoline to reduce the fire hazard in aircraft. Conventional gasoline, because of its high vapor pressure (Reid vapor pressure, 7 lb/sq in.), is much more easily vaporized in an induction system than is low-volatility fuel (Reid vapor pressure, 0.1 lb/sq in.); consequently, safety fuel offers a more rigid test of injection methods. Physical properties for gasoline and low-volatility fuel (reference 5) are compared in the following table:

Property	Gasoline	Low-volatility fuel
Grade.....	100/130	106/139
Tetraethyl lead content, ml/gal.....	4.55	4.63
Flash point, close cup, °F.....	Below -30	122
Distillation range, °F:		
Initial boiling point.....	108	320
10-percent evaporated.....	141	334
50-percent evaporated.....	205	346
90-percent evaporated.....	255	362
Final boiling point.....	332	384
Freezing point, °F.....	Below -76	Below -76
Reid vapor pressure, lb/sq in.....	7	0.1
Residue, copper dish, mg/100 ml.....	2.0	2.0
Accelerated gum content, mg/100 ml.....	2.3	2.0
Accelerated gum precipitate, mg/100 ml.....	0.2	0.6
Sulfur content, percent.....	0.012	0.0001
Heating value, Btu/lb.....	18740	18650
Hydrogen-carbon ratio.....	0.166	0.165
Specific gravity at 60° F.....	0.719	0.782

FIGURE IX-13.—Comparison of standard nozzle bar with impinging-jets nozzle bar. (All dimensions given in inches.) (Fig. 3 of reference 5.)

Previous investigations (references 6 and 7) have shown that low-volatility fuel can be utilized successfully in reciprocating engines by direct injection into the cylinders. However, the complexities of a direct injection system can be avoided by better atomization of fuel and injection into the manifold. Aside from the injection impeller discussed in the preceding paragraphs, the NACA has investigated the impinging-jets nozzle bar as a means of achieving better fuel atomization. With the injection impeller, finely dispersed fuel enters the combustion-air stream near the impeller exit, whereas the impinging-jets nozzle bar introduces the finely atomized fuel into the air stream immediately after the carburetor. A standard nozzle bar and the impinging-jets bar are compared in figure IX-13. In the standard bar are located 24 orifices as compared to 32 for the impinging-jets bar. The orifices in the standard bar are larger and the fuel is discharged in less than half the length of the bar. These factors result in poorer atomization and only partial coverage of the combustion-air duct. The orifices in the impinging-jets bar are at right angles to each other and the sprays impinge to form finely atomized fuel.

(a) Engine speed, 2000 rpm; engine power, 1200 brake horsepower; approximate average fuel-air ratio, 0.070.
(b) Engine speed, 2100 rpm; engine power, 1400 brake horsepower; approximate average fuel-air ratio, 0.082.

FIGURE IX-14.—Comparison of mixture distribution obtained with various methods of fuel injection. Combustion-air temperature, 100° F. (Fig. 6 of reference 5.)

In order to evaluate the three methods of injecting low-volatility fuel, a standard mixture-distribution pattern was selected. This pattern was produced at various powers by injection of gasoline through the standard nozzle bar. Comparisons of mixture-distribution patterns for the three methods of injecting low-volatility fuel with the pattern for the standard gasoline test are shown in figure IX-14. The spreads in fuel-air ratio obtained in the standard engine were 0.017, 0.024, 0.021, and 0.023 at 1200, 1400, 1600, and 1800 brake horsepower, respectively.

At 1200 brake horsepower (fig. IX-14(a)) the injection impeller gave a distribution pattern similar to that of the standard engine; the over-all spread in fuel-air ratio was slightly less than that of the standard engine. The other methods gave patterns somewhat different from those of the standard engine in that the over-all spreads in fuel-air ratio were greater.

At 1400 brake horsepower (fig. IX-14(b)) the injection impeller again gave better distribution with low-volatility fuel than the standard engine did with gasoline; however, the impinging-jets bar was worse than the standard engine.

(c) Engine speed, 2200 rpm; engine power, 1600 brake horsepower; approximate average fuel-air ratio, 0.087.
(d) Engine speed, 2300 rpm; engine power, 1800 brake horsepower; approximate average fuel-air ratio, 0.091.

FIGURE IX-14.—Concluded. Comparison of mixture distribution obtained with various methods of fuel injection. Combustion-air temperature, 100° F. (Fig. 6 of reference 5.)

Similar results were obtained at brake horsepowers of 1600 and 1800 (figs. IX-14(c) and IX-14(d)). Complete data were not obtained at 1800 brake horsepower inasmuch as this power was unattainable with either the standard nozzle bar or the impinging-jets bar.

It can be concluded from the foregoing data that the mixture-distribution patterns produced by the injection impeller with low-volatility fuel are better than those found with a standard nozzle bar and gasoline as a fuel.

EFFECTS OF FUEL VOLATILITY ON ENGINE PERFORMANCE

The effect of fuel volatility on engine performance was investigated by White and Engelman (reference 8). Four fuels were tested over a range of inlet-air temperatures between 46° F and 72° F. In general the results of this study were inconclusive; however, the following summary is offered.

The fuel having the lowest 90-percent point (A. S. T. M. Distillation Procedure D86-40) gave the best power and fuel economy. Differences in performance among the other fuels were relatively slight and could not be attributed to differences in volatility. The 90-percent points of the four fuels were 255°, 270°, 295°, and 306° F. The most volatile fuels were found to give more uniform mixture distribution.

FUEL VAPOR LOSS FROM AIRCRAFT FUEL TANKS

The development of high-altitude, long-range aircraft has resulted in considerable concern over the loss of fuel vapor through fuel tank vents during flight. The loss of fuel represents an increase in the fuel consumed during flight and thus causes a reduction in cruising range and load-carrying capacity.

The variables affecting fuel vapor loss were evaluated in a series of simulated-flight tests (reference 9). A small fuel tank on a bench-test installation (fig. IX-15) was employed to facilitate instrumentation and handling of the equipment during the tests. A similar apparatus was installed in a twin-engine airplane in order to correlate simulated-flight data with actual-flight data. (See fig. IX-16.) Details of the apparatus may be found in reference 9.

Effect of rate of climb on fuel vapor loss.—The fuel in the tank (fig. IX-15) was subjected to simulated flights at rates of climb of 1000, 2000, and 4000 feet per minute to an altitude of 40,000 feet; the results are shown in figure IX-17. These data are replotted in figure IX-18 with fuel vapor loss as a function of altitude. At any given altitude the loss increased only slightly with increased rate of climb for the rates tested; however, the losses due to foaming at the higher rates of climb when the fuel tank is filled close to capacity were not investigated.

Effect of altitude on fuel vapor loss.—The variation of fuel vapor loss with altitude in figure IX-18 is linear above some critical altitude (the theoretical altitude at which fuel vapor loss begins). For this linear portion of the curve the following formula was derived (reference 9):

$$L = \frac{Z - Z_c}{1.9}$$

where

L fuel vapor loss, percent

Z altitude, in 1000 feet

Z_c critical altitude, in 1000 feet (intersection of linear portion of loss-against-altitude curve with base line, fig. IX-18)

FIGURE IX-15.—Bench-test installation for determination of fuel vapor loss under simulated flight conditions. (Fig. 1 of reference 9.)

FIGURE IX-16. Flight-test installation for determination of fuel vapor loss. (Fig. 2 of reference 9.)

Effects of initial fuel temperature on fuel vapor loss.—

The effect of initial fuel temperature on fuel vapor loss is shown in figure IX-19. These results were obtained from simulated flight tests in which the condition of climb to 30,000 feet was investigated for each of the initial fuel temperatures shown on the figure. These data have been replotted in figure IX-20 to illustrate the variation of fuel vapor loss at the end of climb with initial fuel temperature. Above a fuel temperature of about 70° F the loss varies linearly with fuel temperature. It was suggested in reference 9 that the fuel vapor loss during climb to an altitude of

30,000 feet at initial fuel temperatures above 70° F could possibly be predicted from the following equation:

$$L = K(T - T_c)$$

where

L fuel vapor loss, percent

T initial fuel temperature, °F

T_c temperature above which loss varies linearly with temperature (intersection of linear portion of curve in fig. IX-20 with abscissa), °F.

K constant (0.18 percent per °F, from fig. IX-20)

FIGURE IX-17.—Fuel vapor loss during simulated flights to 40,000 feet at various rates of climb. (Fig. 7 of reference 9.)

FIGURE IX-18.—Variation of fuel vapor loss with altitude during simulated flights at various rates of climb. (Fig. 8 of reference 9.)

Effect of fuel weathering on fuel vapor loss.—Several successive standard simulated flights were made on the same tank of fuel in order to determine the effect of weathering on vapor loss. (See fig. IX-21.) In this particular test the total volume loss of fuel resulting from the three simulated flights was about 20 percent. The effects of such losses on fuel properties are discussed later in this chapter.

Effects of fuel agitation on fuel vapor loss.—An attempt was made in reference 9 to determine the effects of agitation on vapor loss. The effects of low-amplitude vibrations were investigated by vibrating the tank vertically during a simulated flight. The tank was vibrated at frequencies of 168 and 120 cycles per second at amplitudes of 0.0009 and 0.0018 inch, respectively. An air-operated vibrator attached to the tank was used for this purpose. This type of vibration had no significant effect on fuel vapor loss.

The effect of turbulence on vapor loss was investigated (reference 9) by use of a three-bladed propeller installed in the tank. This mechanism simulated the turbulence arising from use of submerged fuel booster pumps. Two series of tests were made: one in which the fuel was thrust downward, and another in which the fuel was thrust upward. The results are shown in figure IX-22. For the range of speeds investigated the fuel vapor loss increased with speed irrespective of the direction of thrust.

A third method of agitation was investigated in which the fuel tank was oscillated to simulate sloshing of the fuel during flight. The tank was rocked through an angle of 5° at rates

FIGURE IX-19.—Variation of fuel vapor loss with initial fuel temperature, during simulated flight. (Fig. 11 of reference 9.)

FIGURE IX-20.—Variation of fuel vapor loss at end of climb period with initial fuel temperature during simulated flight. (Fig. 12 of reference 9.)

of 40 and 60 cycles per minute. Fuel vapor loss was increased (fig. IX-23) by this method of agitation.

Flight correlation.—A comparison was made between the flight and bench-test apparatuses used for determination of fuel vapor loss. (See reference 9.) The flight paths followed in these tests are shown in figure IX-24. In both cases the initial fuel temperature was 108° F. The fuel vapor loss resulting from each of the two methods is shown in figure IX-25. The difference in vapor loss measured by the two methods was about 0.06 percent.

EFFECT OF FUEL VAPOR LOSS ON INSPECTION PROPERTIES OF AVIATION FUELS

The effects of fuel vapor loss on the properties of two typical service fuels (AN-F-28 (28-R) and AN-F-33 (33-R)) were investigated in reference 10. These fuels were weathered in a simulated-altitude apparatus shown diagrammatically in figure IX-26. This apparatus represents an improvement over the apparatus described in the preceding section of this chapter. (See fig. IX-15.)

FIGURE IX-21.—Fuel vapor loss during successive standard simulated flights with given fuel sample. (Fig. 13 of reference 9.)

FIGURE IX-22.—Fuel vapor loss at end of standard simulated flight with induced fuel turbulence produced by rotating propeller with blade angle at 30°. (Fig. 17 of reference 9.)

FIGURE IX-23.—Fuel vapor loss during standard simulated flight with fuel tank oscillated through angle of 5°. (Fig. 18 of reference 9.)

The fuels were weathered during a simulated flight consisting of climb at a rate of 1000 feet per minute to an altitude of 30,000 feet. The altitude of 30,000 feet was maintained for approximately 10 minutes after the end of the climb. Because fuel vapor loss is dependent on the temperature (fig. IX-19) of the fuel in an airplane tank at the time of take-off, two initial fuel temperatures (90° and 130° F) were used in the weathering tests of each fuel.

The data obtained from the weathering tests indicated that with 28-R about 3.6 percent (by weight) of the fuel was lost during a simulated flight in which the initial fuel temper-

FIGURE IX-24.—Flight paths followed for both simulated and actual flight tests. (Fig. 19 of reference 9.)

FIGURE IX-25.—Fuel vapor loss during simulated and actual flights. (Fig. 20 of reference 9.) Initial fuel temperature, 108° F.

ature was 90° F. For an initial temperature of 130° F the loss was about 12.8 percent. With 33-R the losses were about 3.5 and 14.3 percent at temperatures of 90° and 130° F, respectively.

Inspection data for both weathered and unweathered fuel samples are shown in table IX-3. The data in this table show that, as a result of the weathering loss, the distillation temperatures were increased and the Reid vapor pressures decreased. The greatest increase in distillation temperature occurred in the low temperature range. Specific gravities, aromatic concentrations, and tetraethyl lead concentrations were increased.

If the data for the weathered samples are compared with the specification limits, it is seen that the samples of 28-R and 33-R fuels, weathered from an initial temperature of 90° F, meet the requirements with the exception of lead concentrations. The 50-percent-evaporated temperature for 33-R is about 3° higher than permitted, but this difference is within the precision of the A. S. T. M. distillation procedure.

For an initial fuel temperature of 130° F the weathered sample of 28-R still meets the requirements with the exception of tetraethyl lead concentration, whereas 33-R is unacceptable because of the high 50-percent-evaporated temperature as well as the high tetraethyl lead concentration. Both weathered samples have a Reid vapor pressure of 4.6 pounds per square inch, which is a lower value than that of most aviation fuels. Under current aviation-fuel specifications, a low Reid vapor pressure is permissible as long as the low-end distillation temperatures are within the specified limits.

FIGURE IX-26.—Simulated-altitude bench-test installation for determination of fuel vapor loss. (Fig. 1 of reference 10.)

In an earlier investigation (reference 11) an equation was derived to permit estimation of fuel vapor loss by change in specific gravity.

$$L = K(A - A_0)$$

where

- L percentage fuel loss
 A final specific gravity of fuel at 20° C (68° F)
 A_0 initial specific gravity of fuel at 20° C (68° F)
 K constant, characteristic of each fuel

The values of the constant K were evaluated (reference 11) for the six fuels used in this study and were plotted against the initial specific gravity (A_0) in figure IX-27.

EFFECT OF FUEL VAPOR LOSS ON KNOCK-LIMITED PERFORMANCE

The A. S. T. M. Aviation (lean) and A. S. T. M. Supercharge (rich) antiknock ratings for 28-R and 33-R are shown in the following table (reference 10). Two rows of ratings are given for each fuel. The first row is milliliters of tetraethyl lead per gallon in S reference fuel and the second row is performance number. The A. S. T. M. Aviation ratings determined for unweathered 28-R and 33-R are higher than the nominal ratings for these fuels.

Fuel	Condition	A. S. T. M. Aviation rating	A. S. T. M. Supercharge rating
28-R	Nominal rating.....	0	1.28
28-R	Unweathered.....	100	130
28-R	Weathered (*90° F).....	0.08	1.31
28-R	Weathered (*130° F).....	103	130
33-R	Nominal rating.....	0.10	1.31
33-R	Unweathered.....	104	130
33-R	Weathered (*90° F).....	0.07	1.52
33-R	Weathered (*130° F).....	103	133
33-R	Nominal rating.....	0.47	2.78
33-R	Unweathered.....	115	145
33-R	Weathered (*90° F).....	0.68	2.68
33-R	Weathered (*130° F).....	120	144
33-R	Weathered (*90° F).....	0.75	2.67
33-R	Weathered (*130° F).....	121	144
33-R	Weathered (*130° F).....	0.75	2.92
33-R	Weathered (*130° F).....	121	146

*Temperature of fuel at start of simulated flight.

The data indicate that the loss of fuel vapor resulting from weathering has little or no effect on the ratings of the two fuels. If the changes in ratings can be assumed to be significant, the A. S. T. M. Aviation and A. S. T. M. Supercharge performance numbers of both fuels increase slightly. These comparisons should be valid inasmuch as the data were obtained on the same operating day.

CHAPTER X

INTERNAL COOLING

Over a period of years, improvements in fuel performance have made it necessary to improve engine-cooling facilities in order to take full advantage of power potentialities of a given fuel. Cooling studies (reference 1) indicate that more and more heat must be disposed of through the engine walls as the specific power output of the engine is increased. If adequate cooling is assumed to be solely dependent on heat transfer through the cylinder walls, the search for better engine cooling is a continuing process accompanying the ever-increasing antiknock quality of conventional fuels. Although these comments pertain primarily to air-cooled engines, the same might be said of liquid-cooled engines in regard to radiator size and cooling drag.

Complete dependency on heat transfer through cylinder walls for adequate cooling can, however, be avoided by a method commonly called *internal cooling*. Internal cooling may be defined as the injection of an auxiliary liquid into the fuel-air charge at some point before the engine intake port. A desirable liquid for internal cooling should have a high latent heat of vaporization, since the more heat extracted from the charge fuel-air mixture, the greater the cooling attained. The reduction in temperature of the mixture achieved by the use of an internal coolant will result in lower cylinder temperatures and will extend the knock-free performance range. In addition to the advantage of increased permissible power, two other goals in the use of internal coolants are savings in fuel and savings in total liquid consumption.

Each of these objectives may be sought in itself by disregarding changes in the other two or it may be sought in combination with one or both of the others in an effort to balance advantages against disadvantages. The most outstanding advantage of internal cooling is, however, the increase in knock-limited or cooling-limited power that it makes possible.

Where gasoline shortages exist because of out-of-the-way destinations of transport airplanes or because of air routes requiring transportation by air of the gasoline used, the possibility of savings in gasoline is particularly pertinent. Such savings may result from the use of internal cooling rather than fuel enrichment to suppress knock at high

power output. In this case water would be the most efficient internal coolant if freezing temperatures were not encountered in the internal-coolant system. Temperatures below freezing would necessitate either the addition of a freezing-point depressant or the use of a lagged or heated water system. Special cases and requirements must obviously determine which of these methods is most advantageous.

The material that appears in the succeeding portions of this chapter considers only the case of internal cooling wherein the coolant is injected at some point in the intake-air system of the engine. Water injection was treated briefly in chapter I, however, where it was found that knock could be suppressed in an engine by injection of water directly into the combustion end zone. This method was suggested as a means of economizing on the quantity of coolant that might be required to reduce knock.

EFFECT OF INTERNAL COOLANTS ON ENGINE PERFORMANCE

Several investigations (references 2 to 4) have been conducted by the NACA in which the effectiveness of internal cooling with respect to knock-limited and temperature-limited performance has been illustrated. In one of these investigations (reference 4) a V-type 12-cylinder liquid-cooled aircraft engine was used as the test engine.

Water was continuously injected through 12 spray bars inserted into the intake manifolds through holes drilled in the top of the manifolds about 1 inch back from the faces of the manifold mounting flanges, as shown in figure X-1. The spray bars (fig. X-2) were of $\frac{5}{32}$ -inch-diameter, stainless steel tubing about $2\frac{1}{2}$ inches long with six holes, each 0.016 inch in diameter, arranged in two rows of three holes each, to spray water directly into each intake port. Water was applied to the spray bars by individual lines from a tank, which was kept under pressure with compressed air.

FIGURE X-1.—Intake manifold with water spray bars in position. (Fig. 1 of reference 4.)

FIGURE X-2.—Closeup of water spray bar inserted in intake manifold. (Fig. 2 of reference 4.)

With this injection system, knock-limited performance data were obtained at carburetor-air temperatures of 158°, 101°, and 50° F (fig. X-3). In figure X-3 (a) the peaks of the knock-limited brake horsepower curves occur at successively leaner mixtures as the water-fuel ratio is increased. At a water-fuel ratio of 0.6, a rapid decrease in knock-limited power was found as the fuel-air ratio was increased beyond about 0.092. Similar results were found at the other carburetor-air temperatures; however, at a carburetor-air temperature of 50° F (fig. X-3 (c)) the sharp decline in knock-limited brake horsepower at a water-fuel ratio of 0.6 occurred at fuel-air ratios greater than 0.08.

At the three carburetor-air temperatures investigated, the brake specific fuel consumption was lower with water injection than without at fuel-air ratios leaner than 0.092. This

(a) Carburetor-air temperature, 158° F. (Fig. 4 of reference 4.)

FIGURE X-3.—Knock-limited performance with water injection. V-type 12-cylinder liquid-cooled engine; fuel, AN-F-28, Amendment-2; engine speed, 3000 rpm.

(b) Carburetor-air temperature, 101° F. (Fig. 5 of reference 4.)

FIGURE X-3.—Continued. Knock-limited performance with water injection. V-type 12-cylinder liquid-cooled engine; fuel, AN-F-28, Amendment-2; engine speed, 3000 rpm.

reduction is caused partly by increased mechanical efficiency of the engine at the high power outputs attainable with water injection.

Cross plots of the data in figure X-3 are shown in figure X-4 for two fuel-air ratios. With the exception of the data at 0.095 fuel-air ratio and 50° F carburetor-air temperature, increases of water-fuel ratio resulted in increases of knock-limited brake horsepower. For the excepted data, water-fuel ratios greater than 0.45 resulted in a decrease of knock-limited power.

The effect of internal cooling on cylinder-head temperature was also observed in reference 4. The average cylinder-head temperatures for the engine are shown in figure X-5 as a function of water-fuel ratio and knock-limited power. It is apparent in this figure that as the water-fuel ratio increases, the power increases continuously; however, the cylinder-head temperatures pass through a maximum. The water-fuel ratio at which this maximum occurs increases as the carburetor-air temperature increases.

(c) Carburetor-air temperature, 50° F. (Fig. 6 of reference 4.)

FIGURE X-3.—Concluded. Knock-limited performance with water injection. V-type 12-cylinder liquid-cooled engine; fuel, AN-F-28, Amendment-2; engine speed, 3000 rpm.

Effect of internal cooling on fuel consumption.—Under high-power cruise operation, over-all fuel enrichment may be necessary in order to prevent an increase in cylinder temperatures beyond the specified maximum. This practice obviously results in higher fuel consumption than would ordinarily be desired in the interest of range considerations. However, the same end result can be achieved by adding additional fuel only to the hottest cylinders.

This fact is substantiated by results obtained in an unpublished NACA investigation conducted in an air-cooled engine. The results indicated that lower brake specific fuel consumptions could be obtained at high cruising power, with no increase in maximum rear-spark-plug-gasket temperatures, by injecting additional fuel to the hottest cylinders and operating the engine in automatic-lean mixture setting instead of the automatic-rich mixture setting usually recommended. The fuel savings varied between 6 and 10 percent for two engines tested in flight and one engine tested in an altitude wind tunnel. It was found, however, that little or no fuel saving

is realized when additional fuel is supplied to the hot cylinders unless the temperature spread among the cylinders before enrichment is very large.

Another investigation conducted in an air-cooled engine (reference 5) showed that further gains in fuel economy could be achieved by using water instead of fuel to cool the hottest cylinders. In this particular study, it was found that the use of water instead of excess fuel to maintain engine temperature limits at powers normally requiring a fuel-air ratio of about 0.09 resulted in a decrease of approximately

FIGURE X-4.—Variation of knock-limited brake horsepower with water-fuel ratio for three carburetor-air temperatures and two fuel-air ratios. V-type 12-cylinder liquid-cooled engine; fuel, AN-F-28, Amendment-2; engine speed, 3000 rpm. Cross plot from figure X-3. (Fig. 14 of reference 4.)

26 percent in brake specific fuel consumption with an increase of about 3 percent in brake specific liquid consumption.

It is obvious from the foregoing discussion that water injection in aircraft engines permits temperature-limited cruising powers to be reached at reduced engine speeds and increased brake mean effective pressures with fuel-air mixtures very near that for maximum economy. Furthermore, significant improvements in fuel consumption can be attained without appreciable increases in over-all liquid consumption.

These findings have been further substantiated by a study reported in reference 6 in which it was found that for typical air-cooled aircraft engines operating under cruising conditions in which overheating is ordinarily prevented by enriching the fuel-air mixture to the entire engine, the fuel consumption may be reduced 7 to 37 percent by adding water or fuel to only the overheated cylinders.

Effect of internal cooling on spark-advance requirements.—Internal cooling can also be utilized to take advantage of gains that may be achieved by retarding the spark timing of an engine. This fact was demonstrated in an investigation (reference 7) conducted in a liquid-cooled single-cylinder test engine. Two positions were used for the injection of

FIGURE X-5.—Variation of average cylinder-head temperature with water-fuel ratio at knock-limited power for three carburetor-air temperatures. internal coolant: position A before the vaporization tank and position B at the intake elbow. In both positions the coolant was discharged downstream. The positions of injection are illustrated in figure X-6.

The effect of internal-coolant—fuel ratio on spark advance for peak power is shown in figure X-7. For both types of injection, the spark advance required for peak power was greater when the coolant was injected before the vaporization tank than at the injection elbow; however, the difference was small when a 50 : 50 mixture of water and ethyl alcohol was used as the coolant. This result indicates that the water, when injected before the vaporization tank and allowed to mix thoroughly with the fuel-air mixture, slowed the flame speed more than when injected at the intake elbow.

FIGURE X-6.—Induction system used with multicylinder-block adaptation to CUE crank-case showing two positions of internal-coolant nozzle. (Fig. 2 of reference 7).

The flame speed was slowed to about the same degree regardless of injection position for the 50 : 50 mixture of water and ethyl alcohol.

At the same internal-coolant—fuel ratios (fig. X-7) and for the same coolant injector location, the water—ethyl-alcohol mixture retarded burning less than the injection of pure water. This difference can be attributed to the fact that the alcohol is a fuel and as such is contributing to the combustion process.

In figure X-8 is illustrated the effect of internal-coolant—fuel ratio on the mixture temperatures corresponding to the data of figure X-7. The data for figure X-8 represent the case in which the coolants were injected ahead of the vaporization tank. The mixture temperature decreased until the fuel-air mixture became saturated and for further additions of coolant beyond this point the mixture temperature remained constant. In a similar manner, the power at peak-power spark advance increased because of the increased charge weight inducted into the cylinder until the internal-coolant—fuel ratio for saturation was reached, at which point the power leveled off. (See fig. X-9.) Beyond the point of complete saturation the additional cooling of the mixture must occur after the intake valves close, which makes it impossible to increase engine power through an effect on air flow. Further additions of coolant caused a

FIGURE X-7.—Effect of internal coolant-fuel ratio on spark advance for peak power for two internal coolants and two positions of injection. Single-cylinder adaptation of multicylinder engine to CUE crankcase; compression ratio, 6.65; engine speed, 3000 rpm; fuel-air ratio 0.08; inlet-oil temperature, 185° F; outlet-coolant temperature, 250° F; inlet-air temperature, 250° F; inlet-air pressure, 50 inches of mercury absolute. (Fig. 11 of reference 7.)

decrease in the power obtainable at peak-power spark advance because some heat of vaporization was extracted from the air during the compression stroke; decreased cycle efficiency resulted. The power increase at peak-power spark advance was small when coolant was injected at the intake elbow (fig. X-9) because so little time was available for charge cooling before the intake valves closed.

The percentage loss in power at various values of spark advance over that obtained by using peak-power spark advance is shown in figure X-10 for each internal-coolant-fuel ratio investigated. The data in this figure indicate that operation with normal spark timing at a given coolant-fuel ratio and position of injection results in a power loss approximately twice as high for water as for the mixture of water and ethyl alcohol.

USE OF INTERNAL COOLING FOR INCREASED TAKE-OFF POWER

In 1944 an analysis was made by the NACA to evaluate the use of internal cooling as a means of increasing take-off power. This study (reference 8) was made for four airplanes to determine the effects of a 25-percent increase in take-off power on the take-off load of the airplane. The operating

characteristics of the airplanes considered are presented in the following table:

Airplane	Normal take-off horsepower	Normal fuel capacity		Gross weight of airplane (lb)
		(gal)	(lb)	
Heavy bomber.....	4800	1433	8598	41,000
Pursuit.....	2000	210	1260	11,870
Torpedo bomber.....	1700	301	1806	15,364
Shipboard fighter.....	2000	344	2064	12,577

For these airplanes the estimated increase in take-off load for a 25-percent increase in take-off power is as follows:

Airplane	Load increase (percent)	Load increase (lb)	Usable load increase (lb)	Usable load (gal of gasoline)	Percentage increase (gal of gasoline)
Heavy bomber.....	11.5	4710	3631	427	30
Pursuit.....	12.0	1430	1097	129	65
Torpedo bomber.....	10.5	1610	1300	153	51
Shipboard fighter.....	10.5	1320	1037	122	36

FIGURE X-8.—Effect of internal coolant-fuel ratio on mixture temperature for two internal coolants injected before the vaporization tank. Single-cylinder adaptation of multicylinder engine to CUE crankcase; compression ratio, 6.65; engine speed, 3000 rpm; fuel-air ratio, 0.03; inlet-oil temperature, 185° F; outlet-coolant temperature, 250° F; inlet-air temperature, 250° F; inlet-air pressure, 50 inches of mercury absolute. (Fig. 12 of reference 7.)

FIGURE X-9.—Effect of internal coolant-fuel ratio on engine power at spark advance for peak power for two internal coolants and two positions of injection. Single-cylinder adaptation of multicylinder engine to CUE crankcase; compression ratio, 6.65; engine speed, 3000 rpm; fuel-air ratio, 0.08; inlet-oil temperature, 185° F; outlet-coolant temperature, 250° F; inlet-air temperature, 250° F; inlet-air pressure, 50 inches of mercury absolute. (Fig. 13 of reference 7.)

The data presented in the foregoing table indicate that marked increases in the usable load, or in this usable load translated into gallons of gasoline, may be achieved through use of internal cooling for 25-percent increased take-off power. These numerical estimates are necessarily dependent upon the assumed values for many factors. For example, these particular calculations include the following assumptions:

- (1) that 0.78 pound of coolant per pound of fuel is required to produce a 25-percent increase in take-off power. This quantity of coolant is about 45 percent higher than is indicated by experimental data in order to provide a factor of safety in the calculations.
- (2) that sufficient coolant is provided for 5-minute operation
- (3) that the increase in propeller weight for the additional power output is about 100 pounds
- (4) that the coolant system exclusive of the tank weight is about 75 pounds.

FIGURE X-10.—Loss in power incurred by operating without peak-power spark advance for several internal coolant-fuel ratios and for two positions of injection. Single-cylinder adaptation of multicylinder engine to CUE crankcase; compression ratio, 6.65; engine speed, 3000 rpm; fuel-air ratio, 0.08; inlet-oil temperature, 185° F; outlet-coolant temperature, 250° F; inlet-air temperature, 250° F; inlet-air pressure, 50 inches of mercury absolute. (Fig. 14 of reference 9.)

Other details of the estimates may be found in reference 8. In addition to the gains in usable load, certain gains may be realized in rate of climb and take-off run. The increase of 25 percent in take-off power indicated an increase in rate

of climb from 3100 to 4100 feet per minute up to an altitude of 12,000 feet for the pursuit-type airplane and 1600 to 2200 feet per minute for the torpedo bomber. The estimated take-off distances for the four airplanes are as follows:

Airplane	Normal take-off distance (ft)	Take-off distance 25-percent increase in take-off power (ft)
Heavy bomber.....	1700	1300
Pursuit.....	1300	1000
Torpedo bomber.....	340	200
Shipboard fighter.....	350	250

PRACTICAL ASPECTS OF INTAKE-AIR COOLING BY WATER INJECTION

Inasmuch as the application of internal cooling to aircraft would necessarily require the installation of additional equipment, consideration has been given to means by which internal cooling might be applied without significant increase in aircraft weight. Calculations have been made (reference 9) to determine the extent to which the engine intake air is cooled by water injection. The results of these calculations,

presented in figure X-11, indicate that the degree of cooling achieved by water injection is sufficient to permit the elimination of normal intercooling and after-cooling in the supercharger. Consequently, the weight of equipment necessary for internal cooling might be offset by the elimination of the supercharger intercooler or aftercooler.

Further calculations reported in reference 9 indicate that the water to be used as internal coolant can be obtained by recovery from the exhaust gas. Sufficient water can be recovered from 50 percent of the exhaust gas to provide an inducted water-fuel ratio of 0.5.

EVALUATION OF VARIOUS LIQUIDS AS INTERNAL COOLANTS

As part of the problem of applying internal cooling to aircraft, extensive investigations have been conducted to evaluate the performance of various liquids as internal coolants. One such investigation, reported in reference 10, compares the performance of (1) water, (2) methyl alcohol and water, (3) ammonia, methyl alcohol, and water, (4) monomethylamine and water, (5) dimethylamine and water, and (6) trimethylamine and water. These studies were made on a high-speed supercharged CFR engine which is described in detail in reference 10. The internal coolant was continuously injected at room temperature into the injection elbow just above the fuel injection nozzle and parallel to the air flow.

The results of the investigation summarized in table X-1 indicate that when water is used as an internal coolant the greatest improvement in knock-limited performance of AN-F-28 fuel is achieved at lean fuel-air ratios. The mixture of methyl alcohol and water is a slightly better coolant than water at lean mixtures but considerably better at rich mixtures. As pointed out earlier in this chapter, the methyl alcohol is a fuel and as such contributes to the combustion process as well as the cooling. Of the coolants listed in table X-1, mixtures of water with monomethylamine or dimethylamine showed the greatest improvements in the knock-limited performance of AN-F-28; the increases in

• Afterfiring encountered.

knock-limited indicated mean effective pressure ranged between 78 and 98 percent for different fuel-air ratios. The use of trimethylamine-water solution as an internal coolant lowered the knock-limited performance of AN-F-28.

The addition of anhydrous ammonia to the solution of methyl alcohol and water before injection (reference 10) reduced the knock-inhibiting effects of the solution of methyl alcohol and water and promoted afterfiring. Afterfiring also occurred when monomethylamine-water solution was used as an internal coolant (table X-1).

The effect of inlet-air temperature on the knock-limited performance of the internal coolants discussed previously is also reported in reference 10. A summary of these data (table X-2) shows that the addition of water reduced the temperature sensitivity of AN-F-28 fuel. The other coolants appeared to increase the sensitivity at lean fuel-air ratios but decreased the sensitivity at rich fuel-air ratios.

Perhaps the most impressive example of the advantages found for the internal coolants evaluated in reference 10 is the knock-limited performance of monomethylamine-water mixture at an inlet-air temperature of 150° F. This particular internal coolant, when added to AN-F-28 fuel, allowed a knock-limited power of 1.96 horsepower per cubic inch of cylinder displacement (imep of 620 lb/sq in.) at a fuel-air ratio of 0.049. The corresponding indicated specific fuel and liquid consumptions were 0.37 and 0.55 pound per horsepower-hour, respectively.

The investigations reported in reference 10 were conducted in an engine installation in which the range of operation was limited to a fuel flow of 30 pounds per hour and an inlet-air pressure of 150 inches of mercury absolute. Because of the continued interest in monomethylamine and dimethylamine as internal coolants, the installation was later revised to extend the range of operation to a fuel flow of 80 pounds per hour and an inlet-air pressure of 225 inches of mercury absolute. Following these revisions the tests with monomethylamine and dimethylamine were resumed; however, two engine cylinders were cracked when the knock-limited performance with the internal coolants reached a level of 700

* Any contribution of the amines to the energy of combustion was entirely neglected in computing fuel flows.

pounds per square inch. In order to resume the investigation, a specially designed CFR cylinder was obtained to permit studies at the exceptionally high powers attained with monomethylamine and dimethylamine. The investigation was again resumed and virtually completed before the next engine failure occurred.

In the extended study of the two internal coolants (reference 11) tests were conducted over a wider range of fuel-air ratio and at higher ratios of coolant to fuel. The results are summarized in table X-3. It is seen in this table that the amines are considerably better than water as internal coolants. Of the two amines examined, monomethylamine is superior to dimethylamine at coolant-fuel ratios of 0.25; however, at a coolant-fuel ratio of 0.50, monomethylamine is better than dimethylamine at lean fuel-air ratios but slightly poorer at rich fuel-air ratios. It is of interest to note that the injection of 0.75 pound of dimethylamine-water solution per pound of fuel permitted the attainment of a knock-limited indicated mean effective pressure of 967 pounds per square inch, corresponding to 3.05 indicated horsepower per cubic-inch displacement, at a fuel-air ratio of 0.092. Failure of a cylinder stud terminated the tests at this point; however, after an overhaul the tests were again resumed and the cylinder wall failed at an indicated mean effective pressure of 895 pounds per square inch during a test with dimethylamine-water solution at a coolant-fuel ratio of 0.75.

During the investigation reported in reference 11 a run was made to determine the influence of exhaust back pressure on the knock-limited performance when dimethylamine-water solution was used as an internal coolant. The results indicated that increases in exhaust back pressure had little or no effect on the performance at fuel-air ratios leaner than 0.095. At richer fuel-air ratios serious decreases in power output were encountered and engine operation was quite rough.

An examination of the data in reference 11 indicated that for certain power levels in the rich-mixture range the following combinations of internal coolants resulted in the lowest indicated specific liquid consumptions:

Imep range (lb/sq in.)	Corresponding minimum isle range (lb/hp-hr)	Internal coolant	Internal coolant- fuel ratio
Below 220	0.44 to 0.53	None	
220 to 370	0.53 to 0.63	Monomethylamine solution	0.25
370 to 440	0.63 to 0.71	Dimethylamine solution	.50
440 to 960	0.71 to 1.10	Dimethylamine solution	.75

The success of aliphatic amines as internal coolants, reported in references 10 and 11, led to further studies with other amines reported in reference 12. The additional amines evaluated were ethylenediamine, diethylamine, triethylamine, and butylamine. The results of the investigation (reference 12) are summarized in table X-4.

It is apparent in table X-4 that of all the amines tested monomethylamine and dimethylamine still offer the greatest possibilities as internal coolants, although ethylenediamine does permit higher knock-free power at lean fuel-air ratios.

In the investigation (reference 12) an effort was made to reach the highest possible knock-limited indicated mean effective pressure with dimethylamine. At a fuel-air ratio of 0.093 and a coolant-fuel ratio of 0.75, a knock-limited indicated mean effective pressure of 1024 pounds per square inch was attained. No engine failure occurred but this test was limited by the available intake-air supply.

TABLE X-4.—RELATIVE KNOCK-LIMITED POWERS RESULTING FROM USE OF INTERNAL-COOLANT ADDITIVES IN WATER AT COOLANT-FUEL RATIO OF 0.50

[CFR engine; fuel AN-F-28, Amendment-2; compression ratio, 7.0; engine speed, 2500 rpm; inlet-air temperature, 250° F; spark advance, 30° B. T. C.; jacket temperature, 250° F]

(a) Paraffins and olefins; 25 volume percent blends.

[For 17.6 engine: compression ratio, 7.0; engine speed, 1800 rpm; coolant temperature, 212° F; spark advance, 30° B. T. C. For full-scale single-cylinder at simulated take-off: compression ratio, 7.3; engine speed, 2500 rpm; inlet-air temperature, 250° F; spark advance, 30° B. T. C.; cooling-air flow such that rear-spark-plug-bushing temperature equals 365° F at 140 bme and 0.10 fuel-air ratio. For full-scale single-cylinder engine at simulated cruise: same conditions as for take-off except for engine speed, 2000 rpm; inlet-air temperature, 210° F.]

TABLE A-10.—PERFORMANCE RATINGS OBTAINED IN A. S. T. M. AVIATION AND A. S. T. M. SUPERCHARGE ENGINES

[Three rows of values are given for each fuel: The first row is imep, lb/sq in.; the second row for A. S. T. M. Aviation ratings is octane number or tetraethyl lead in S reference fuel, ml/gal; the second row for A. S. T. M. Supercharge ratings is S reference fuel in M reference fuel, percent, or tetraethyl lead in S reference fuel, ml/gal; the third row is performance number. The following abbreviations are used throughout the table: VBS for virgin base stock; alkylate for aviation alkylate; one-pass stock for one-pass catalytic stock; MTB ether for methyl *tert*-butyl ether.]

* Each fuel contains approximately 4 ml TEL/gal.

^b Based on fixed reference-fuel framework (ch. VIII, reference 13).

^c Knock-limited performance of the engine with one-pass catalytic stock was low on day fuels were investigated.

^d Estimated value.

* Values for knock-limited imep were averaged from three curves.

REPORT 1027

BUCKLING OF THIN-WALLED CYLINDER UNDER AXIAL COMPRESSION AND INTERNAL PRESSURE¹

By HSU LO, HAROLD CRATE, and EDWARD B. SCHWARTZ

SUMMARY

An investigation was made of a thin-walled cylinder under axial compression and various internal pressures to study the effect of the internal pressure on the compressive buckling stress of the cylinder. A theoretical analysis based on a large-deflection theory was also made. The theoretically predicted increase of compressive buckling stress due to internal pressure agrees fairly well with the experimental results.

INTRODUCTION

The buckling of thin-walled cylinders under axial compression and lateral pressure has been investigated by Flügge (reference 1) who found that the effect of the internal pressure on the buckling load is negligible. Flügge's conclusion is in contradiction to the results of a series of tests, made at the Langley Aeronautical Laboratory of the NACA, of two curved panels under axial compression and various lateral pressures. These test results, reported in reference 2, showed an appreciable strengthening effect of the lateral pressure on the buckling load of the curved panels. The apparent discrepancy between these experimental results and the prediction by Flügge's theory made it desirable to investigate this problem further. Consequently, additional tests were made of a cylinder under axial compression and various internal pressures for which results are presented herein. A theoretical analysis of this problem is also presented which differs from that of Flügge in that the present analysis is based on large-, rather than small-, deflection theory.

APPARATUS AND PROCEDURES

Test specimen.—The specimen used for the tests was a cylinder, 32 inches long with a 15-inch inside radius, made of 24S-T aluminum alloy sheet of 0.0249-inch average thickness. It was closely riveted around two heavy steel rings, one at each end. The butt joint of the two longitudinal edges was covered both inside and outside by straps, 0.032 inch thick and 1½ inches wide, along the total length of the cylinder. (See fig. 1.)

The two heavy steel rings were made of ½- by 4-inch steel bar stock rolled to the diameter of the cylinder. Two ¾- by 2-inch spreader bars were used to reinforce the ring as shown in figure 1. A ring with a flange, machined flat, was fastened to the ½- by 4-inch steel ring to provide an even bearing surface on which a steel cover plate was fitted.

FIGURE 1.—Test specimen and strain-gage positions.

Three steel blocks were placed on top of the plate. The applied compressive load was transmitted from the machine head through the three steel blocks to the cover plate. The joint between the cylinder and the cover plates was sealed.

Equally spaced along the inside circumference of the cylinder at midlength were 16 strain gages, and directly opposite to them on the outside were 16 more gages. These gages were placed to measure strains in the longitudinal direction. Six more gages, three inside and three outside, were placed to measure the circumferential strains.

Test procedures.—The specimen was subjected to compressive load in the 1,200,000-pound universal testing machine of the Langley Structures Research Laboratory. Compressed air was used to produce internal pressure, which could be maintained at any desired constant value. The pressure was measured by a manometer. The strains were recorded by standard electric strain-gage equipment and the end-shortening was measured by dial gages.

The cylinder was preloaded and the strain-gage readings were taken. The three steel blocks were so adjusted that all longitudinal strain-gage readings around the circumference of the cylinder were equal.

¹ Supersedes NACA TN 2021, "Buckling of Thin-Walled Cylinder under Axial Compression and Internal Pressure" by Hsu Lo, Harold Crate, and Edward B. Schwartz, 1950.

The compressed air was then let into the cylinder until the desired internal pressure was reached. The axial compressive load was increased in increments until buckling was observed. At each load increment, all gage readings were recorded. The load was then decreased until the buckles disappeared and increased a second time to check the reading obtained the first time. During all these steps the internal pressure was maintained constant.

The axial load was then reduced and the internal pressure was changed to another value. For each value of internal pressure the same procedure was repeated.

EXPERIMENTAL RESULTS

A typical experimental result is shown in figures 2(a) and 2(b) for the case in which the internal pressure was $1\frac{1}{2}$ psi. In figure 2(a) the compressive load is plotted against the strain-gage readings for four different pairs of gages, within the range where the load-strain relation is linear. In figure 2(b) the strain-gage reading is plotted for all strain gages at three compressive loadings close to the buckling load. Figure 2(b) indicates that buckling occurs at a compressive load of 12,700 pounds between strain gages 22 and 23. (Note the intersection of the curves at two consecutive loadings.) A buckle at this location was observed during the test. The compressive load at which this phenomenon occurs is considered the buckling load.

Since the buckling occurs locally and not simultaneously at all the gages, the local buckling strain is obtained by dividing the buckling load by the slope of the linear portion of the load-strain curve corresponding to the gage at which the buckling occurs. The corresponding stress is the buckling stress. The buckling stresses for various internal pressures were determined in this same way.

The results are tabulated in table 1 and plotted in figure 3 in terms of the two nondimensional parameters

$$\bar{\sigma}_{cr} = \frac{\sigma_{u_{cr}}}{E} \frac{R}{t}$$

$$\bar{p} = \frac{p}{E} \left(\frac{R}{t} \right)^2$$

where $\sigma_{u_{cr}}$ is the buckling stress, p is the internal pressure, R is the radius of the cylinder, t is the wall thickness, and E is Young's modulus. Except for the first test corresponding to $\bar{p}=0.1028$ in which the cylinder had undergone no previous buckling, all the tests were carried out on the cylinder with possible permanent set.

THEORETICAL RESULTS

A theoretical analysis for calculating the buckling stress of a cylindrical shell under axial compression and internal pressure was obtained by a "large-deflection" theory for

(a) Linear part of load-strain curve for four typical pairs of strain gages.

FIGURE 2.—Typical experimental result. Internal pressure, $1\frac{1}{2}$ psi.

(b) Close to buckling load.

FIGURE 2.—Concluded.

which details are given in the appendix. The large-deflection theory was first advanced by Von Kármán and Tsien (reference 3) in the study of buckling stress of cylindrical shells under axial compression (but without internal pressure). This theory was subsequently improved by Leggett and Jones (reference 4). In reference 3 the buckling stress was shown to depend on whether the load was applied by a

rigid loading machine or by a dead-weight machine. In the present analysis, the loading machine is assumed to be rigid.

The existing procedures for computation of the buckling stress by large-deflection theory involve the solution of four simultaneous nonlinear equations for each pressure loading. The numerical work is quite lengthy. The method used in the present study introduces a fifth equation which governs the conditions at which the buckling occurs. The fifth equation is based on consideration of conservation of energy, which is an extension of Tsien's buckling criterion given in reference 5. Although a solution of five simultaneous equations is now necessary, the numerical work is actually

FIGURE 4.—Theoretical and experimental results showing the increment of buckling stress due to internal pressure.

reduced to a small fraction of that required if the existing procedures were used. This reduction in labor is made possible through a proper choice of the parameters in the equations and the process of the computations. The results calculated by the present method are presented in table 1 and are represented by the solid-line curve in figure 3. The curve is cut off at a value of $\bar{\sigma}_{cr}=0.605$, corresponding to $\bar{p}\approx 0.169$. This constant value of $\bar{\sigma}_{cr}=0.605$ for $\bar{p}>0.169$ is the same as that obtained by the classical theory.

DISCUSSION AND CONCLUSIONS

From the theoretical and experimental results shown in figure 3, the internal pressure is seen to have an appreciable strengthening effect on the cylinder. Although the two curves obtained from theoretical and experimental results do not coincide, both show the same trends as regards the effect of internal pressure on the buckling stresses. If the increment of the buckling stress $\Delta\bar{\sigma}_{cr}$ due to the presence of internal pressure (that is, the difference between the buckling stress with the pressure $\bar{\sigma}_{cr}$ and that without the pressure $(\bar{\sigma}_{cr})_{\bar{p}=0}$) is plotted against the internal pressure, as shown in figure 4, a good agreement is obtained between the theoretical and experimental results. These data indicate that, although further improvement of the theory is necessary for the determination of the magnitude of the compressive buckling stress, the theory gives a fairly good prediction of the increase of buckling compressive stress that may be expected as a result of internal pressure. The discrepancy between the theoretical curve and the experimental curve of figure 3 is believed to be caused by such factors as manufacturing imperfections in the specimens, material irregularities, and energy absorbed by the loading machine, which have not been included in the theory.

APPENDIX

THEORETICAL ANALYSIS OF BUCKLING LOAD OF CYLINDRICAL SHELLS UNDER AXIAL COMPRESSION AND INTERNAL PRESSURE BY LARGE-DEFLECTION THEORY

BACKGROUND OF THEORY

The use of large-deflection theory for shells under axial compression was first advanced by Von Kármán and Tsien (reference 3) in an attempt to explain the discrepancies between the buckling loads predicted by classical theory and those obtained from experimental results. (See, for instance, reference 6.) The results of reference 3 indicated that cylindrical shells can be maintained in equilibrium in the buckled state by a compressive load considerably lower than that predicted by classical theory. A plausible explanation of this result is that, before the classical buckling load is reached during a test, the cylindrical shell "jumps" from an equilibrium unbuckled state to an equilibrium buckled state. The physical phenomena of the jump were further examined in reference 5 by Tsien.

The treatment of Von Kármán and Tsien in reference 3 was left incomplete, however, in that the equilibrium positions at the buckled state were determined by differentiating the total potential energy with respect to some but not all of the physical parameters involved. The resulting equations gave a relation between the average compressive stress σ and the end-shortening ϵ in terms of the remaining parameters. A set of curves of σ against ϵ were thus obtained for various combinations of the remaining parameters.

Improvement of the theory of Von Kármán and Tsien was made by Leggett and Jones (reference 4), who took the derivatives of the energy with respect to all the parameters and thus obtained a single curve between σ and ϵ , representing all equilibrium positions of the cylindrical shell in the buckled state. The same result was obtained by Michielsen (reference 7) in a similar process. Such a curve is shown by BC of figure 5.

Theoretically, when the cylinder is compressed, the relation between σ and ϵ follows the straight line ODA which represents the unbuckled state and will reach the point A if everything is perfect; the cylinder then buckles and the relationship follows the curve ABC which represents the buckled state. Before point A is reached, however, some external disturbance may possibly cause the cylinder to jump from the unbuckled state represented by the point D to the buckled state represented by the point E. The positions of D and E on the respective curves depend on the actual physical conditions of the jump.

If the physical condition which governs the jump is known or defined, the buckling stress corresponding to the point D can be obtained directly without going through the labor of finding the curve ABC. This procedure can greatly reduce the amount of numerical work.

FIGURE 5.—Relation between the average compressive stress σ and the end-shortening ϵ .

In reference 5, Tsien introduced a criterion which governs the jump DE for the condition of loading obtained in a rigid testing machine; namely, that the strain energy remains the same before and after the jump and that the jump occurs at constant end-shortening. According to this criterion the line DE must be vertical and must cut the curve ABC in such a way that the two shaded areas ADG and GBE are equal. In fact, the area ADG represents the additional energy that is needed to assist the cylinder in jumping from a condition represented by D to that represented by G and the area GBE represents the energy that is given up by the cylinder when it arrives at the lower energy level, point E. The energy represented by the area ADG is very small, and therefore a slight disturbance from the surrounding air might assist the cylinder to jump from the unbuckled state to the buckled state at a compressive stress well below the classical buckling stress corresponding to point A.

Since the external disturbance is required to assist the cylinder to jump from the state corresponding to D to that corresponding to G, a slightly larger external disturbance can well cause the cylinder to make the transition from the state represented by D' to that represented by B, except that in the case in which the cylinder jumps from D' to B the cylinder absorbs the energy of the external disturbance and does not re-emit it. The buckling stress can be then as low as point D'. This fact was pointed out by Tsien in reference 8.

In addition to the two criterions just mentioned, there are still others that might be used. In view of the fact that the choice of the buckling criterion is a much less important factor in the determination of buckling stress than are such other factors as, for example, the initial imperfections, Tsien's criterion of reference 5, as represented by the line DE, is as reasonable as any other, and the choice of this criterion greatly simplifies the numerical work.

Tsien's criterion of reference 5 cannot be applied directly to the present analysis, however, because with the presence of the internal pressure the strain energy is no longer the same before and after the jump. In addition, the criterion is applied herein in quite a different manner from that of reference 5. In reference 5, a series of values of wave number n and aspect ratio β were chosen and the criterion was applied to each pair of values of n and β ; the pair of values of n and β which gave the minimum value of buckling load was considered to correspond to the buckling condition. In the present analysis, since the variation of σ with ϵ can be plotted only as a single curve, this criterion need be applied only once for each internal pressure. The results correspond to the minimum-potential-energy condition.

In the derivation of the present analysis, the basic equations in reference 3 are first extended to include the effect of internal pressure, Tsien's criterion governing the jump for rigid machine loading (reference 5) is modified, and the buckling stress is finally obtained.

SYMBOLS

A list of symbols follows. Most of the symbols used in the present report are the same as those in reference 3; exceptions are the use of μ for Poisson's ratio, λ for wave length, and β for aspect ratio of the buckled waves.

λ_a	half wave length in longitudinal direction
λ_b	half wave length in circumferential direction
f_0, f_1, f_2	parameters used in deflection function
m	number of waves in longitudinal direction within length equal to circumference of cylinder
n	number of waves in circumference
p	internal pressure
t	thickness of cylinder wall
x, y	coordinates measured in longitudinal and circumferential directions, respectively
u	component of displacement of a point on median surface of shell in x -direction
w	component of displacement of a point on median surface of shell in radial direction

α	measure of average circumferential stress per wave length in longitudinal direction
ϵ	end-shortening of cylinder
σ	average compressive stress
$\beta = \frac{m}{n}$	aspect ratio of buckled waves
μ	Poisson's ratio
ϕ	total potential energy
E	Young's modulus
ψ	strain energy
$B_1, B_2, \dots B_5$ $B_1', B_2', \dots B_5'$	certain functions of β
$D_1, D_2, \dots D_5$	certain functions of ρ and β
$(D)_\rho = \frac{\partial D}{\partial \rho}$	(D represents the functions $D_1, D_2, \dots D_5$)
$(D)_\beta = \beta \frac{\partial D}{\partial \beta}$	(D represents the functions $D_1, D_2, \dots D_5$)
R	radius of cylinder
W_1	elastic extensional energy
W_2	bending energy
W_3	work done by applied compressive load
W_p	work done by internal pressure

Nondimensional parameters:

$$\rho = \frac{f_2}{f_1}$$

$$\zeta = f_1 \frac{R}{t}$$

$$\eta = n^2 \frac{t}{R}$$

$$\bar{\sigma} = \frac{\sigma}{E} \frac{R}{t}$$

$$\bar{p} = \frac{p}{t} \left(\frac{R}{t} \right)^2$$

$$\bar{W} = \frac{W}{\frac{1}{2} E t \lambda_a \lambda_b}$$

($\bar{W}_1, \bar{W}_2, \bar{W}_3$, and $\bar{W}_p$ are defined in the same manner.)

$$\bar{\phi} = \frac{\phi}{\frac{1}{2} E t \lambda_a \lambda_b}$$

$$\bar{\psi} = \frac{\psi}{\frac{1}{2} E t \lambda_a \lambda_b}$$

$$\bar{\epsilon} = \epsilon \frac{R}{t}$$

$$\bar{\sigma}' = \left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta D_1$$

DERIVATION OF BASIC EQUATIONS

Three basic equations are derived in the following analysis to include the effect of internal pressure. They are the expression for the total potential energy, the expression for the strain energy, and the relation between the end-shortening and the average compressive stress.

In order to calculate the total potential energy, the work done by the internal pressure should be included in addition to the energies W_1 , W_2 , and W_3 , which are given by equations (25), (26), and (27) of reference 3 as:

$$\frac{W_1}{\frac{1}{2}Et\lambda_a\lambda_b} = 4 \left[(1-\mu^2) \left(\frac{\sigma}{E} \right)^2 + n^4 \left(\frac{3}{64} f_1^2 + \frac{1}{16} f_1 f_2 + \frac{1}{16} f_2^2 \right)^2 + \left(f_0 + \frac{1}{4} f_1 \right)^2 - 2n^2 \left(\frac{3}{64} f_1^2 + \frac{1}{16} f_1 f_2 + \frac{1}{16} f_2^2 \right) \left(f_0 + \frac{1}{4} f_1 \right) \right] + \left[\frac{A^2}{8} + \frac{B^2\beta^4}{8} + \frac{\beta^4 C^2}{(1+\beta^2)^2} + \frac{\beta^4 D^2}{(1+9\beta^2)^2} + \frac{\beta^4 G^2}{(9+\beta^2)^2} + \frac{\beta^4 H^2}{16(1+\beta^2)^2} \right] \quad (1)$$

$$\frac{W_2}{\frac{1}{2}Et\lambda_a\lambda_b} = \frac{1}{6(1-\mu^2)} \left(\frac{t}{R} \right)^2 n^4 \left\{ f_1^2 \left[\frac{1}{8} (1+\beta^2)^2 + \frac{1}{4} (1+\beta^4) \right] + (1+\beta^4) f_1 f_2 + (1+\beta^4) f_2^2 \right\} \quad (2)$$

$$\frac{W_3}{\frac{1}{2}Et\lambda_a\lambda_b} = \left[2(1-\mu^2) \left(\frac{\sigma}{E} \right)^2 + n^2 \frac{\sigma}{E} (\mu + \beta^2) \left(\frac{3}{32} f_1^2 + \frac{1}{8} f_1 f_2 + \frac{1}{8} f_2^2 \right) - 2\mu \frac{\sigma}{E} \left(f_0 + \frac{1}{4} f_1 \right) \right] \quad (3)$$

where a , b , μ , and ν have been changed to λ_a , λ_b , β , and μ , respectively, to agree with the notation of the present report and where

$$A = \frac{1}{8} f_1^2 n^2 - \left(\frac{1}{2} f_1 + f_2 \right)$$

$$B = \frac{1}{8} f_1^2 n^2$$

$$C = \frac{1}{2} f_1 n^2 \left(\frac{1}{2} f_1 + f_2 \right) - \frac{1}{2} f_1$$

$$D = \frac{1}{4} f_1 n^2 \left(\frac{1}{2} f_1 + f_2 \right)$$

$$G = \frac{1}{4} f_1 n^2 \left(\frac{1}{2} f_1 + f_2 \right)$$

and

$$H = n^2 \left(\frac{1}{2} f_1 + f_2 \right)^2$$

The work done by the internal pressure is, for a complete wave panel,

$$W_p = -4 \int_0^{\lambda_a} \int_0^{\lambda_b} w p \, dx \, dy$$

The negative sign is introduced because the radial deflection w is considered positive inward.

If the same deflection function given in equation (16) of reference 3 is used, that is,

$$\frac{w}{R} = \left(f_0 + \frac{f_1}{4} \right) + \frac{f_1}{2} \left(\cos \frac{mx}{R} \cos \frac{ny}{R} + \frac{1}{4} \cos \frac{2mx}{R} + \frac{1}{4} \cos \frac{2ny}{R} \right) + \frac{f_2}{4} \left(\cos \frac{2mx}{R} + \cos \frac{2ny}{R} \right) \quad (4)$$

the work done by the internal pressure becomes

$$W_p = -4pR\lambda_a\lambda_b \left(f_0 + \frac{f_1}{4} \right). \quad (5)$$

If the total potential energy

$$\phi = W_1 + W_2 - W_3 - W_p$$

is differentiated with respect to f_0 and the derivative is set equal to zero, the following expression is obtained:

$$f_0 + \frac{f_1}{4} = \frac{1}{16} n^2 \left(\frac{3}{4} f_1^2 + f_1 f_2 + f_2^2 \right) - \mu \frac{\sigma}{E} - \frac{pR}{Et} \quad (6)$$

Substitute this expression into equations (1), (2), (3), and (5) for W_1 , W_2 , W_3 , and W_p , respectively, and the following equations are obtained:

$$\begin{aligned} \frac{W_1}{\frac{1}{2}Et\lambda_a\lambda_b} = & 4 \left[\left(\frac{\sigma}{E} \right)^2 + 2\mu \left(\frac{\sigma}{E} \right) \left(\frac{pR}{Et} \right) + \left(\frac{pR}{Et} \right)^2 \right] + \\ & n^4 \left(B_1 f_1^4 + B_2 f_1^3 f_2 + B_3 f_1^2 f_2^2 + B_4 f_1 f_2^3 + \frac{B_4}{2} f_2^4 \right) - \\ & n^2 \left[\left(2B_4 + \frac{1}{64} \right) f_1^3 + \left(4B_4 + \frac{1}{32} \right) f_1^2 f_2 \right] + \\ & \left[\left(2B_4 + \frac{1}{32} \right) f_1^2 + \frac{1}{8} f_1 f_2 + \frac{1}{8} f_2^2 \right] \end{aligned} \quad (7)$$

$$\frac{W_2}{\frac{1}{2}Et\lambda_a\lambda_b} = \left(\frac{t}{R} \right)^2 (B_5 f_1^2 + B_6 f_1 f_2 + B_6 f_2^2) n^4 \quad (8)$$

$$\begin{aligned} \frac{W_3}{\frac{1}{2}Et\lambda_a\lambda_b} = & 4 \left[2 \left(\frac{\sigma}{E} \right)^2 + 2\mu \left(\frac{\sigma}{E} \right) \left(\frac{pR}{Et} \right) + \right. \\ & \left. \frac{1}{8} \left(\frac{\sigma}{E} \right) n^2 \beta^2 \left(\frac{3}{4} f_1^2 + f_1 f_2 + f_2^2 \right) \right] \end{aligned} \quad (9)$$

$$\frac{W_p}{\frac{1}{2}Et\lambda_a\lambda_b} = 8 \left[\left(\frac{pR}{Et} \right)^2 + 8\mu \left(\frac{\sigma}{E} \right) \left(\frac{pR}{Et} \right) - n^2 \left(\frac{pR}{Et} \right) \frac{1}{16} \left(\frac{3}{4} f_1^2 + f_1 f_2 + f_2^2 \right) \right] \quad (10)$$

where

$$B_1 = \frac{1}{64} \left[\frac{1+\beta^4}{8} + \frac{17}{4} \frac{\beta^4}{(1+\beta^2)^2} + \frac{\beta^4}{(1+9\beta^2)^2} + \frac{\beta^4}{(9+\beta^2)^2} \right]$$

$$B_2 = \frac{1}{16} \left[\frac{9}{2} \frac{\beta^4}{(1+\beta^2)^2} + \frac{\beta^4}{(1+9\beta^2)^2} + \frac{\beta^4}{(9+\beta^2)^2} \right]$$

$$B_3 = \frac{1}{16} \left[\frac{11}{2} \frac{\beta^4}{(1+\beta^2)^2} + \frac{\beta^4}{(1+9\beta^2)^2} + \frac{\beta^4}{(9+\beta^2)^2} \right]$$

$$B_4 = \frac{1}{8} \frac{\beta^4}{(1+\beta^2)^2}$$

$$B_5 = \frac{1}{6(1-\mu^2)} \left[\frac{1}{8} (1+\beta^2)^2 + \frac{1}{4} (1+\beta^4) \right]$$

$$B_6 = \frac{1}{6(1-\mu^2)} (1+\beta^4)$$

Equations (7) to (10) may be expressed in terms of the nondimensional parameters $\bar{\sigma}$, $\bar{p}$, ρ , η , ζ , and $\bar{W}$ as

$$\bar{W}_1 = 4(\bar{\sigma}^2 + 2\mu\bar{\sigma}\bar{p} + \bar{p}^2) + \eta^2\zeta^4 D_2 + \eta\zeta^3(-D_3) + \zeta^2 D_4 \quad (11)$$

$$\bar{W}_2 = \eta^2\zeta^2 D_5 \quad (12)$$

$$\bar{W}_3 = 8\bar{\sigma}^2 + 8\mu\bar{\sigma}\bar{p} + \bar{\sigma}\eta\zeta^2 D_1 \quad (13)$$

$$\bar{W}_p = 8\mu\bar{\sigma}\bar{p} + 8\bar{p}^2 - \frac{1}{\beta^2} \bar{p}\eta\zeta^2 D_1 \quad (14)$$

where

$$D_1 = \frac{1}{2} \beta^2 \left(\frac{3}{4} + \rho + \rho^2 \right)$$

$$D_2 = B_1 + B_2\rho + B_3\rho^2 + B_4\rho^3 + \frac{1}{2} B_4\rho^4$$

$$D_3 = \left(2B_4 + \frac{1}{64} \right) (1+2\rho)$$

$$D_4 = \left(2B_4 + \frac{1}{32} \right) + \frac{1}{8} (\rho + \rho^2)$$

$$D_5 = B_5 + B_6(\rho + \rho^2)$$

The nondimensional total-potential-energy parameter $\bar{\phi}$ is

$$\begin{aligned} \bar{\phi} &= \bar{W}_1 + \bar{W}_2 - \bar{W}_3 - \bar{W}_p \\ &= -4(\bar{\sigma}^2 + 2\mu\bar{\sigma}\bar{p} + \bar{p}^2) - \left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta\zeta^2 D_1 + \\ &\quad \eta^2\zeta^4 D_2 - \eta\zeta^3 D_3 + \zeta^2 D_4 + \eta^2\zeta^2 D_5 \end{aligned} \quad (15)$$

The nondimensional strain-energy parameter $\bar{\psi}$ is

$$\begin{aligned} \bar{\psi} &= \bar{W}_1 + \bar{W}_2 \\ &= 4(\bar{\sigma}^2 + 2\mu\bar{\sigma}\bar{p} + \bar{p}^2) + \eta^2\zeta^4 D_2 - \\ &\quad \eta\zeta^3 D_3 + \zeta^2 D_4 + \eta^2\zeta^2 D_5 \end{aligned} \quad (16)$$

The relation between the end-shortening ϵ and the average compressive stress can be determined from equation (23) of reference 3 by integrating; thus,

$$\begin{aligned} \epsilon &= -\frac{1}{\lambda_a} \int_0^{\lambda_a} \frac{\partial u}{\partial x} dx \\ &= \left(\frac{\sigma}{E} + \mu \frac{\alpha}{E} \right) + \frac{1}{16} n^2 \beta^2 \left(\frac{3}{4} f_1^2 + f_2^2 + f_1 f_2 \right) \end{aligned}$$

where α/E , as determined from equation (24) of reference 3, together with equation (6) herein is

$$\frac{\alpha}{E} = \frac{pR}{Et}$$

Therefore, the relation between $\bar{\epsilon}$ and $\bar{\sigma}$ in nondimensional form becomes

$$\begin{aligned} \bar{\epsilon} &= \epsilon \frac{R}{t} \\ &= \bar{\sigma} + \mu\bar{p} + \frac{1}{8} \eta\zeta^2 D_1 \end{aligned} \quad (17)$$

Equations (15), (16), and (17) are for cylinders in the buckled state. For cylinders in the unbuckled state, the corresponding equations are

$$\bar{\phi}_u = -4(\bar{\sigma}_u^2 + 2\mu\bar{\sigma}_u\bar{p} + \bar{p}^2) \quad (18)$$

$$\bar{\psi}_u = 4(\bar{\sigma}_u^2 + 2\mu\bar{\sigma}_u\bar{p} + \bar{p}^2) \quad (19)$$

$$\bar{\epsilon}_u = \bar{\sigma}_u + \mu\bar{p} \quad (20)$$

EQUILIBRIUM POSITIONS OF CYLINDERS IN BUCKLED STATE

The equilibrium positions of cylinders in the buckled state can be obtained by differentiating the total potential energy of equation (15) with respect to each of the parameters η , ζ , ρ , and β and by setting the derivatives equal to zero. Four simultaneous, nonlinear equations are thus obtained:

$$\left. \begin{aligned} \frac{\partial \bar{\phi}}{\partial \eta} &= 0 = - \left[\left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta D_1 - 2(\eta\zeta)^2 D_2 + (\eta\zeta) D_3 - 2\eta^2 D_5 \right] \left(\frac{\zeta^2}{\eta} \right) \\ \frac{\partial \bar{\phi}}{\partial \zeta} &= 0 = - \left[\left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta D_1 - 2(\eta\zeta)^2 D_2 + 1.5(\eta\zeta) D_3 - \right. \\ &\quad \left. D_4 - \eta^2 D_5 \right] (2\zeta) \\ \frac{\partial \bar{\phi}}{\partial \rho} &= 0 = - \left[\left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta (D_1)_\rho - (\eta\zeta)^2 (D_2)_\rho + (\eta\zeta) (D_3)_\rho - \right. \\ &\quad \left. (D_4)_\rho - \eta^2 (D_5)_\rho \right] \zeta^2 \\ \frac{\partial \bar{\phi}}{\partial \beta} &= 0 = - \left[\left(\bar{\sigma} - \frac{1}{\beta^2} \bar{p} \right) \eta (D_1)_\beta - (\eta\zeta)^2 (D_2)_\beta + (\eta\zeta) (D_3)_\beta - \right. \\ &\quad \left. (D_4)_\beta - \eta^2 (D_5)_\beta + \frac{2}{\beta^2} \bar{p} \eta D_1 \right] \frac{\zeta^2}{\beta} \end{aligned} \right\} \quad (21)$$

where

$$(D_1)_\rho = \frac{1}{2} \beta^2 (1 + 2\rho)$$

$$(D_2)_\rho = B_2 + 2B_3\rho + 3B_4\rho^2 + 2B_4\rho^3$$

$$(D_3)_\rho = 2 \left(B_4 + \frac{1}{64} \right)$$

$$(D_4)_\rho = \frac{1}{8} (1 + 2\rho)$$

$$(D_5)_\rho = B_6 (1 + 2\rho)$$

$$(D_1)_\beta = \beta^2 \left(\frac{3}{4} + \rho + \rho^2 \right) = 2D_1$$

$$(D_2)_\beta = B_1' + B_2'\rho + B_3'\rho^2 + B_4'\rho^3 + \frac{1}{2} B_4'\rho^4$$

$$(D_3)_\beta = 2B_4' (1 + 2\rho)$$

$$(D_4)_\beta = 2B_4'$$

$$(D_5)_\beta = B_5' + B_6'(\rho + \rho^2)$$

and

$$B_1' = \frac{1}{16} \left[\frac{\beta^4}{8} + \frac{17}{4} \frac{\beta^4}{(1+\beta^2)^3} + \frac{\beta^4}{(1+9\beta^2)^3} + 9 \frac{\beta^4}{(9+\beta^2)^3} \right]$$

$$B_2' = \frac{1}{4} \left[\frac{9}{2} \frac{\beta^4}{(1+\beta^2)^3} + \frac{\beta^4}{(1+9\beta^2)^3} + 9 \frac{\beta^4}{(9+\beta^2)^3} \right]$$

$$B_3' = \frac{1}{4} \left[\frac{11}{2} \frac{\beta^4}{(1+\beta^2)^3} + \frac{\beta^4}{(1+9\beta^2)^3} + 9 \frac{\beta^4}{(9+\beta^2)^3} \right]$$

$$B_4' = \frac{1}{2} \frac{\beta^4}{(1+\beta^2)^3}$$

$$B_5' = \frac{1}{6(1-\mu^2)} \frac{1}{2} \beta^2 (1 + 3\beta^2)$$

$$B_6' = \frac{4}{6(1-\mu^2)} \beta^4$$

Let

$$\bar{\sigma}' = \left(\bar{\sigma} - \frac{1}{2} \bar{p} \right) \eta D_1$$

The four simultaneous equations (21) become

$$\bar{\sigma}' = (\eta \zeta)^2 (2D_2) - (\eta \zeta) D_3 + 2\eta^2 D_5 \quad (22a)$$

$$\bar{\sigma}' = (\eta \zeta)^2 (2D_2) - (\eta \zeta) (1.5D_3) + D_4 + \eta^2 D_5 \quad (22b)$$

$$\bar{\sigma}' = [(\eta \zeta)^2 (D_2)_\rho - (\eta \zeta) (D_3)_\rho + (D_4)_\rho + \eta^2 (D_5)_\rho] \frac{D_1}{(D_1)_\rho} \quad (22c)$$

$$\bar{\sigma}' = [(\eta \zeta)^2 (D_2)_\beta - (\eta \zeta) (D_3)_\beta + (D_4)_\beta + \eta^2 (D_5)_\beta] \frac{1}{2} - \frac{\bar{p}}{\beta^2} \eta D_1 \quad (22d)$$

Theoretically these four simultaneous equations can be solved for η , ζ , ρ , and β in terms of $\bar{\sigma}$ for a given pressure. If they are substituted into equation (17), a relation between end-shortening $\bar{\epsilon}$ and the compressive stress $\bar{\sigma}$ is obtained which represents all equilibrium positions at the buckled state. In fact, this solution is essentially that obtained by Leggett and Jones (reference 4) and Michielsen (reference 7) for cylinders with axial compression but no internal pressure.

Practically, however, the solution of the four simultaneous equations (22) requires a long and tedious numerical process. If only the buckling stress is required, calculation of only one point on the curve of $\bar{\sigma}$ against $\bar{\epsilon}$ rather than the whole curve is necessary. This solution can be obtained by the introduction of one more equation which governs the condition at buckling.

BUCKLING CRITERION

In reference 5, Tsien gave the following criterion which governs the condition at buckling: That the strain-energy of the buckled cylinder is the same as the strain energy of the unbuckled cylinder when the cylinder is tested in the rigid testing machine so that the end-shortening does not change during buckling. This criterion is apparently established from considerations of conservation of energy. Although other physical criteria can be used (for instance, see reference 8), the criterion of reference 5 was chosen and extended to include the case for which the internal pressure is present. The choice of this criterion simplifies the numerical work.

When internal pressure is present in the cylinder, work is done by the pressure during buckling. The strain energy in the buckled state is no longer equal to that in the unbuckled state, but

$$\bar{\psi} = \bar{\psi}_u + \Delta \bar{W}_p \quad (23)$$

where $\Delta \bar{W}_p$ is the work done by the pressure during buckling, or

$$\begin{aligned} \Delta \bar{W}_p &= \frac{1}{\frac{1}{2} E t \lambda_a \lambda_b} \left(\frac{R}{t} \right)^2 \left[- \int_0^{\lambda_a} \int_0^{\lambda_b} p(w - w_u) dx dy \right] \\ &= \bar{W}_p - (\bar{W}_p)_u \end{aligned} \quad (24)$$

Equation (14) can be rearranged as follows:

$$\bar{W}_p = 8(\bar{p}^2 + \mu \bar{\sigma} \bar{p}) - \frac{1}{\beta^2} \bar{p} \eta \zeta^2 D_1 \quad (25)$$

Therefore, for the unbuckled state, the last term is eliminated and

$$(\bar{W}_p)_u = 8(\bar{p}^2 + \mu \bar{\sigma}_u \bar{p}) \quad (26)$$

Then, from equations (24), (25), and (26)

$$\Delta \bar{W}_p = 8\mu \bar{p} (\bar{\sigma} - \bar{\sigma}_u) - \frac{1}{\beta^2} \bar{p} \eta \zeta^2 D_1 \quad (27)$$

The buckling criterion becomes (equations (23) and (27))

$$\bar{\psi} = \bar{\psi}_u + 8\mu\bar{p}(\bar{\sigma} - \bar{\sigma}_u) - \frac{1}{\beta^2} \bar{p}\eta\zeta^2 D_1$$

or, from equations (16) and (19),

$$4(\bar{\sigma}^2 + 2\mu\bar{\sigma}\bar{p} + \bar{p}^2) + \eta^2\zeta^4 D_2 - \eta\zeta^3 D_3 + \zeta^2 D_4 + \eta^2\zeta^2 D_5 \\ = 4(\bar{\sigma}_u^2 + 2\mu\bar{\sigma}_u\bar{p} + \bar{p}^2) + 8(\bar{\sigma} - \bar{\sigma}_u)\mu\bar{p} - \frac{1}{\beta^2} \bar{p}\eta\zeta^2 D_1 \quad (28)$$

Since the end-shortening remains unchanged during buckling, that is, $\bar{\epsilon} = \bar{\epsilon}_u$, the following relation is obtained from equations (17) and (20):

$$\bar{\sigma}_u = \bar{\sigma} + \frac{1}{8} \eta\zeta^2 D_1 \quad (29)$$

If this relation is substituted in equation (28) and if the relation $\bar{\sigma}' = \left(\bar{\sigma} - \frac{1}{\beta^2} p\right) \bar{\eta} D_1$ is used, the buckling criterion becomes

$$\bar{\sigma}' = (\eta\zeta)^2 \left(D_2 - \frac{1}{16} D_1^2\right) - (\eta\zeta) D_3 + D_4 + \eta^2 D_5 \quad (30)$$

The solution of the five equations (22a), (22b), (22c), (22d), and (30) gives the buckling stress for a given internal pressure. The following section presents a very simple method for the solution of these five simultaneous equations.

METHOD OF SOLUTION

From equations (22b) and (30) and equations (22a) and (22c), the following equations are obtained:

$$\eta\zeta = \frac{D_3}{2 \left(D_2 + \frac{1}{16} D_1^2\right)} \quad (31)$$

$$\eta^2 = \frac{D_4 - \frac{1}{2} D_3(\eta\zeta)}{D_5} \quad (32)$$

For a preassigned value of β , assume various values of ρ and compute $\eta\zeta$ and η^2 from equations (31) and (32). Substitute these values in equations (22a) and (22c) to obtain $(\bar{\sigma}')_a$ and $(\bar{\sigma}')_c$, respectively. Plot both $(\bar{\sigma}')_a$ and $(\bar{\sigma}')_c$ against ρ .

The intersection of these two curves determines a pair of values $\bar{\sigma}'$ and ρ which are called $\bar{\sigma}'_o$ and ρ_o . The corresponding values of $(\eta\zeta)_o$ and $(\eta^2)_o$ are computed and substituted in equation (22d) from which the pressure p can be calculated. For each assigned value of β , there are obtained corresponding values of $\bar{\sigma}'_o$ and $\bar{p}$. A curve of $\bar{\sigma}'_o$ against $\bar{p}$ can thus be determined. If the following relations are used

$$\bar{\sigma}'_o = (\eta D_1)_o \left(\bar{\sigma}_o - \frac{1}{\beta^2} \bar{p}\right)$$

$$\bar{\sigma}_{cr} = (\bar{\sigma}_u)_o = \bar{\sigma}_o + \frac{1}{8} (\eta\zeta^2 D_1)_o$$

the relation between $\bar{\sigma}_{cr}$ and $\bar{p}$ is obtained as shown in figure 3.

CUT-OFF BUCKLING STRESS

When equation (31) is derived from equations (22b) and (30), a factor $(\eta\zeta) = 0$ is also obtained. If this relation is used instead of equation (31), it can be shown that the buckling stress $\bar{\sigma}_{cr}$ can never exceed the classical buckling stress 0.605 which is independent of pressure.

REPORT 1028

EFFECT OF ASPECT RATIO ON THE AIR FORCES AND MOMENTS OF HARMONICALLY OSCILLATING THIN RECTANGULAR WINGS IN SUPERSONIC POTENTIAL FLOW¹

By CHARLES E. WATKINS

SUMMARY

This report treats the effect of aspect ratio on the air forces and moments of an oscillating flat rectangular wing in supersonic potential flow. The linearized velocity potential for the wing undergoing sinusoidal torsional oscillations simultaneously with sinusoidal vertical translations is derived in the form of a power series in terms of a frequency parameter. The series development is such that the differential equation for the velocity potential is satisfied to the required power of the frequency parameter considered and the linear boundary conditions are satisfied exactly. The method of solution can be utilized for other plan forms—that is, plan forms for which certain steady-state solutions are known.

Simple, closed expressions that include the reduced frequency to the third power, which is sufficient for application to a large class of practicable problems, are given for the velocity potential, the components of total force and moment coefficients, and the components of chordwise section force and moment coefficients. The components of total force and moment coefficients indicate the over-all effect of aspect ratio on these quantities; however, the components of chordwise coefficients yield more information because they account for the spanwise distribution of aerodynamic loading of a rectangular wing and may therefore be more useful for flutter calculations. It is found that the components of force and moment coefficients for a small-aspect-ratio wing may deviate considerably from those of an infinite-aspect-ratio wing. Thickness effects which may alter some of the conclusions are not taken into account in the analysis. Results of some selected calculations are presented in several figures and discussed.

INTRODUCTION

The effect of aspect ratio on the single-degree torsional instability of a finite rectangular wing oscillating in a supersonic stream was treated in reference 1 by expanding, in powers of the frequency of oscillation, the linearized velocity potential developed in reference 2. Since only slow oscillations were considered pertinent to single-degree torsional instability, terms in the expansion involving the frequency of oscillation to powers higher than the first were not considered.

In the present report the expanded linearized velocity potential is used to study the effect of aspect ratio on the air

forces and moments of an oscillating, thin, flat, finite, rectangular wing when higher powers of the frequency of oscillation are taken into account. The motions considered are sinusoidal torsional oscillations about a spanwise axis taken simultaneously with sinusoidal vertical translations of this axis. The velocity potential is developed by use of sources and doublets, so as to include all powers of the frequency of oscillations up to any desired power. Simple, closed expressions are given for the velocity potential, components of the total force and moment coefficients, and components of the chordwise section force and moment coefficients involving powers of the frequency up to and including the third power. Extension of the results to include higher powers of the frequency is straightforward.

A recent publication, reference 3, that became available after this investigation was completed, is partly devoted to the treatment of a rectangular wing undergoing the same types of harmonic motions as those considered herein. The velocity potential is determined in the form of a double integral, by application of the Fourier transform to the boundary-value problem for this potential, and expressions for forces and moments are given in terms of this double integral. The reduction of the integral expressions of reference 3 to forms desirable for flutter calculations—that is, chordwise section forces and moments—is not given.

SYMBOLS

ϕ	disturbance-velocity potential
x, y, z	rectangular coordinates attached to wing moving in negative x -direction
ξ, η	rectangular coordinates used to represent space location of sources or doublets in xy -plane
Z_m	function defining mean ordinates of any chordwise section of wing such as $y=y_1$ as shown in figure 1
$w(x, y_1, t)$	vertical velocity at surface of wing along chordwise section at $y=y_1$
x_0	abscissa of axis of rotation of wing (elastic axis) as shown in figure 1
t	time
h	vertical displacement of axis of rotation
h_0	amplitude of vertical displacement of axis of rotation, positive downward

¹ Supersedes NACA TN 2064, "Effect of Aspect Ratio on the Air Forces and Moments of Harmonically Oscillating Thin Rectangular Wings in Supersonic Potential Flow" by Charles E. Watkins, 1950.

α	angle of attack
α_0	amplitude of angular displacement about axis of rotation, positive leading edge up
$\dot{h}, \dot{\alpha}$	time derivative of h and α , respectively
V	velocity of main stream
c	velocity of sound
M	free-stream Mach number (V/c)
$\beta = \sqrt{M^2 - 1}$	
$\tau_1, \tau_2, \eta_1, \eta_2$	functions defined with equation (7)
$W(\xi, \eta)$	function used to represent space variation of source and doublet strengths
$w(t)$	function used to represent time variation of source and doublet strengths
ω	frequency of oscillation
$\bar{\omega} = \frac{M^2 \omega}{V \beta^2}$	
k	reduced frequency ($\omega b/V$)
$R = \beta \sqrt{(\eta - \eta_1)(\eta_2 - \eta)}$	
a_{nm}	represents functions of $\bar{\omega}$, x , and M , defined in equations (15)
f_1, f_2, f_3	represent functions of x , x_0 , and $\bar{\omega}$, defined in equations (19)
D_n	function used to denote doublet distributions (see equation (22))
F_n	function defined in equation (28)
G_n	function defined in equation (29)
ρ	density
Δp	local pressure difference measured positive downward, defined in equation (31)
b	half-chord
s	half-span
A	aspect ratio (s/b)
$\bar{P}$	total force acting on wing defined in equation (32)
$\bar{L}_1, \bar{L}_2, \bar{L}_3, \bar{L}_4$	components of total force coefficients, defined in equations (35)
$\bar{M}_\alpha$	total moment acting on wing, defined in equation (36)
$\bar{M}_1, \bar{M}_2, \bar{M}_3, \bar{M}_4$	components of total moment coefficients, defined in equations (38)
P	section force (total force at any spanwise station), defined in equation (39)
L_1, L_2, L_3, L_4	components of section force coefficients, defined in equations (41) and (42)
M_α	section moment (total moment at any spanwise station), defined in equation (40)
M_1, M_2, M_3, M_4	components of section moment coefficients, defined in equations (43) and (44)
$\bar{F}_n, \bar{G}_n$	functions related to F_n and G_n , defined in appendix

ANALYSIS

BOUNDARY-VALUE PROBLEMS FOR VELOCITY POTENTIALS

Consider a thin flat rectangular wing moving at a constant supersonic speed in a chordwise direction normal to its leading edge as shown in figure 1. The boundary-value problems for the velocity potential for such a wing may be conveniently classified into two types associated with the nature of the flow over different portions of the wing. On the portion of the wing between the Mach cones emanating from the foremost point of each tip (region N in fig. 1 (a)) there is no interaction between the flow on the upper and lower surfaces of the wing. The type of boundary-value problem

FIGURE 1.—Sketch illustrating chosen coordinate system and the two degrees of freedom α and h .

for this portion of the wing is referred to herein as "purely supersonic" and the velocity potential for region N is denoted by ϕ_N . On portions of the wing within the Mach cones emanating from the foremost point of each tip (regions T₁, T₂, and T₃ in fig. 1 (a)), there is interaction between the flow on the upper and lower surfaces of the wing. The type of boundary-value problem for these portions of the wing is referred to as "mixed supersonic" and the velocity potentials for these regions are designated by ϕ_{T_1} , ϕ_{T_2} , and ϕ_{T_3} , respectively. The complete velocity potential at a point may then be expressed as ϕ_N , ϕ_{T_1} , ϕ_{T_2} , or ϕ_{T_3} according to the region that contains the point.

As customary in linear theory, as applied to thin flat surfaces, the boundary conditions are to be ultimately satisfied by the velocity potentials at the projection of the wing onto a plane (the xy -plane) with respect to which all deflections are considered small and which lies parallel to the free-stream direction. Thickness effects are not taken into account; hence, the velocity potentials are associated only with conditions that yield lift and are consequently anti-symmetrical with respect to the plane of the projected wing. It is therefore necessary to consider the potentials at only one surface, upper or lower, of the projected wing. The upper surface is chosen for this analysis.

The differential equation for the propagation of small disturbances that must be satisfied by the velocity potentials is (when referred to a rectangular coordinate system x, y, z with the xy -plane coincident with the reference plane and moving uniformly in the negative x -direction, fig. 1)

$$\frac{1}{c^2} \left(\frac{\partial}{\partial t} + V \frac{\partial}{\partial x} \right)^2 \phi = \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} \quad (1)$$

The boundary conditions that must be satisfied by the velocity potential are: (a) In regions T₁, T₂, T₃, and N the flow must be tangent to the surface of the wing or

$$\left(\frac{\partial \phi}{\partial z} \right)_{z \rightarrow 0} = w(x, y, t) = V \frac{\partial Z_m}{\partial x} + \frac{\partial Z_m}{\partial t} \quad (2)$$

where Z_m is the vertical displacement of the ordinates of the surface of any chordwise section of the wing (see fig. 1 (b)). (b) In regions T₁ and T₂ the pressure must fall to zero along the wing tips and remain zero in the portion of the Mach cones emanating from the foremost points of the wing tips not occupied by the wing. (Another condition, that the potential must be zero ahead of the wing and in the region off the wing adjacent to the Mach cones emanating from the foremost points of the tips, is automatically satisfied by the type of source and doublet synthesis employed in the solutions.)

For the particular case of a wing independently performing small sinusoidal torsional oscillations of amplitude $|\alpha_0|$ and frequency ω about some spanwise axis x_0 and small sinusoidal vertical translations of amplitude $|h_0|$ and frequency ω , the equation of Z_m is

$$Z_m = e^{i\omega t} [\alpha_0(x - x_0) + h_0] = \alpha(x - x_0) + h \quad (3)$$

Substituting this expression for Z_m into equation (2) gives

$$w(x, y, t) = V\alpha + \dot{\alpha}(x - x_0) + \dot{h} \quad (4)$$

The velocity potential may thus be expressed as the sum of separate effects due to position and motion of the wing associated with the individual terms in equation (4) as

$$\phi = \phi_a + \phi_\alpha + \phi_h \quad (5)$$

DERIVATION OF ϕ_N

The boundary-value problem in the purely supersonic region (fig. 2 (a)) is the same as that for the two-dimensional wing treated in reference 4. This problem is there shown to be satisfied by a distribution of sources referred to, in this case, as moving sources because of the uniform motion; that is,

$$\phi_N(x, y, z, t) = -\frac{1}{2\beta\pi} \int_0^{x-\beta z} \int_{\eta_1}^{\eta_2} W(\xi, \eta) \phi_1 d\eta d\xi \quad (6)$$

In equation (6), $W(\xi, \eta)$ represents the space variation of source strength and must be evaluated in accordance with the individual terms of equation (4), and ϕ_1 is the potential of a moving source situated at the point $(\xi, \eta, 0)$ that may be expressed as

$$\phi_1 = \frac{w(t - \tau_1) + w(t - \tau_2)}{\sqrt{(\eta - \eta_1)(\eta_2 - \eta)}} \quad (7)$$

where $w(t)$ is the time variation of source strength and the symbols with subscripts appearing in equation (7) are defined as

$$\tau_1 = \frac{M(x - \xi)}{c\beta^2} - \frac{\sqrt{(\eta - \eta_1)(\eta_2 - \eta)}}{\beta c}$$

$$\tau_2 = \frac{M(x - \xi)}{c\beta^2} + \frac{\sqrt{(\eta - \eta_1)(\eta_2 - \eta)}}{\beta c}$$

$$\eta_1 = y - \frac{1}{\beta} \sqrt{(x - \xi)^2 - \beta^2 z^2}$$

$$\eta_2 = y + \frac{1}{\beta} \sqrt{(x - \xi)^2 - \beta^2 z^2}$$

The time variation of source strength $w(t)$ for harmonic oscillations may be written as

$$w(t) = e^{i\omega t} \quad (8)$$

FIGURE 2.—Sketch illustrating areas of integration for purely supersonic and mixed supersonic regions of flow.

The numerator in equation (7) thus becomes

$$\begin{aligned} w(t-\tau_1) + w(t-\tau_2) &= e^{i\omega(t-\tau_1)} + e^{i\omega(t-\tau_2)} \\ &= 2e^{i\omega t} e^{-i\omega \frac{\tau_2+\tau_1}{2}} \cos \omega \frac{\tau_2-\tau_1}{2} \end{aligned} \quad (9)$$

Substituting equations (7) and (9) into equation (6) yields

$$\phi_N(x, y, z, t) = -\frac{e^{i\omega t}}{\pi} \int_0^{x-\beta z} \int_{\eta_1}^{\eta_2} \frac{W(\xi, \eta) e^{-i\bar{\omega}(x-\xi)} \cos\left(\frac{\bar{\omega}}{M} R\right) d\eta d\xi}{R} \quad (10)$$

where, for brevity,

$$\bar{\omega} = \frac{\omega M}{c\beta^2} = \frac{M^2 \omega}{V\beta^2}$$

and

$$R = \sqrt{(x-\xi)^2 - \beta^2(y-\eta)^2 - \beta^2 z^2} = \beta \sqrt{(\eta-\eta_1)(\eta_2-\eta)}$$

The values of $W(\xi, \eta)$ associated with the different terms of equation (4) are

For h

$$W(\xi, \eta) = \frac{iV\beta^2 \bar{\omega}}{M^2} h_0 \quad (11)$$

For $V\alpha$

$$W(\xi, \eta) = V\alpha_0 \quad (12)$$

For $\dot{\alpha}(x-x_0)$

$$W(\xi, \eta) = \frac{iV\beta^2 \bar{\omega}}{M^2} \alpha_0 (\xi - x_0) \quad (13)$$

If any of the values of $W(\xi, \eta)$ given in equations (11), (12), and (13) is put into equation (10), the integration with

respect to η can be readily performed and the remaining integral evaluated as a series of Bessel functions. (See, for example, reference 4.) However, in order to be consistent with and to lead naturally to a succeeding part of the analysis the integrand is expanded into a Maclaurin's series with respect to $\bar{\omega}$. The expansion yields

$$\begin{aligned} \phi_N(x, y, z, t) &= -\frac{e^{i\omega t}}{\pi} \int_0^{x-\beta z} \int_{\eta_1}^{\eta_2} W(\xi, \eta) \left[\left(a_{01} \frac{1}{R} + a_{11} \frac{\xi}{R} + \dots \right. \right. \\ &\quad \left. \left. + a_{n1} \frac{\xi^n}{R} + \dots \right) + (a_{02} R + a_{12} \xi R + \dots \right. \\ &\quad \left. + a_{n2} \xi^n R + \dots \right) + \dots + (a_{0m} R^{2m-3} + a_{1m} \xi R^{2m-3} \\ &\quad \left. + \dots + a_{nm} \xi^n R^{2m-3} + \dots \right) + \dots \Big] d\eta d\xi \end{aligned} \quad (14)$$

where the coefficients a_{nm} are functions of $\bar{\omega}$, x , and M ; those coefficients involving $\bar{\omega}$, up to and including the third power, are

$$\left. \begin{aligned} a_{01} &= 1 - i\bar{\omega}x - \frac{\bar{\omega}^2}{2}x^2 + \frac{i\bar{\omega}^3}{6}x^3 \\ a_{11} &= i\bar{\omega} + \bar{\omega}^2x - \frac{i\bar{\omega}^3}{2}x^2 \\ a_{21} &= -\frac{\bar{\omega}^2}{2} + \frac{i\bar{\omega}^3}{2}x \\ a_{31} &= -\frac{i\bar{\omega}^3}{6} \\ a_{02} &= -\frac{\bar{\omega}^2}{2M^2} + \frac{i\bar{\omega}^3}{2M^2}x \\ a_{12} &= -\frac{i\bar{\omega}^3}{2M^2} \end{aligned} \right\} \quad (15)$$

Observe the following identity that is valid regardless of the highest power of $\bar{\omega}$ considered and that will be of subsequent use, namely

$$a_{01} + xa_{11} + \dots + x^n a_{n1} \equiv 1 \quad (16)$$

It will be noted in equation (14) that the potential of a moving source when expanded in terms of the frequency appears as a series of terms similar to steady-state source potentials plus series of terms involving various powers of R . By grouping the terms in equation (14) with respect to powers of ξ , the following form of the source potential convenient for later use is obtained:

$$\begin{aligned} \phi_N(x, y, z, t) &= -\frac{e^{i\omega t}}{\pi} \int_0^{x-\beta z} \int_{\eta_1}^{\eta_2} W(\xi, \eta) \left[\left(a_{01} \frac{1}{R} + a_{02} R + \dots \right. \right. \\ &\quad \left. \left. + a_{0m} R^{2m-3} + \dots \right) + \xi \left(a_{11} \frac{1}{R} + a_{12} R + \dots \right. \right. \\ &\quad \left. \left. + a_{1m} R^{2m-3} + \dots \right) + \dots + \xi^n \left(a_{n1} \frac{1}{R} + a_{n2} R \right. \right. \\ &\quad \left. \left. + \dots + a_{nm} R^{2m-3} + \dots \right) + \dots \right] d\eta d\xi \end{aligned} \quad (17)$$

With the terms of the series grouped in this manner, in view of the fact that the differential equation (1) is independent

of ξ , it is apparent that the coefficient of each power of ξ in equation (17) is a solution to the differential equation.

If the values of $W(\xi, \eta)$ in equations (11), (12), and (13) are put into either equation (14) or equation (17), the integrations of each term can be easily carried out in closed form. Moreover it can readily be shown that, when all the terms involving $\bar{\omega}$ up to a given power are taken into account, the differential equation (1) is satisfied to the highest power of $\bar{\omega}$ considered. The boundary condition of tangential flow as expressed in equation (4) is satisfied exactly and does not depend on the order of $\bar{\omega}$ considered.

Putting the values of $W(\xi, \eta)$ in equations (11), (12), and (13) successively into either equation (14) or equation (17), carrying out the indicated integration, and setting $z=0$ yields for the velocity potential, to the third power of $\bar{\omega}$ at the upper surface of the wing, in the purely supersonic region:

$$\phi_N = -\frac{1}{\beta}(\bar{h}f_1 + V\alpha f_2 + \dot{\alpha}f_3) \quad (18)$$

where

$$\left. \begin{aligned} f_1 &= x - \frac{i\bar{\omega}}{2}x^2 - \frac{\bar{\omega}^2}{12M^2}(2\beta^2 + 3)x^3 \\ f_2 &= x - \frac{i\bar{\omega}}{2}x^2 - \frac{\bar{\omega}^2}{12M^2}(2\beta^2 + 3)x^3 + \frac{i\bar{\omega}^3}{48M^2}(2\beta^2 + 5)x^4 \\ f_3 &= \frac{x}{2}(x - 2x_0) - \frac{i\bar{\omega}x^2}{6}(x - 3x_0) - \frac{\bar{\omega}^2}{48M^2}(2\beta^2 + 3)x^3(x - 4x_0) \end{aligned} \right\} \quad (19)$$

DERIVATION OF ϕ_{T_1} , ϕ_{T_2} , AND ϕ_{T_3} [†]

In order to satisfy the boundary-value problem in regions of mixed supersonic flow it is convenient to start with the potential of a moving doublet. Then, for a given order of the frequency of oscillation, this potential, as will be shown in the following analysis, can be modified so that when integrated over the appropriate region the results will satisfy, as in the purely supersonic case, the differential equation to the given order of the frequency and will satisfy the condition of tangential flow exactly. The potential of the type of doublet required may be obtained by partial differentiation of the potential of a moving source (see integrand of equation (17)) with respect to the direction normal to the plane of the wing, namely

$$\begin{aligned} \phi_2 &= \frac{e^{i\omega t}}{\pi} \frac{\partial}{\partial z} \left[\left(a_{01} \frac{1}{R} + a_{02}R + \dots + a_{0m}R^{2m-3} + \dots \right) + \right. \\ &\quad \xi \left(a_{11} \frac{1}{R} + a_{12}R + \dots + a_{1m}R^{2m-3} + \dots \right) + \\ &\quad \left. \dots + \xi^n \left(a_{n1} \frac{1}{R} + a_{n2}R + \dots + a_{nm}R^{2m-3} + \dots \right) + \dots \right] \quad (20) \end{aligned}$$

Examination of equation (20), like equation (17), shows that the coefficient of each power of ξ satisfies the differential equation and, since the differential equation is linear, it is permissible in synthesizing the solution to the boundary-

value problem to weight these coefficients separately. Furthermore the coefficient of each power of ξ consists of a term that has the form of a steady-state doublet potential, namely

$$a_{n1} \frac{\partial}{\partial z} \left(\frac{1}{R} \right) \quad (21)$$

plus a series of other terms involving various powers of R . In the following analysis, attention is first directed to the treatment of the first term of the coefficient ξ^n , (expression (21)). The other terms will be treated subsequently.

Expression (21) has the form that in steady flow is convenient for treating the (antisymmetric) problem of satisfying the condition of tangential flow for a distribution of normal velocity prescribed, at the wing surface, independent of y but proportional to x^n ; that is, a weight or distribution function $D_n(\xi, \eta)$ can be determined so that

$$\lim_{z \rightarrow 0} \frac{\partial^2}{\partial z^2} \int_r \int D_n(\xi, \eta) \frac{\xi^n}{R} d\xi d\eta = \pi x^n \quad n=(0, 1, 2, \dots) \quad (22)$$

where the region of integration r is the portion of the wing situated in the fore cone emanating from the field point (x, y, z) (shown in fig. 2(b) for the rectangular wing with $z=0$).

The distribution function D_n for rectangular wings may be easily determined when D_0 , the distribution function for this wing at constant angle of attack in steady supersonic flow, is known. The expression for D_0 is derived in reference 1 and found to be

$$D_0 = \frac{2}{\beta} \left[\sqrt{\beta\eta(\xi - \beta\eta)} + \xi \sin^{-1} \sqrt{\frac{\beta\eta}{\xi}} \right] \quad (23)$$

From this expression and equation (22) it follows by direct substitution and reduction that

$$D_n = n! \int_0^\xi \int_0^\xi \dots \int_0^\xi D_0(\xi, \eta) (d\xi)^n = n \int_0^\xi (\xi - \lambda)^{n-1} D_0(\lambda, \eta) d\lambda \quad (24)$$

With D_n known so that equation (22) is satisfied it may be demonstrated, with use of identity (16), that these "doublet-type" terms alone satisfy the condition of tangential flow. For example, let it be required to satisfy this condition for vertical translations; then,

$$\begin{aligned} w(x, t) &= \frac{h}{\pi} \frac{\partial^2}{\partial z^2} \int_r \int \sum_{m=0}^n \left[a_{m1} D_m(\xi, \eta) \frac{\xi^m}{R} \right] d\xi d\eta \\ &= h(a_{01} + x a_{11} + \dots + x^n a_{n1}) = h \end{aligned}$$

The next step in the analysis is to consider terms of the type

$$\frac{\partial}{\partial z} (a_{nm} R^{2m-3}) \quad m > 1 \quad (25)$$

appearing in the coefficients of ξ^n (equation (20)). It is to be noted that, when the power of $\bar{\omega}$ to which the potential is to be derived is chosen, the number of terms in equation (20) that are to be treated is determined by the expressions a_{mn} that contain $\bar{\omega}$ to the chosen order (see equations (15) for $\bar{\omega}$ to the third power).

[†]Although the derivation of these potentials in NACA TN 2064 led to correct results, the procedure followed therein is based on erroneous arguments. The present procedure is correct and general.

If the distribution function D_n (equation (24)) is introduced into equation (20) and the resulting equation is integrated over the appropriate region of the rectangle (fig. 2(b)), it is found that in the limit as $z \rightarrow 0$ terms of the type given in expression (25) do not contribute to the resulting potential, but they do contribute to the resulting vertical velocity. Therefore, since it has been shown that the doublet-type terms, taken alone, satisfy the condition of tangential flow, the distribution of vertical velocity would now contain extraneous terms that need to be canceled. This canceling may be achieved by what is essentially an iterative process: the functions D_n (equation (24)) are used with terms in equation (20) that have the form given in expression (25) to calculate the velocity that is to be canceled; then, terms involving $1/R$ that may be individually weighted and which, of course, must satisfy the differential equation to the order of $\bar{\omega}$ to which the velocity potential is to be derived are added to equation (20); finally, by making use of equation (22), weight or distribution functions for these additional terms may be determined so as to cancel the extraneous velocity.

This process is illustrated for ω to the third power as follows:

$$\begin{aligned} \phi_{r_1} = & -\lim_{z \rightarrow 0} \frac{e^{i\omega t}}{\pi} \frac{\partial}{\partial z} \int_r \int W(\xi, \eta) \left[D_0 \left(a_{01} \frac{1}{R} + a_{02} R \right) + \right. \\ & D_1 \xi \left(a_{11} \frac{1}{R} + a_{12} R \right) + D_2 a_{21} \frac{\xi^2}{R} + D_3 a_{31} \frac{\xi^3}{R} + \\ & \left. a_{02} (\xi D_1 - D_2) \frac{\xi^2}{R} + a_{12} \left(\frac{\xi D_2 - D_3}{2} \right) \frac{\xi^2}{R} \right] d\xi d\eta \quad (26) \end{aligned}$$

where it is noted in the integrand that two extra terms have been added to equation (20) to accomplish the desired canceling. Substituting the values of $W(\xi, \eta)$ defined in equations (11), (12), and (13) into equation (26) gives the expression for the velocity potential at the upper surface of the wing

$$\begin{aligned} \phi_{r_1} = & -\frac{1}{\beta\pi} \left(h \left[2F_1 - \left(2i\bar{\omega} + \frac{\bar{\omega}^2 x}{M^2} \right) F_2 - \frac{\beta^2 \bar{\omega}^2}{M^2} F_3 \right] + \right. \\ & V\alpha \left[2F_1 - \left(2i\bar{\omega} + \frac{\bar{\omega}^2}{M^2} x - \frac{i\bar{\omega}^3}{2M^2} x^2 \right) F_2 - \right. \\ & \left. \frac{\beta^2 \bar{\omega}^2}{M^2} F_3 + \frac{i\bar{\omega}^3}{6M^2} (2\beta^2 - 1) F_4 \right] + \alpha \left\{ 2(x - x_0) F_1 - \right. \\ & \left[2 + 2i\bar{\omega}(x - x_0) + \frac{\bar{\omega}^2}{2M^2} (x^2 - 2xx_0) \right] F_2 + \\ & \left. \left[2i\bar{\omega} - \frac{\beta^2 \bar{\omega}^2}{M^2} (x - x_0) \right] F_3 + \frac{\bar{\omega}^2}{2M^2} (2\beta^2 + 1) F_4 \right\} \quad (27) \end{aligned}$$

where the terms are grouped conveniently by the definition of F_n in the following integral:

$$F_n = \int_0^x x^{n-1} \sin^{-1} \sqrt{\frac{\beta y}{x}} dx \quad (n=1, 2, 3, 4) \quad (28)$$

(The functions F_n , given in equation (28), and certain related functions are of particular importance in the remainder of this development. Integrated values of this function for the first few values of n and expressions for related functions needed later in this analysis are given in the appendix.)

Examination of equation (27) shows that along the Mach line $x = \beta y$, separating region T_1 from region N , the expression ϕ_{r_1} reduces to the expression for ϕ_N given in equation (18).

The corresponding potentials for regions T_2 and T_3 can now be obtained. The potential ϕ_{r_2} is obtained from equation (27) by merely substituting $2s - y$ for y in equation (28) so that

$$G_n = \int_0^x x^{n-1} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}} dx \quad (n=1, 2, 3, 4) \quad (29)$$

The potential in region T_3 (that is for $1 \leq A\beta < 2$) is a simple superposition of the potentials for regions N , T_1 , and T_2 , as in the steady case (see, for example, reference 5), and may be written as

$$\phi_{r_3} = \phi_{r_1} + \phi_{r_2} - \phi_N \quad (30)$$

FORCES AND MOMENTS

Two types of force and moment coefficients are derived. First, in order to gain some insight into the over-all effect of aspect ratio on the forces and moments, expressions for total force and moment coefficients are derived. Then, in order to present expressions that are more suitable for use in flutter calculations, expressions for section force and moment coefficients for any station along the span are derived.

Total forces and moments.—The local pressure difference between the upper and lower surfaces on the wing may be written

$$\Delta p = -2\rho \left(\frac{\partial \phi}{\partial t} + V \frac{\partial \phi}{\partial x} \right) \quad (31)$$

In order to derive expressions for total forces and total moments, it is only necessary to consider the velocity potential in two regions—either regions N and T_1 or regions N and T_2 . Therefore the expression for the total force, positive downward, on the wing may be written as

$$\bar{P} = -2 \int_N \int \Delta p_N dy dx - 2 \int_{T_1} \int \Delta p_{r_1} dy dx \quad (32)$$

where Δp_N is to be calculated from equation (18) and the integrations in the first term are to be extended over the shaded portion of region N shown in figure 2 (a), and where Δp_{r_1} is to be calculated from equation (27) and the integrations in the second term are to be extended over region T_1 . (The integrations in the first term are simple and may be performed by inspection. Those in the second term may be readily performed by making use of the relations given in the appendix.)

After the indicated integrations have been performed and all position coordinates involved have been referred to the chord $2b$ (but the original coordinate symbols maintained), the results can be written as

$$\bar{P} = -8\rho b^2 V^2 k^2 A e^{i\omega t} \left[\frac{h_0}{b} (\bar{L}_1 + i\bar{L}_2) + \alpha_0 (\bar{L}_3 + i\bar{L}_4) \right] \quad (33)$$

where the reduced frequency k is related to ω and $\bar{\omega}$ by the relations

$$k = \frac{b\omega}{V} = \frac{b\beta^2}{M^2} \bar{\omega} \quad (34)$$

and where

$$\bar{L}_1 = \frac{1}{3\beta^4} \left(3\beta - \frac{2+\beta^2}{A} \right) \quad (35a)$$

$$\bar{L}_2 = \frac{1}{\beta k} - \frac{M^2 k}{\beta^5} - \frac{1}{2A} \left[\frac{1}{\beta^2 k} - \frac{M^2 k}{3\beta^6} (4+\beta^2) \right] \quad (35b)$$

$$\bar{L}_3 = \frac{1}{\beta k^2} - \frac{1}{3\beta^5} (3+\beta^2+6\beta^2 x_0) - \frac{1}{2A} \left\{ \frac{1}{\beta^2 k^2} - \frac{1}{3\beta^6} [(3\beta^2+4)+4\beta^2 x_0(2+\beta^2)] \right\} \quad (35c)$$

$$\bar{L}_4 = \frac{1}{\beta^3 k} (\beta^2 - 1 - 2\beta^2 x_0) + \frac{M^2 k}{6\beta^7} (5+\beta^2+12\beta^2 x_0) + \frac{1}{3A} \left[\frac{1}{\beta^4 k} (2+3\beta^2 x_0) - \frac{M^2 k}{5\beta^8} (8+4\beta^2+20\beta^2 x_0+5\beta^4 x_0) \right] \quad (35d)$$

The quantities $\bar{L}_i$ ($i=1, 2, 3, 4$) are the in-phase and out-of-phase components of the total force coefficients, $\bar{L}_1$ and $\bar{L}_3$ being the in-phase and $\bar{L}_2$ and $\bar{L}_4$ being the out-of-phase components. It will be noted that $\bar{L}_1$ and $\bar{L}_2$ are associated only with vertical translations of the wing and are independent of axis-of-rotation location x_0 . The components $\bar{L}_3$ and $\bar{L}_4$ are associated with angular position and rotation of the wing about any axis $x=x_0$ and depend partly on the location of x_0 .

The total moment, positive clockwise, on the wing about the arbitrary axis of rotation $x=x_0$ is

$$\bar{M}_a = -2 \int_N \int (x-x_0) \Delta p_N dy dx - 2 \int_{T_1} \int (x-x_0) \Delta p_{T_1} dy dx \quad (36)$$

If steps similar to those required to obtain equation (33) are performed, there is obtained

$$\bar{M}_a = -8\rho b^3 V^2 k^2 A e^{i\omega t} \left[\frac{h_0}{b} (\bar{M}_1 + i\bar{M}_2) + \alpha_0 (\bar{M}_3 + i\bar{M}_4) \right] \quad (37)$$

where

$$\bar{M}_1 = \frac{2}{3\beta^3} (2-3x_0) - \frac{1}{6A\beta^4} [3\beta^2+1-4x_0(2+\beta^2)] \quad (38a)$$

$$\bar{M}_2 = \frac{1}{\beta k} (1-2x_0) - \frac{M^2 k}{2\beta^5} (3-4x_0) - \frac{1}{3A} \left\{ \frac{1}{\beta^2 k} (2-3x_0) - \frac{M^2 k}{5\beta^6} [4(\beta^2+4)(4-5x_0)] \right\} \quad (38b)$$

$$\bar{M}_3 = \frac{1}{\beta k^2} (1-2x_0) - \frac{1}{2\beta^5} [3+\beta^2+4x_0(\beta^2-1)-8\beta^2 x_0^2] - \frac{1}{3A} \left\{ \frac{1}{\beta^2 k^2} (2-3x_0) - \frac{1}{5\beta^6} [4(4+3\beta^2)+5x_0(3\beta^4+3\beta^2-4)-20\beta^2 x_0^2(\beta^2+2)] \right\} \quad (38c)$$

$$\bar{M}_4 = \frac{2}{3\beta^3 k} [2(\beta^2-1)-3x_0(2\beta^2-1)+6\beta^2 x_0^2] + \frac{M^2 k}{15\beta^7} (20+4\beta^2-25x_0+40\beta^2 x_0-60\beta^2 x_0^2) + \frac{1}{3A} \left\{ \frac{1}{\beta^4 k} [3+4x_0(\beta^2-1)-6\beta^2 x_0^2] - \frac{M^2 k}{15\beta^8} [20(2+\beta^2)-24x_0(2-3\beta^2-\beta^4)-30\beta^2 x_0^2(4+\beta^2)] \right\} \quad (38d)$$

The quantities $\bar{M}_1$ and $\bar{M}_2$ are, respectively, the in-phase and out-of-phase components of total moment coefficients about the axis $x=x_0$ associated with vertical translations of the wing; $\bar{M}_3$ and $\bar{M}_4$ are the corresponding components due to angular position and rotation of the wing about $x=x_0$.

It is of interest to note in equations (35) and (38) that the components $\bar{L}_1$ and $\bar{M}_1$ do not involve the reduced frequency k . The effect of frequency on these two components comes from terms involving the frequency to the fourth and higher powers; but for values of k thought likely to be encountered in supersonic flutter ($k < 0.1$), the contribution of these higher-power terms to any of the components in equations (35) and (38) is, for the most part, negligible.

Section forces and moments.—The section forces and moments at any spanwise station are derived by integrating the pressure difference along the chord for the forces and the pressure difference multiplied by a moment arm for the moments. Since the distribution over the entire wing is symmetrical with regard to the midspan section, it is only necessary to derive expressions for the forces and moments at any station of the half-span adjacent to the origin. (See figs. 1, 2, and 3.)

Under the restrictions previously stipulated, two cases that can arise are considered (see fig. 3): (1) the Mach lines from the tips do not intersect on the wing (or $A\beta > 2$), and (2) the Mach lines intersect on the wing but the Mach line from one tip does not intersect the opposite tip ahead of the trailing edge (or $1 \leq A\beta \leq 2$). Only the final forms of the section force and moment equations are given. These forms are easily calculated by deriving the pressure difference for the different regions from the appropriate velocity potential, making use of figure 3 to determine the limits of

integration for the regions involved, and using the relations given in the appendix to carry out the more troublesome integrations. The integrated expression for any region can then be reduced to the forms

$$P = -4\rho b V^2 k^2 e^{i\omega t} \left[\frac{h_0}{b} (L_1 + iL_2) + \alpha_0 (L_3 + iL_4) \right] \quad (39)$$

and

$$M_a = -4\rho b^2 V^2 k^2 e^{i\omega t} \left[\frac{h_0}{b} (M_1 + iM_2) + \alpha_0 (M_3 + iM_4) \right] \quad (40)$$

where the position coordinates are referred to the chord length $2b$.

The components of force and moment coefficients for the half-span adjacent to the origin are as follows:

Case 1 (see fig. 3(a)): For any section between the tip and the point where the Mach line intersects the trailing edge, or where $0 < y < \frac{1}{\beta}$, the components of section force coefficients are

$$L_1 = -\frac{4}{\beta\pi} \left(\bar{F}_1 - \frac{1+2\beta^2}{\beta^2} \bar{F}_2 \right) \quad (41a)$$

$$L_2 = \frac{4}{\beta\pi} \left\{ \frac{1}{2k} \bar{F}_1 + \frac{M^2 k}{\beta^4} [(2\beta^2 - 1)\bar{F}_2 - 3\beta^2 \bar{F}_3] \right\} \quad (41b)$$

$$L_3 = \frac{4}{\beta\pi} \left[\frac{1}{2k^2} \bar{F}_1 - (1 - 2x_0) \bar{F}_1 + \frac{6\beta^4 + 3\beta^2 - 1}{\beta^4} \bar{F}_2 - \frac{2(2\beta^2 + 1)x_0}{\beta^2} \bar{F}_2 - \frac{6\beta^2 + 5}{\beta^2} \bar{F}_3 \right] \quad (41c)$$

$$L_4 = \frac{4}{\beta\pi} \left\{ \frac{1}{k} \left[(2 - x_0) \bar{F}_1 - \frac{3\beta^2 + 1}{\beta^2} \bar{F}_2 \right] + \frac{M^2 k}{3\beta^6} [3(1 - \beta^2 + 2\beta^4 + 2\beta^2 x_0 - 4\beta^4 x_0) \bar{F}_2 - 6\beta^4 (4 - 3x_0) \bar{F}_3 - (1 - 7\beta^2 - 20\beta^4) \bar{F}_4] \right\} \quad (41d)$$

where $\bar{F}_n$ ($n=1, 2, 3, 4$), given in the appendix, is obtained from F_n (equation (28)) when $x=2b$. For any section between the point where the Mach line intersects the trailing edge and the midspan, or where $\frac{1}{\beta} \leq y \leq \frac{A}{2}$, the components of section forces are:

$$\left. \begin{aligned} L_1 &= \frac{1}{\beta^3} \\ L_2 &= \frac{1}{\beta k} - \frac{M^2 k}{\beta^5} \\ L_3 &= \frac{1}{\beta k^2} - \frac{1}{3\beta^5} [(3 + \beta^2) + 6\beta^2 x_0] \\ L_4 &= \frac{1}{\beta^3 k} [(\beta^2 - 1) - 2\beta^2 x_0] + \frac{M^2 k}{6\beta^7} (5 + \beta^2 + 12\beta^2 x_0) \end{aligned} \right\} \quad (42)$$

As a check on the results in equations (41) and (42) the expressions in equations (41) reduce to those in equations (42) when $y = \frac{1}{\beta}$.

(a) Mach lines from tips do not intersect on wing.

(b) Mach lines from tips intersect on wing but Mach line from one tip does not intersect opposite tip.

(c) Mach lines from tips intersect on wing and Mach line from one tip intersects opposite tip at trailing edge.

FIGURE 3.—Sketch illustrating different Mach line locations accounted for in analysis.

The components of section moment coefficients for case 1 are as follows:

For $0 < y < \frac{1}{\beta}$,

$$M_1 = -\frac{4}{\beta\pi} \left[(1 - 2x_0) \bar{F}_1 + 2x_0 \frac{2\beta^2 + 1}{\beta^2} \bar{F}_2 - \frac{3\beta^2 + 2}{\beta^2} \bar{F}_3 \right] \quad (43a)$$

$$M_2 = \frac{4}{\beta\pi} \left\{ \frac{1}{k} (\bar{F}_2 - x_0 \bar{F}_1) + \frac{M^2 k}{\beta^2} \left[\frac{(2\beta^2 - 1)(1 - 2x_0)}{\beta^2} \bar{F}_2 + 6x_0 \bar{F}_3 - \frac{4\beta^2 + 1}{\beta^2} \bar{F}_4 \right] \right\} \quad (43b)$$

$$M_3 = \frac{4}{\beta\pi} \left[\frac{1}{k^2} (\bar{F}_2 - x_0 \bar{F}_1) - \frac{4(1-3x_0+3x_0^2)}{3} \bar{F}_1 + \frac{(6\beta^4+3\beta^2-1)(1-2x_0)+4\beta^2x_0^2(1+2\beta^2)}{\beta^4} \bar{F}_2 + \frac{6(1+\beta^2)}{\beta^2} x_0 \bar{F}_3 - \frac{20\beta^4+21\beta^2+3}{3\beta^4} \bar{F}_4 \right] \quad (43c)$$

$$M_4 = \frac{4}{\beta\pi} \left(\frac{2}{k} \left[(1-x_0)^2 \bar{F}_1 + \frac{2\beta^2+1}{\beta^2} x_0 \bar{F}_2 - \frac{2\beta^2+1}{\beta^2} \bar{F}_2 \right] + \frac{4M^2k}{\beta^2} \left\{ \frac{1}{6\beta^4} [(4\beta^4-2\beta^2+1)(1-3x_0+3x_0^2)+1-3x_0^2] \bar{F}_2 - (2-4x_0+3x_0^2) \bar{F}_3 - \frac{x_0}{6\beta^4} (8\beta^4+4\beta^2-1) \bar{F}_4 + \frac{1}{3\beta^2} (5\beta^2+3) \bar{F}_5 \right\} \right) \quad (43d)$$

and for $\frac{1}{\beta} \leq y \leq \frac{A}{2}$,

$$\left. \begin{aligned} M_1 &= \frac{2}{3\beta^3} (2-3x_0) \\ M_2 &= \frac{1}{\beta k} (1-2x_0) - \frac{M^2k}{2\beta^5} (3-4x_0) \\ M_3 &= \frac{1}{\beta k^2} (1-2x_0) - \frac{1}{2\beta^5} (3+\beta^2-4x_0+4\beta^2x_0-8\beta^2x_0^2) \\ M_4 &= \frac{2}{3\beta^3k} [2(\beta^2-1)-3x_0(2\beta^2-1)+6\beta^2x_0^2] + \frac{M^2k}{15\beta^7} [4(5+\beta^2)+5x_0(8\beta^2-5)-60\beta^2x_0^2] \end{aligned} \right\} \quad (44)$$

The expressions in equations (43) reduce to those in equations (44) when $y = \frac{1}{\beta}$. The expressions in equations (42) and (44) correspond to the more exact two-dimensional components of force and moment coefficients derived in reference 4. For values of $k < 0.1$ these expressions yield, for the most part, values that are in good agreement with those that may be calculated from the tables in reference 4.

Case 2 (see fig. 3 (b)): For any section between the tip at $y=0$ and the point where the Mach line from the tip at $y=2s$ intersects the trailing edge (or where $0 < y \leq A - \frac{1}{\beta}$), the components of section force coefficients are given by equations (41) and the components of section moment coefficients, by equation (43). For any section between the point where the Mach line from the tip at $y=2s$ intersects the trailing edge and the midspan (or where $A - \frac{1}{\beta} < y \leq \frac{A}{2}$), the components of section force coefficients are

$$L_1 = - \left\{ \frac{4}{\beta\pi} \left[(\bar{F}_1 + \bar{G}_1) - \frac{1+2\beta^2}{\beta^2} (\bar{F}_2 + \bar{G}_2) \right] + \frac{1}{\beta^3} \right\} \quad (45a)$$

$$L_2 = \frac{4}{\beta\pi} \left\{ \frac{1}{2k} (\bar{F}_1 + \bar{G}_1) + \frac{M^2k}{\beta^4} [(2\beta^2-1)(\bar{F}_2 + \bar{G}_2) - 3\beta^2(\bar{F}_3 + \bar{G}_3)] - \left(\frac{1}{\beta k} - \frac{M^2k}{\beta^5} \right) \right\} \quad (45b)$$

$$L_3 = \frac{4}{\beta\pi} \left[\frac{1}{2k^2} (\bar{F}_1 + \bar{G}_1) - 2(1-2x_0)(\bar{F}_1 + \bar{G}_1) + \frac{6\beta^4+3\beta^2-1}{\beta^4} (\bar{F}_2 + \bar{G}_2) - \frac{2(2\beta^2+1)x_0}{\beta^2} (\bar{F}_2 + \bar{G}_2) - \frac{6\beta^2+5}{\beta^2} (\bar{F}_3 + \bar{G}_3) \right] - \left\{ \frac{1}{\beta k^2} - \frac{1}{3\beta^5} [(3+\beta^2)+6\beta^2x_0] \right\} \quad (45c)$$

$$L_4 = \frac{4}{\beta\pi} \left\{ \frac{1}{k} \left[(2-x_0)(\bar{F}_1 + \bar{G}_1) - \frac{3\beta^2+1}{\beta^2} (\bar{F}_2 + \bar{G}_2) \right] + \frac{M^2k}{3\beta^6} [3(1-\beta^2+2\beta^4+2\beta^2x_0-4\beta^4x_0)(\bar{F}_2 + \bar{G}_2) - 6\beta^4(4-3x_0)(\bar{F}_3 + \bar{G}_3) - (1-7\beta^2-20\beta^4)(\bar{F}_4 + \bar{G}_4)] \right\} - \left\{ \frac{1}{\beta^3k} [(\beta^2-1)-2\beta^2x_0] + \frac{M^2k}{6\beta^7} (5+\beta^2+12\beta^2x_0) \right\} \quad (45d)$$

where $\bar{G}_n$ ($n=1, 2, 3, 4$), given in the appendix, is obtained from G_n (equation (29)) when $x=2b$. The corresponding components of section moment coefficients are

$$M_1 = - \left\{ \frac{4}{\beta\pi} \left[(1-2x_0)(\bar{F}_1 + \bar{G}_1) + \frac{2x_0(2\beta^2+1)}{\beta^2} (\bar{F}_2 + \bar{G}_2) \right] - \frac{3\beta^2+1}{\beta^2} (\bar{F}_3 + \bar{G}_3) + \frac{2}{3\beta^3} (2-3x_0) \right\} \quad (46a)$$

$$M_2 = \frac{4}{\beta\pi} \left\{ \frac{1}{k} [(\bar{F}_2 + \bar{G}_2) - x_0(\bar{F}_1 + \bar{G}_1)] + \frac{M^2k}{\beta^2} \left[\frac{(2\beta^2-1)(1-2x_0)}{\beta^2} (\bar{F}_2 + \bar{G}_2) + 6x_0(\bar{F}_3 + \bar{G}_3) - \frac{4\beta^2+1}{\beta^2} (\bar{F}_4 + \bar{G}_4) \right] \right\} - \left[\frac{1}{\beta k} (1-2x_0) - \frac{M^2k}{2\beta^5} (3-4x_0) \right] \quad (46b)$$

$$M_3 = \frac{4}{\beta\pi} \left\{ \frac{1}{k^2} [(\bar{F}_2 + \bar{G}_2) - x_0(\bar{F}_1 + \bar{G}_1)] - 4 \frac{1-3x_0+3x_0^2}{3} (\bar{F}_1 + \bar{G}_1) + \frac{(6\beta^4+3\beta^2-1)(1-2x_0)+4\beta^2x_0^2(1+2\beta^2)}{\beta^4} (\bar{F}_2 + \bar{G}_2) + \frac{6x_0(1+\beta^2)}{\beta^2} (\bar{F}_3 + \bar{G}_3) - \frac{20\beta^4+21\beta^2+3}{3\beta^4} (\bar{F}_4 + \bar{G}_4) \right\} - \left\{ \frac{1}{\beta k^2} (1-2x_0) - \frac{1}{2\beta^5} [(3+\beta^2)-4x_0(1-\beta^2)-8\beta^2x_0^2] \right\} \quad (46c)$$

$$M_4 = \frac{4}{\beta\pi} \left\{ \frac{2}{k} \left[(1-x_0)(\bar{F}_1 + \bar{G}_1) + \frac{2\beta^2+1}{\beta^2} x_0(\bar{F}_2 + \bar{G}_2) - \frac{2\beta^2+1}{\beta^2} (\bar{F}_3 + \bar{G}_3) \right] + \frac{4M^2k}{\beta^2} \left\{ \frac{1}{6\beta^4} [(4\beta^4-2\beta^2+1)(1-3x_0+3x_0^2)+1-3x_0^2](\bar{F}_2 + \bar{G}_2) - (2-4x_0+3x_0^2)(\bar{F}_3 + \bar{G}_3) - \frac{x_0}{6\beta^4} (8\beta^4+4\beta^2-1)(\bar{F}_4 + \bar{G}_4) + \frac{1}{3\beta^2} (5\beta^2+3)(\bar{F}_5 + \bar{G}_5) \right\} \right\} - \left\{ \frac{2}{3\beta^3k} [2(\beta^2-1)-3x_0(2\beta^2-1)+6\beta^2x_0^2] + \frac{M^2k}{15\beta^7} [4(5+\beta^2)+5x_0(8\beta^2-5)-60\beta^2x_0^2] \right\} \quad (46d)$$

FIGURE 4.—Components of total force coefficients as functions of M^2 for $x_0=0.4$, $k=0.02$, and various values of A .

For the limiting condition of case 2—that is, when the Mach line from one tip intersects the opposite tip at the trailing edge, or $A=1/\beta$ (see fig. 3(c))—the components of section force coefficients are given by equations (45) and the corresponding components of moment coefficients, by equations (46).

SOME PARTICULAR CALCULATIONS AND DISCUSSIONS

From the expressions for total force and moment coefficients (equations (35) and (38), respectively) the over-all effect of aspect ratio on the magnitude of the forces and moments can be calculated for particular values of the parameters M , k , x_0 , and A . Examination of these equations shows that varying some of the parameters might cause some terms in the equations to vanish and to change sign. For example, if x_0 is continuously increased from some value less than $1/2$ to some value greater than $1/2$, the first terms in the expressions for $\bar{M}_2$ and $\bar{M}_3$ vanish at $x_0=1/2$ and

FIGURE 4.—Continued.

change sign when x_0 becomes greater than $1/2$. In particular, decreasing the aspect ratio decreases the components of force and moment coefficients $\bar{L}_1$, $\bar{L}_2$, $\bar{L}_3$, $\bar{M}_1$, $\bar{M}_2$, and $\bar{M}_3$ but increases the two important components $\bar{L}_4$ and $\bar{M}_4$.

Although the effect of aspect ratio may change considerably with only a small change in any one (or more) of the parameters M , k , and x_0 , some insight into what the over-all effect might be can be gained from calculations of all the components of total force and moment coefficients for various values of M and A and fixed values of the parameters k and x_0 . Results of such a set of calculations are presented in figures 4 to 7.

In figures 4 and 5 the components of total force and moment coefficients for various values of A and for $x_0=0.4$ and $k=0.02$ are plotted as functions of M^2 . The curves in these figures calculated for infinite aspect ratio correspond to the two-dimensional results of reference 4. The dashed curves represent calculations for aspect ratio and Mach number combinations that cause the Mach lines from one tip to intersect the opposite tip at the trailing edge so that

FIGURE 4.—Continued.

along the dashed curves the aspect ratio is not constant but varies with M^2 according to the previously given expression

$$A = \frac{1}{\beta} = \frac{1}{\sqrt{M^2 - 1}}$$

The difference, at any value of M^2 , between the dashed curves and the curves corresponding to infinite aspect ratio in figures 4 and 5 is, therefore, for the chosen values of k and x_0 , the maximum effect of aspect ratio on the components of total force and moment coefficients for a rectangular wing under the restrictions of the foregoing analysis. It will be noted in figures 4 and 5 that, when the aspect ratio is small, the deviation of the three-dimensional results from two-dimensional results may be quite large.

In figures 6 and 7 the components of the total force and moment coefficients are plotted as functions of aspect ratio for $x_0=0.4$, $k=0.02$, and some particular values of M . It will be noted in these figures that all the components of force and moment coefficients undergo rapid changes with

FIGURE 4.—Concluded.

respect to varying aspect ratio when A becomes less than 4 or 5. It may be remarked that the directions of the changes with respect to aspect ratio appear to be such that they would have favorable effects on the flutter characteristics of a wing.

The spanwise distribution of the components of section force and moment coefficients computed from equations (41) to (44) for $A=4$, $x_0=0.4$, $k=0.02$, and $M=2$ are plotted in figures 8 and 9. The portions of the curves in these figures corresponding to values of y in the range $\frac{1}{\beta} \leq y \leq A - \frac{1}{\beta}$ are the two-dimensional values, and the effect of aspect ratio may be noted in the tip regions, $0 \leq y \leq \frac{1}{\beta}$ and $A - \frac{1}{\beta} \leq y \leq A$, as deviations from these two-dimensional values.

In conclusion, it may be stated that, in regard to the effect of aspect ratio on supersonic flutter, an important item that has not been discussed herein but can be studied for any particular case with the aid of equations (33) and (36) is the change in center of pressure, associated with prescribed motions of the wing, with change in aspect ratio. An investigation to find the effect that thickness might have on the center-of-pressure location is also needed. An extension of the foregoing analysis to include the effect of an aileron as an additional degree of freedom would follow in a straightforward manner.

SOME INTEGRATED VALUES OF $F_n, G_n, \bar{F}_n, \bar{G}_n$, AND OTHER RELATED FUNCTIONS

Values of F_n and G_n .—The values of the functions F_n (equation (28)) and G_n (equation (29)) for the first few values of n are as follows:

$$F_n = \int_0^x x^{n-1} \sin^{-1} \sqrt{\beta y/x} dx \quad (n=1, 2, 3, \dots)$$

$$F_1 = \sqrt{\beta y(x-\beta y)} + x \sin^{-1} \sqrt{\beta y/x}$$

$$F_2 = \frac{x+2\beta y}{6} \sqrt{\beta y(x-\beta y)} + \frac{x^2}{2} \sin^{-1} \sqrt{\beta y/x}$$

$$F_3 = \frac{3x^2+4\beta yx+8\beta^2 y^2}{45} \sqrt{\beta y(x-\beta y)} + \frac{x^3}{3} \sin^{-1} \sqrt{\beta y/x}$$

$$F_4 = \frac{5x^3+6\beta yx^2+8\beta^2 y^2x+16\beta^3 y^3}{140} \sqrt{\beta y(x-\beta y)} + \frac{x^4}{4} \sin^{-1} \sqrt{\beta y/x}$$

$$F_5 = \frac{35x^4+40\beta yx^3+48\beta^2 y^2x^2+64\beta^3 y^3x+128\beta^4 y^4}{1575} \sqrt{\beta y(x-\beta y)} + \frac{x^5}{5} \sin^{-1} \sqrt{\beta y/x}$$

$$G_n = \int_0^x x^{n-1} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}} dx \quad (n=1, 2, 3, \dots)$$

$$G_1 = \sqrt{\beta(2s-y)[x-\beta(2s-y)]} + x \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}}$$

$$G_2 = \frac{x+2\beta(2s-y)}{6} \sqrt{\beta(2s-y)[x-\beta(2s-y)]} + \frac{x^2}{2} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}}$$

$$G_3 = \frac{3x^2+4\beta x(2s-y)+8\beta^2(2s-y)^2}{45} \sqrt{\beta(2s-y)[x-\beta(2s-y)]} + \frac{x^3}{3} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}}$$

$$G_4 = \frac{5x^3+6x^2\beta(2s-y)+8x\beta^2(2s-y)^2+16\beta^3(2s-y)^3}{140} \sqrt{\beta(2s-y)[x-\beta(2s-y)]} + \frac{x^4}{4} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}}$$

$$G_5 = \frac{35x^4+40x^3\beta(2s-y)+48x^2\beta^2(2s-y)^2+64x\beta^3(2s-y)^3+128\beta^4(2s-y)^4}{1575} \sqrt{\beta(2s-y)[x-\beta(2s-y)]} + \frac{x^5}{5} \sin^{-1} \sqrt{\frac{\beta(2s-y)}{x}}$$

Values of $\bar{F}_n$ and $\bar{G}_n$.—The following expressions define the functions $\bar{F}_n$ and $\bar{G}_n$ appearing in equations (41), (43), (45), and (46) in the body of the report. In these expressions the variable y has been referred to the chord $2b$; that is $y/2b$ has been replaced by y and in the expressions for $\bar{G}_n$ the ratio s/b has been replaced by A :

$$\bar{F}_1 = \sqrt{\beta y(1-\beta y)} + \sin^{-1} \sqrt{\beta y}$$

$$\bar{F}_2 = \frac{1+2\beta y}{6} \sqrt{\beta y(1-\beta y)} + \frac{1}{2} \sin^{-1} \sqrt{\beta y}$$

$$\bar{F}_3 = \frac{3+4\beta y+8\beta^2 y^2}{45} \sqrt{\beta y(1-\beta y)} + \frac{1}{3} \sin^{-1} \sqrt{\beta y}$$

$$\bar{F}_4 = \frac{5+6\beta y+8\beta^2 y^2+16\beta^3 y^3}{140} \sqrt{\beta y(1-\beta y)} + \frac{1}{4} \sin^{-1} \sqrt{\beta y}$$

$$\bar{F}_5 = \frac{35+40\beta y+48\beta^2 y^2+64\beta^3 y^3+128\beta^4 y^4}{1575} \sqrt{\beta y(1-\beta y)} + \frac{1}{5} \sin^{-1} \sqrt{\beta y}$$

$$\bar{\bar{G}}_1 = \sqrt{\beta(A-y)[1-\beta(A-y)]} + \sin^{-1} \sqrt{\beta(A-y)}$$

$$\bar{\bar{G}}_2 = \frac{1+2\beta(A-y)}{6} \sqrt{\beta(A-y)[1-\beta(A-y)]} + \frac{1}{2} \sin^{-1} \sqrt{\beta(A-y)}$$

$$\bar{\bar{G}}_3 = \frac{3+4\beta(A-y)+8\beta^2(A-y)^2}{45} \sqrt{\beta(A-y)[1-\beta(A-y)]} + \frac{1}{3} \sin^{-1} \sqrt{\beta(A-y)}$$

$$\bar{\bar{G}}_4 = \frac{5+6\beta(A-y)+8\beta^2(A-y)^2+16\beta^3(A-y)^3}{140} \sqrt{\beta(A-y)[1-\beta(A-y)]} + \frac{1}{4} \sin^{-1} \sqrt{\beta(A-y)}$$

$$\bar{\bar{G}}_5 = \frac{35+40\beta(A-y)+48\beta^2(A-y)^2+64\beta^3(A-y)^3+128\beta^4(A-y)^4}{1575} \sqrt{\beta(A-y)[1-\beta(A-y)]} + \frac{1}{5} \sin^{-1} \sqrt{\beta(A-y)}$$

Some integral relations for F_n and G_n .—Some pertinent integral relations for F_n are as follows:

$$\int_0^x F_n dx = x F_n - F_{n+1}$$

$$\int_0^x x F_n dx = \frac{1}{2} (x^2 F_n - F_{n+2})$$

$$\int_0^x x^2 F_n dx = \frac{1}{3} (x^3 F_n - F_{n+3})$$

$$\int_0^x (x-x_0) F_n dx = \frac{x^2-2xx_0}{2} F_n + x_0 F_{n+1} - \frac{1}{2} F_{n+2}$$

$$\int_0^x (x-x_0)^2 F_n dx = \frac{x^3-3x_0x^2+3x_0^2x}{3} F_n - x_0^2 F_{n+1} + x_0 F_{n+2} - \frac{1}{3} F_{n+3}$$

Corresponding integral relations for G_n may be obtained from these relations by simply replacing F by G .

Integral relations for $\bar{\bar{F}}_n$.—Integral relations for $\bar{\bar{F}}_n$ that may be used in calculating total forces and moments from sectional forces and moments are as follows:

$$2b \int_0^{1/\beta} \bar{\bar{F}}_1 dy = \frac{3b\pi}{4\beta}$$

$$2b \int_0^{1/\beta} \bar{\bar{F}}_2 dy = \frac{b\pi}{3\beta}$$

$$2b \int_0^{1/\beta} \bar{\bar{F}}_3 dy = \frac{5b\pi}{24\beta}$$

$$2b \int_0^{1/\beta} \bar{\bar{F}}_4 dy = \frac{3b\pi}{20\beta}$$

$$2b \int_0^{1/\beta} \bar{\bar{F}}_5 dy = \frac{7b\pi}{60\beta}$$

REPORT 1029

COMPRESSIVE STRENGTH OF FLANGES¹

By ELBRIDGE Z. STOWELL

SUMMARY

The maximum compressive stress carried by a hinged flange is computed from a deformation theory of plasticity combined with the theory for finite deflections for this structure. The computed stresses agree well with those found experimentally. Empirical observation indicates that the results will also apply fairly well to the more commonly used flanges which are not hinged.

INTRODUCTION

Ordinarily the ability of columns and plates to carry additional load does not entirely cease when they buckle. If the load is increased sufficiently beyond the buckling load, they will ultimately refuse to carry more load, with subsequent permanent distortion. In the case of columns, the maximum load is not far above the buckling load (see reference 1); in the case of plates, there may be a considerable spread between the two loads.

The first essential requirement for the solution of the problem of maximum load is the existence of a finite-deflection theory for the behavior of the structure. Maximum load always occurs at some finite deflection or distortion beyond the buckling load. The problem of the load for a given distortion is thus nonlinear even without the introduction of plasticity. Few such solutions exist for post-buckling behavior of structures even in the elastic region.

The second essential requirement for computation of maximum load is the ability to describe the nonlinear behavior of the structure that results from plasticity of the material. Neither columns nor plates would ever possess a maximum load in compression, if the material of which the structure was made obeyed Hooke's law at all times, although they might be tremendously distorted. In such a structure it would always be possible to add still another increment of load, which would result in still another increment of distortion. The question of a maximum load must therefore be directly linked with the failure of the material to obey Hooke's law—that is, with the plasticity of the material and the nonlinear behavior of the structure which results from that plasticity.

For the calculation of the maximum load carried by a buckled structure, these two essential but difficult requirements must be met. This report treats the maximum compressive strength of a simple plate structure for which the effects of both types of nonlinearity can be found—that is, the compressed flange hinged along one side edge.

The maximum load carried by a long hinged flange is computed as follows: The strain distribution across the flange at any angle of twist is found from knowledge of nonlinearity due to finite deflection. This elastic strain distribution is assumed to persist into the plastic region. This strain distribution is transformed, with the aid of knowledge of nonlinearity due to plasticity, into a stress distribution by means of some appropriate stress-strain relation. The load carried by the flange at the particular twist is then obtained by integrating the stress distribution across the flange. The load is then investigated to see if it has a maximum value as the twist increases; the maximum load should correspond with the experimentally observed maximum load.

Experimental data on the behavior of hinged flanges have been obtained in the Langley Structures Research Division by the methods of reference 2. These data are used in the present report for comparison with theoretical relations.

The theoretical treatment of the behavior of a hinged flange commences in the next section with a discussion of the effects due to finite deflections. Details of the theoretical calculations are presented in two appendixes.

NONLINEAR BEHAVIOR DUE TO FINITE DEFLECTION

Theoretical strain relations.—A flange of length L , width b , and thickness t is shown in figure 1 together with the coordinate system. The flange is hinged along the line $z=0$ and has a free edge along the line $z=b$. Compression is applied longitudinally.

The load is applied uniformly at first. The theory of appendix A shows that, for strains below a certain critical strain ϵ_{cr} , the flange will shorten without twisting. The critical strain ϵ_{cr} at which twisting begins is shown to be

$$\epsilon_{cr} = \frac{(t/b)^2}{2(1+\mu)} + \frac{1}{3} \left(\frac{\pi t}{L} \right)^2 \quad (1)$$

where μ is Poisson's ratio.

As the load is increased beyond that required to start twisting, both the middle-surface strain and the stress distribution across the flange width become nonuniform, larger than the average at the hinge, less than the average at the free edge. The middle-surface strain at any point (x, z) of the flange is shown by the theory of appendix A to be

$$\epsilon_z = \frac{(t/b)^2}{2(1+\mu)} + \frac{m^2}{12} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \left(1 - 3 \frac{z^2}{b^2} \right) \text{sn}^2 \left(\frac{4Kx}{L} \right) \quad (2a)$$

¹ Supersedes NACA TN 2020, "Compressive Strength of Flanges" by Elbridge Z. Stowell, 1950.

in which k^2 is a parameter lying between 0 and 1 which specifies the amount of twist,

$$K = \int_0^{\pi/2} \frac{d\alpha}{\sqrt{1 - k^2 \sin^2 \alpha}}$$

is the complete elliptic integral of the first kind, and

$$m^2 = 12 \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} \right] = K^2(1+k^2) \left(\frac{4t}{L} \right)^2$$

The average middle-surface strain ϵ_{av} in the elastic range is the average stress divided by the elastic modulus E .

(a) Without distortion. (b) With large distortion.
(c) Enlargement of section aac'c.

FIGURE 1.—Cruciform section, consisting of four identical flanges, before and after buckling. Coordinate system is shown on one flange.

Thus, if a value is assigned to k^2 (a certain amount of twist), both the quantities K and m^2 are determined; the strain at any point (x, z) may then be computed.

Equation (2a) may be simplified as shown in appendix A to the following expression which holds over the essentially straight part of the flange:

$$\epsilon_x = \epsilon_{av} + \frac{5}{4} (\epsilon_{av} - \epsilon_{cr}) \left(1 - 3 \frac{z^2}{b^2} \right) \quad (2b)$$

Theory also shows that over most of the flange length (except at the middle and extreme ends) the relation between the middle-surface strain at the hinge ϵ_h , the average middle-surface strain over the width of the flange ϵ_{av} , and the critical strain ϵ_{cr} is

$$\epsilon_{av} = \frac{4}{9} \epsilon_h + \frac{5}{9} \epsilon_{cr} \quad (3)$$

and the rotation ϕ_{max} at the middle of the flange is

$$\phi_{max} = \sqrt{5} \frac{t}{b} \cosh^{-1} \frac{1}{\sqrt{1 - k^2}} \quad (4a)$$

or approximately

$$\phi_{max} = 1.37 \frac{L}{b} \sqrt{\epsilon_{av} - \epsilon_{cr}} - 1.55 \frac{t}{b} \quad (4b)$$

Relations (1), (2), (3), and (4) are susceptible to experimental check, and the following section describes the results of experiments designed to test these relations.

Experimental check of strain relations.—The hinged flange shown in figure 1 was realized experimentally by the cruciform column shown under test in figure 2. The cruciform column has four identical flanges which, if equally loaded, will twist at the same time without restraint to each other; thus the condition of zero restraint against rotation is fulfilled. The columns were all sufficiently short to cause them to buckle by twisting rather than by Euler bending.

The tests included measurement of the stress-strain curve for the material from which the different groups of specimens were made, determination of the buckling and maximum load for each specimen, a study of the strain distribution across the flanges of two specimens, and a measurement of rotation of each specimen at the middle.

Results of the buckling-load measurements and their connection with the stress-strain curves for the specimens were given in reference 3 and are shown in figure 3 of this report where the buckling stress is plotted against the calculated elastic buckling strain. Because the experimental points follow along the stress-strain curve, the proper reduced modulus for pure twisting in the plastic range is concluded to be the secant modulus, which agrees with the theoretical value of reference 3.

The relation between the computed and experimental middle-surface strain distribution over the width of the flange for one specimen at the quarter height for a number of different loads is shown in figure 4. The highest average stresses exceeded the proportional limit of the material. The measured strains for the four flanges were averaged to give the points shown in the figure. These average strains

were somewhat larger than the ratio of average stress to E at the very highest loads where plasticity reduced the average effective modulus. From the experimentally observed average strain across the flange at each load and the critical strain at which buckling began, the corresponding theoretical strain distributions were computed from equation (2b) and are presented as the curves in figure 4. This calculated strain distribution agrees fairly well with that observed experimentally.

FIGURE 2.—Buckling of a cruciform section in compression.

FIGURE 3.—Experimental values of the buckling stress for cruciform-section columns of 24S-T4 extruded aluminum alloy compared with the compressive stress-strain curve for that material.

The relation between average strain, corner strain, and critical strain given by equation (3) was investigated experimentally. From measurement of the strain in two opposite flanges of one buckled specimen, averages were taken to give mean values of ϵ_{av} and ϵ_h . The critical strain ϵ_{cr} was also accurately known. Figure 5 shows the theoretical relation of equation (3) compared with the averaged experimental points. The agreement is good. The strain ϵ_h ceases to be elastic at a value of 0.0025, so that both the curve and the points extend well into the plastic region. The persistence of the agreement between equation (3) and the experimental points up to the highest strains indicates that, even though equation (3) was derived on an elastic basis, it is a good approximation in the plastic region also.

Figure 6 compares the theoretical rotation of three cruciform specimens of widely different lengths with the measured rotations. The ordinate in figure 6 is the shortening δ/L , which is the hinge strain ϵ_h . Rotation was measured by a pointer attached to the flange and moving past a circular scale. Equation (4b) was used to compute the theoretical rotations. The agreement between theory and experiment is good in this case also.

NONLINEAR BEHAVIOR DUE TO PLASTICITY OF THE MATERIAL

The material of the flanges (24S-T aluminum alloy) is defined by the stress-strain curve of figure 3. The figure shows that above 25 ksi the material starts to depart from

FIGURE 4.—Theoretical middle-surface strain distribution across a hinged flange at the quarter-length station along a cruciform-section column compared with experiment. (Experimental values are average for the four flanges; $\epsilon_{cr} = 0.0016$.)

FIGURE 5.—Theoretical middle-surface strain relation between ϵ_{av} , ϵ_h , and ϵ_{cr} for a hinged flange compared with experiment. ($\epsilon_{av} = \frac{4}{9}\epsilon_h + \frac{5}{9}\epsilon_{cr}$ for $\epsilon_{av} > \epsilon_{cr}$.)

purely elastic behavior and becomes partly plastic. As a result of this plasticity, the flanges exhibit nonlinear behavior above about 25 ksi.

The most elementary consequence of the plastic nonlinear behavior is the substitution of E_{sec} for E in the formula for critical stress which, for a hinged flange, is (reference 3)

$$\sigma_{cr} = E_{sec} \epsilon_{cr} \quad (5)$$

Another consequence of the nonlinear behavior due to plasticity is the existence of a maximum load. Experimentally, as the load is increased more and more, the twist of the flange will increase until a value of load is reached at which the flange ceases to carry more load; this value is the maximum load. As was pointed out in the introduction, if the material of the flange obeyed Hooke's law strictly at all times, the rotation of the flange would increase indefinitely with increase in load. The existence of a maximum load is therefore directly attributable to plasticity of the material.

As the structure twists more and more beyond the buckling load, greater and greater shear strains are set up through the thickness of the flange. The shear strains are zero at the middle surface and have opposite signs at the faces. These shear strains will combine with the compressive strain already present to form a strain intensity; at a point where the compressive strain is ϵ_z and the shear strain is γ ,

the strain intensity is $\epsilon_i = \sqrt{\epsilon_z^2 + \frac{\gamma^2}{3}}$. (In order not to have to

consider variations of γ through the thickness, a mean value of γ^2 is used.) According to the deformation theory of

FIGURE 6.—Relation between the shortening δ/L and the rotation ϕ of a hinged flange compared with experiment. $\frac{b}{t} = 12$.

plasticity used herein (reference 3), the value of ϵ_i at any stage of deformation determines the reduced modulus of the material at that stage.

Since the maximum load always occurs at a finite rotation of the flange, the two effects of nonlinearity must be combined in order to account for the maximum load. Such a combination is effected in appendix B and the results are given in the following section.

MAXIMUM LOAD OF A FLANGE

It is shown in appendix B how the maximum load on a hinged flange may be computed from the dimensions of the flange and the stress-strain curve for the material.

The middle-surface strain distribution across the flange is given by equation (2a). In addition to these strains which arise directly from the compressive load, there are also shear strains in the flange due to its twist. These shear strains become as large as two-thirds of the compressive strains upon which they are superposed. Although, strictly speaking, the deformation theory of plasticity has only been shown to hold for simple loading (reference 4), its validity is also assumed herein for complex loading. The square of the compressive strains and the mean square of the shear strains were added in the proper manner to give a strain intensity. (The highly localized effects of bending at the middle and ends have been neglected.) From the compressive stress-strain curve for the material the value of the secant modulus E_{sec} was read at this strain intensity. For increasing strain intensities the compressive stress σ at any point across the width of the flange is then simply E_{sec} times the compressive strain at the point. Near the free edge the strain intensity decreases; in such a case, the elastic modulus E is used to compute the corresponding stress reduction. The average stress σ_{av} across the flange is then

$$\sigma_{av} = \frac{1}{b} \int_0^b \sigma dz \quad (6)$$

The value of σ_{av} is computed for a number of different twists until a maximum average stress σ_{max} is found.

Figure 7 shows the results plotted in a nondimensional form similar to that employed in reference 2. The parameters used have some theoretical justification and have the effect of making the information given by the plot largely independent of the material. The agreement between the computed curve and the experimental points for cruciform-section columns is satisfactory.

The fact that maximum loads may be computed in this case solely on the basis of deformation theory suggests that the theory is sufficiently accurate when the stress state changes from pure compression to combined compression and shear, for shear strains up to two-thirds of the largest compressive strains.

An interesting side light on this computation is revealed by the values of stress intensity at the supported edge when the load is a maximum. The stress intensity for eight widely different cruciforms is a constant, to about 1 percent, equal to about 47 ksi. (See table 1.) This value is close to the yield stress for the material (46 ksi).

When the flanges are present in actual structures, they are generally connected to other members which offer a certain elastic restraint against rotation along the supported edge. The question arises as to what effect this connection has upon the calculations based on the assumption of a hinge connection. The elastic restraint along the supported edge will have two major effects: The critical strain will be appreciably raised and the effective length L of the buckles will be appreciably shortened. A necessary consequence is that the rotation (which is proportional to L) is reduced

FIGURE 7.—Comparison of theoretical curve for the maximum strength of 24S-T4 aluminum alloy cruciforms with test results. Compressive yield stress σ_{cy} = 46 ksi. (Experimental values for H-sections of various aluminum alloys have been added for comparison with the theoretical curve.)

and, therefore, is more nearly of the shape of a circular sine along the length of the flange than it would be when a hinge is present along the joint. A third effect is the introduction of a slight curvature across the width of the flange. When the revised critical strain and the revised length are inserted into the formulas of appendix A, which were derived for a flange supported along a hinge, it is found that the rotation and the strain relations may still be accurately predicted for flanges with restraint along the supported edge. Such a result seems to indicate that the small amount of transverse curvature introduced by the restraint does not have an important effect on the formulas.

In view of the fact that the theory of appendix A applies fairly well to flanges with restrained edges, it might be expected that the maximum strength, also, might be given by the same theory. Experiment shows that such is the case; the values of maximum strength for H-sections are included in the experimental points shown in figure 7 and the points intermingle with the cruciform points such that one set cannot be distinguished from the other. The theory of this report may then be said to apply approximately to flanges with elastic restraint along one side edge as well as to flanges without elastic restraint.

CAUSE OF MAXIMUM LOAD

Maximum load occurs when it is no longer possible for the stress, on the average, to grow with increasing strain. The natural tendency for the stress to grow is defeated by the decrease in effective modulus.

In order to illustrate this effect graphically, figures 8(a) and 8(b) have been prepared. These figures illustrate the calculated strain and stress distributions across a hinged flange of 24S-T4 aluminum alloy and of proportions $\frac{b}{t}=14$ and $\frac{L}{b}=12$. These distributions hold over the greater part of the flange where the bending is negligible. Up to the critical strain of 0.002 and the critical stress of 21.5 psi, the distributions are uniform. As the load is increased beyond the critical value, the distributions become more and more nonuniform as a result of twisting of the flange. With increasing load, the strain increases faster at the hinge than at the middle of the flange as shown in figure 8(a). For a time, the corresponding stress also increases faster at the hinge than at the middle of the flange, as shown in figure 8(b). Eventually, however, the strain intensity at the hinge (averaged over the thickness) becomes so large that the modulus is greatly reduced. When that occurs, the stress at the hinge line ceases to grow with increase in strain and even

starts to decrease (see fig. 8(b)). The maximum area under the stress curve, and therefore the maximum load, occurs just as the hinge stress starts to recede.

CONCLUSIONS

A theoretical analysis of the compressive strength of flanges, based on a deformation theory of plasticity combined with the theory for finite deflections for this structure, and comparison with experimental data lead to the following conclusions:

1. The maximum load for a flange under compression and hinged along one edge may be accurately computed from the dimensions of the flange and the compressive stress-strain curve for the material.

2. Maximum load occurs when, because of the onset of plasticity, the effective modulus has been reduced to such a low value that it is no longer possible for the average stress to increase with increasing strain. Failure is not a local

phenomenon but is an integrated effect over the cross section of the flange.

3. For a wide variety of cruciform sections, the stress intensity (averaged over the thickness) along the hinge line at maximum load is a constant to about 1 percent. This value of stress intensity is very close to the yield stress for the material.

4. The fact that maximum loads may be computed in this case suggests that the deformation theory of plasticity is sufficiently accurate when the stress state changes from compression to combined compression and shear in the case when the shear strains are less than about two-thirds of the compressive strains.

APPENDIX A

FINITE DEFLECTION THEORY FOR A HINGED FLANGE UNDER COMPRESSION

ELLIPTIC-FUNCTION SOLUTION

The coordinate system and dimensions of the hinged flange (one-fourth of a cruciform-section column) are shown in figure 1 (a); the form of the distorted shape is shown in figure 1 (b). The fundamental hypothesis of the calculation is that at any section $x = \text{Constant}$ there is no curvature of the flange in the direction of z . The correctness of this hypothesis is amply borne out by tests on the flanges while under twist. With this assumption it becomes possible to avoid a formalized plate treatment of the problem.

For infinitesimal rotations, the differential equation of equilibrium for a column under the simultaneous action of a compressive stress σ and torque T has been shown by Wagner (reference 5) to be

$$(GJ - \sigma I_p) \frac{d\phi}{dx} - EC_{BT} \frac{d^3\phi}{dx^3} = T \quad (\text{A1})$$

where

$GJ \frac{d\phi}{dx}$ St. Venant component of internal resisting torque

$\sigma I_p \frac{d\phi}{dx}$ component of internal torque due to application of compressive force. (This component is not a resisting torque but aids the applied torque T in twisting the column; its sign is therefore negative.)

$-EC_{BT} \frac{d^3\phi}{dx^3}$ component of internal resisting torque due to bending of column as it twists

For the case in which the applied torque T is zero, such as for a compressed hinged flange, equation (A1) becomes

$$(GJ - \sigma I_p) \frac{d\phi}{dx} - EC_{BT} \frac{d^3\phi}{dx^3} = 0 \quad (\text{A2})$$

As previously mentioned, equations (A1) and (A2) are limited to infinitesimal rotations and thus cannot be used to determine the behavior of a column above the buckling load where rotations may become large.

In order to investigate the behavior of a compressed hinged flange above buckling, a theory which permits the calculation of the large deformations which may occur after buckling must be employed. The differential equation (A2) must therefore be amended to include the effects which appear at finite values of the rotation ϕ .

DERIVATION OF THE BASIC DIFFERENTIAL EQUATION FOR FINITE ROTATIONS

The effects of finite rotation involve the changes in the middle-surface strain that occur after buckling. As the plate twists, the longitudinal fibers will be inclined at a small angle to the hinge line as shown in figure 1 (b). As a result, the longitudinal fibers are stretched in varying amounts and the horizontal components of the forces along the fibers produce a torque which resists twisting of the plate. The resisting torque increases very rapidly with twisting of the plate, which thus becomes progressively stiffer. The rapid increase of stiffness with rotation provides the required mechanism for maintaining the rotation at a finite value.

Stretching of middle-surface fibers after buckling.—A short section of the plate as shown in figure 1 (c) will have the length ac before the plate buckles. After buckling, the length ac' will be greater than ac because ac' is inclined at an angle γ_b with the hinge line. (See fig. 1 (c).) Thus the strain at the free edge ϵ_b due to stretching for small values of γ_b is

$$-\epsilon_b = \frac{ac' - ac}{ac} = \sec \gamma_b - 1 \approx \frac{\gamma_b^2}{2} \quad (\text{A3})$$

(The strain ϵ_b is positive when compressive.)

If the line aa (fig. 1 (c)) has been rotated an angle ϕ from its original position, the free-edge fiber at c moves a distance $b(\phi + d\phi)$. The angle of inclination of the free-edge fiber is thus

$$\gamma_b = \frac{b(\phi + d\phi) - b\phi}{dx} = b \frac{d\phi}{dx} \quad (\text{A4})$$

If the point c is not at the free edge but at some interior position a distance z from the hinge line, it can similarly be shown that

$$-\epsilon_z = \frac{\gamma_z^2}{2} \quad (\text{A5})$$

$$\gamma_z = z \frac{d\phi}{dx} \quad (\text{A6})$$

From equations (A5) and (A6), the strain ϵ_z resulting from the stretching action can be given as

$$\epsilon_z = -\frac{z^2}{2} \left(\frac{d\phi}{dx} \right)^2 \quad (\text{A7})$$

Equation (A7) gives the difference between the hinge-line strain and the strain at any fiber due to the stretching action, for a given position along the width of the flange. It is this

difference which causes the middle-surface strain distribution after buckling to differ from the uniform strain distribution at the instant of buckling and which will now be considered.

Middle-surface strain distribution after buckling.—A compressive load P applied to the hinged flange will cause the ends to approach each other by a distance δ . The unit shortening e is δ/L . Equilibrium of the internal compressive forces with the applied force P requires that

$$P = tE \int_0^b (e + \epsilon_z) \cos \gamma_z dz \quad (\text{A8})$$

The angle γ_z is usually so small that $\cos \gamma_z$ may be taken as unity. Then, substituting the expression for ϵ_z from equation (A7) into equation (A8) yields

$$P = tE \int_0^b \left[e - \frac{z^2}{2} \left(\frac{d\phi}{dx} \right)^2 \right] dz = EA \left[e - \frac{b^2}{6} \left(\frac{d\phi}{dx} \right)^2 \right] \quad (\text{A9})$$

The unit shortening e is therefore

$$e = \frac{P}{AE} + \frac{b^2}{6} \left(\frac{d\phi}{dx} \right)^2 \quad (\text{A10})$$

The ratio P/AE is the average strain over the cross section. If P/AE is denoted by ϵ_{av} , equation (A10) becomes

$$e = \epsilon_{av} + \frac{\gamma_b^2}{6} \quad (\text{A11})$$

The longitudinal middle-surface strain ϵ_x at any fiber z in the cross section is therefore

$$\epsilon_x = e + \epsilon_z = \epsilon_{av} + \frac{\gamma_b^2}{6} - \frac{z^2}{2} \left(\frac{d\phi}{dx} \right)^2 \quad (\text{A12})$$

Moment due to axial stress after buckling.—The longitudinal strain ϵ_x does not have the direction of the hinge line but of the slightly inclined longitudinal fibers (the angle γ_z , equation (A6)). Consequently, $E\epsilon_x$ has components perpendicular to the hinge line which create the moment ΔM resulting from the applied compressive force.

The component of $E\epsilon_x$ perpendicular to the hinge line at any fiber z is $E\epsilon_x \sin \gamma_z$ and for small angles is approximately equal to $E\epsilon_x z \frac{d\phi}{dx}$. As this component has a lever arm z , the internal resisting moment ΔM is

$$\Delta M = -Et \int_0^b \left(\epsilon_x z \frac{d\phi}{dx} \right) z dz \quad (\text{A13})$$

Substituting the expression for ϵ_x from equation (A12) into equation (A13) results in the following relationship:

$$\Delta M = -\sigma I_p \frac{d\phi}{dx} + \frac{2}{15} E b^2 I_p \left(\frac{d\phi}{dx} \right)^3 \quad (\text{A14})$$

The term $\sigma I_p \frac{d\phi}{dx}$ is the same term that appears in equation (A2). The last term of equation (A14) is the required additional term which takes into account the stretching actions, which occur for finite rotations of the flange, and permits the computation of the rotation ϕ .

Basic differential equation of torque for a compressed hinged flange which includes the effects of finite rotation.—The complete differential equation of torque which replaces equation (A2) and includes the last term of equation (A14) is

$$(GJ - \sigma I_p) \frac{d\phi}{dx} - EC_{BT} \frac{d^3\phi}{dx^3} + \frac{2}{15} E b^2 I_p \left(\frac{d\phi}{dx} \right)^3 = 0 \quad (\text{A15})$$

The constants of equation (A15) are

$$\left. \begin{aligned} J &= \frac{bt^3}{3} \\ I_p &= \frac{b^3t}{3} \\ C_{BT} &= \frac{b^3t^3}{36} \\ G &= \frac{E}{2(1+\mu)} \end{aligned} \right\} \quad (\text{A16})$$

Substituting equations (A16) into (A15) yields

$$\frac{d^3\phi}{dx^3} + \frac{12}{t^2} \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} \right] \frac{d\phi}{dx} - \frac{8}{5} \left(\frac{b}{t} \right)^2 \left(\frac{d\phi}{dx} \right)^3 = 0 \quad (\text{A17})$$

A further simplification is effected by the use of

$$\left. \begin{aligned} \gamma_b &= b \frac{d\phi}{dx} \\ \xi &= \frac{x}{t} \\ m^2 &= 12 \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} \right] \end{aligned} \right\} \quad (\text{A18})$$

The substitution of relations (A18) into equation (A17) gives the basic differential equation for a compressed hinged flange

$$\frac{d^2\gamma_b}{d\xi^2} + m^2\gamma_b - \frac{8}{5}\gamma_b^3 = 0 \quad (\text{A19})$$

SOLUTION OF THE BASIC DIFFERENTIAL EQUATION FOR FINITE ROTATION

The basic differential equation (A19) has the solution

$$\xi + \xi_0 = \pm \int \frac{d\gamma_b}{\sqrt{c^2 - m^2\gamma_b^2 + \frac{4}{5}\gamma_b^4}} \quad (\text{A20})$$

where c and ξ_0 are constants of integration. (The sign of

the radical must be chosen so as to keep $d\xi$ positive.) With the condition that $\gamma=0$ for $\xi=0$ ($\frac{d\phi}{dx}$ equals zero at the ends) and the substitutions

$$\left. \begin{aligned} g^2 &= \frac{m^2}{2} + \sqrt{\frac{m^4}{4} - \frac{4}{5}c^2} \\ h^2 &= \frac{m^2}{2} - \sqrt{\frac{m^4}{4} - \frac{4}{5}c^2} \end{aligned} \right\} \quad (\text{A21})$$

equation (A20) may be written

$$\xi = \int_0^{\gamma_b} \frac{d(\gamma_b/c)}{\sqrt{[1-g^2(\gamma_b/c)^2][1-h^2(\gamma_b/c)^2]}} \quad (\text{A22})$$

With new variables Ψ and k defined by

$$\left. \begin{aligned} \frac{1}{g} \sin \Psi &= \frac{\gamma_b}{c} \\ k &= \frac{h}{g} \end{aligned} \right\} \quad (\text{A23})$$

equation (A22) is transformed into

$$\xi = \frac{1}{g} \int_0^{\Psi} \frac{d\Psi}{\sqrt{1-k^2 \sin^2 \Psi}} \quad (\text{A24})$$

In order to determine the constant c , use is made of the condition that $\gamma_b=0$ for $\xi=\frac{L}{2t}$ or $x=\frac{L}{2}$. The upper limit for equation (A24) corresponding to $x=\frac{L}{2}$ must then be $\Psi=\pi$ in order to satisfy the first of equations (A23):

$$\begin{aligned} \frac{L}{2t} &= \frac{1}{g} \int_0^{\pi} \frac{d\Psi}{\sqrt{1-k^2 \sin^2 \Psi}} \\ \text{or} \quad g &= \frac{4t}{L} \int_0^{\pi/2} \frac{d\Psi}{\sqrt{1-k^2 \sin^2 \Psi}} \end{aligned} \quad (\text{A25})$$

In elliptic-function notation,

$$\left. \begin{aligned} \int_0^{\pi/2} \frac{d\alpha}{\sqrt{1-k^2 \sin^2 \alpha}} &= K(k) \\ \int_0^{\Psi} \frac{d\alpha}{\sqrt{1-k^2 \sin^2 \alpha}} &= \text{sn}^{-1}(\sin \Psi) = \text{sn}^{-1}\left(\frac{g\gamma_b}{c}\right) \end{aligned} \right\} \quad (\text{A26})$$

Equation (A25) therefore may be written

$$g = \frac{4Kt}{L} \quad (\text{A27})$$

and equation (A24) becomes

$$\frac{4Kx}{L} = \int_0^{\Psi} \frac{d\alpha}{\sqrt{1-k^2 \sin^2 \alpha}} = \text{sn}^{-1}\left(\frac{g\gamma_b}{c}\right)$$

so that taking the elliptic sine of both sides gives

$$\gamma_b = \frac{c}{g} \text{sn}\left(\frac{4Kx}{L}\right) \quad (\text{A28})$$

The coefficient c/g is readily found from the definitions of g and h in equations (A21). From the first of these equations

$$h = \sqrt{m^2 - g^2} = \sqrt{12} \sqrt{\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{g^2}{12}}$$

and from the second

$$\frac{c}{g} = \frac{\sqrt{5}}{2} h = \sqrt{15} \sqrt{\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{g^2}{12}}$$

Making use of equation (A27) leads to the general solution

$$\gamma_b = \sqrt{15} \sqrt{\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{1}{12} \left(\frac{4Kt}{L}\right)^2} \text{sn}\left(\frac{4Kx}{L}\right) \quad (\text{A29})$$

Another form of the solution which is sometimes convenient may be obtained by using a different expression for h . Since addition of equations (A21) gives

$$m^2 = g^2 + h^2 = g^2(1+k^2) = \left(\frac{4Kt}{L}\right)^2 (1+k^2) \quad (\text{A30})$$

it follows that

$$g = \frac{m}{\sqrt{1+k^2}}$$

and that

$$h = kg = \frac{km}{\sqrt{1+k^2}}$$

Hence,

$$\gamma_b = \frac{\sqrt{5}}{2} h \text{sn}\left(\frac{4Kx}{L}\right) = \frac{\sqrt{5}}{2} \frac{km}{\sqrt{1+k^2}} \text{sn}\left(\frac{4Kx}{L}\right) \quad (\text{A31})$$

With either equation (A29) or equation (A31) now available as an accurate expression for the fiber slope γ_b , it is possible, besides checking the known formula for the critical compressive stress, to write formulas also for the rotation at any station along the flange, for the middle-surface strain distribution along and across the flange, for the relation between hinge-line, average, and critical strains, and for the fractional shortening. The formulas will now be given in that order.

Check of critical compressive stress.—In order to show that equations (A29) or (A31) give the correct buckling stress at the start of the rotation ($\gamma_b=0$), the behavior of the elliptic function is considered as the rotation approaches zero.

The preceding section showed that the angle γ_b is proportional to h , and therefore to k . As k approaches zero, K approaches $\pi/2$, and the elliptic sine approaches the circular sine. Hence for loads only slightly above the critical, from equation (A29),

$$\gamma_b = \sqrt{15} \sqrt{\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{1}{12} \left(\frac{2\pi t}{L} \right)^2} \sin \frac{2\pi x}{L}$$

At the critical load, $\gamma_b = 0$, and for loaded edges clamped,

$$(\epsilon_{av})_{\gamma_b=0} = \epsilon_{cr} = \frac{(t/b)^2}{2(1+\mu)} + \frac{1}{12} \left(\frac{2\pi t}{L} \right)^2 \quad (\text{A32})$$

This is the expression given as equation (1) in the body of the report. The critical compressive stress σ_{cr} is obtained by multiplying both sides of equation (A32) by the effective modulus in compression E_{sec} . Then

$$\sigma_{cr} = E_{sec} \epsilon_{cr} = E_{sec} \left[\frac{(t/b)^2}{2(1+\mu)} + \frac{1}{12} \left(\frac{2\pi t}{L} \right)^2 \right] \quad (\text{A33})$$

Since

$$m = g \sqrt{1+k^2} = \frac{4Kt}{L} \sqrt{1+k^2}$$

the general integral becomes

$$\begin{aligned} \phi &= \frac{\sqrt{5}}{2} \frac{t}{b} \left[\cosh^{-1} \frac{1}{\sqrt{1-k^2}} - \cosh^{-1} \frac{\sqrt{1-k^2} \operatorname{sn}^2(4Kx/L)}{\sqrt{1-k^2}} \right] & \left(\frac{1}{4} \leq \frac{x}{L} \leq 0 \right) \\ \phi &= \frac{\sqrt{5}}{2} \frac{t}{b} \left[\cosh^{-1} \frac{1}{\sqrt{1-k^2}} + \cosh^{-1} \frac{\sqrt{1-k^2} \operatorname{sn}^2(4Kx/L)}{\sqrt{1-k^2}} \right] & \left(\frac{3}{4} \leq \frac{x}{L} \leq \frac{1}{4} \right) \\ \phi &= \frac{\sqrt{5}}{2} \frac{t}{b} \cosh^{-1} \frac{1}{\sqrt{1-k^2}} & \left(\frac{x}{L} = \frac{1}{4} \text{ or } \frac{x}{L} = \frac{3}{4} \right) \\ \phi_{max} &= \sqrt{5} \frac{t}{b} \cosh^{-1} \frac{1}{\sqrt{1-k^2}} & \left(\frac{x}{L} = \frac{1}{2} \right) \end{aligned}$$

Variation of middle-surface strain over length and width of flange.—The middle-surface strain ϵ_x at any distance z from the hinge line was given in equation (A12) as

$$\epsilon_x = \epsilon_{av} + \frac{\gamma_b^2}{6} \left(1 - 3 \frac{z^2}{b^2} \right)$$

The slope of the free-edge fiber γ_b may now be inserted in this expression from either equation (A29) or equation (A31). Thus

$$\epsilon_x = \epsilon_{av} + \frac{5}{2} \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{1}{12} \left(\frac{4Kt}{L} \right)^2 \right] \left(1 - 3 \frac{z^2}{b^2} \right) \operatorname{sn}^2 \left(\frac{4Kx}{L} \right) \quad (\text{A36a})$$

or

$$\epsilon_x = \epsilon_{av} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \left(1 - 3 \frac{z^2}{b^2} \right) \operatorname{sn}^2 \left(\frac{4Kx}{L} \right) \quad (\text{A36b})$$

or

$$\epsilon_x = \frac{\left(\frac{t}{b} \right)^2}{2(1+\mu)} + \frac{m^2}{12} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \left(1 - 3 \frac{z^2}{b^2} \right) \operatorname{sn}^2 \left(\frac{4Kx}{L} \right) \quad (\text{A36c})$$

This is the expression given as equation (5) in the body of the report.

Rotation of any station along the flange.—By symmetry, the rotation of any station a distance x from either end is given by

$$\phi = \frac{L}{b} \int \gamma_b d \left(\frac{x}{L} \right) \quad (\text{A34})$$

and so is obtained by a simple integration of the fiber angle distribution along the length of the flange, subject to the condition that the rotation is zero at both ends of the flange.

If an analytical expression for ϕ is desired, either equation (A29) or its alternate (A31) may be integrated. Integration of equation (A31) gives

$$\begin{aligned} \phi &= \frac{\sqrt{5}}{2} \frac{km}{\sqrt{1+k^2}} \frac{L}{4bK} \int_0^{4Kx/L} \operatorname{sn} \left(\frac{4Kx}{L} \right) d \left(\frac{4Kx}{L} \right) \\ &= \frac{\sqrt{5}}{2} \frac{m}{\sqrt{1+k^2}} \frac{L}{4bK} \left[\cosh^{-1} \frac{1}{\sqrt{1-k^2}} - \cosh^{-1} \frac{\sqrt{1-k^2} \operatorname{sn}^2(4Kx/L)}{\sqrt{1-k^2}} \right] \end{aligned} \quad (\text{A35})$$

Relationships between hinge-line, average, and critical strains.—Along the hinge line $z=0$, and equations (A36) give

$$(\epsilon_x)_{z=0} = \epsilon_{av} + \frac{5}{2} \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} - \frac{1}{12} \left(\frac{4Kt}{L} \right)^2 \right] \text{sn}^2 \left(\frac{4Kx}{L} \right)$$

or

$$(\epsilon_x)_{z=0} = \epsilon_{av} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \text{sn}^2 \left(\frac{4Kx}{L} \right)$$

Along the hinge line at $x = \frac{L}{4}$ and $x = \frac{3L}{4}$,

$$(\epsilon_x)_{z=0} = \frac{7}{2} \epsilon_{av} - \frac{5}{2} \left[\frac{(t/b)^2}{2(1+\mu)} + \frac{1}{12} \left(\frac{4Kt}{L} \right)^2 \right] \quad (\text{A37a})$$

or

$$(\epsilon_x)_{z=0} = \epsilon_{av} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \quad (\text{A37b})$$

Along the hinge line at $x=0$, $x = \frac{L}{2}$, and $x=L$,

$$(\epsilon_x)_{z=0} = \epsilon_{av}$$

Thus at the ends and at the middle the strain is uniformly distributed across the width of the hinged flanges.

Fractional shortening.—The fractional shortening of the flange δ/L (1/4 of its length is considered for convenience) is

$$\begin{aligned} e &= \frac{\delta}{L} \\ &= \frac{4}{L} \int_0^{L/4} (\epsilon_x)_{z=0} dx \\ &= \frac{1}{K} \int_0^K (\epsilon_x)_{z=0} d \left(\frac{4Kx}{L} \right) \\ &= \epsilon_{av} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \frac{1}{K} \int_0^K \text{sn}^2 \left(\frac{4Kx}{L} \right) d \left(\frac{4Kx}{L} \right) \\ &= \epsilon_{av} + \frac{5}{24} \frac{m^2}{1+k^2} \left(1 - \frac{\bar{E}}{K} \right) \end{aligned}$$

where $\bar{E} = \int_0^{\pi/2} \sqrt{1-k^2 \sin^2 \alpha} d\alpha$. From equation (A30)

$m = \frac{4Kt}{L} \sqrt{1+k^2}$, and by use of this value of m ,

$$e = \frac{\delta}{L} = \epsilon_{av} + \frac{10}{3} \left(\frac{t}{L} \right)^2 K(K - \bar{E}) \quad (\text{A38})$$

APPROXIMATE RELATIONSHIPS FOR POSTBUCKLING BEHAVIOR

The preceding relationships for the behavior of a hinged flange when compressed beyond the buckling load may be greatly simplified if the flange is long enough so that bending is negligible compared with the twist. Under such conditions the term $EC_{BT} \frac{d^3 \phi}{dx^3}$ in the differential equation (A15) may be neglected. The basic differential equation (A19) then reduces to a simple algebraic equation

$$m^2 \gamma_b - \frac{8}{5} \gamma_b^3 = 0$$

The fiber angle γ_b .—Solutions of the preceding equation are

$$\gamma_b = 0$$

and

$$\gamma_b = \pm \sqrt{\frac{5}{8}} m = \pm \sqrt{\frac{15}{2}} \sqrt{\epsilon_{av} - \epsilon_{cr}} \quad (\text{A39})$$

in which $\epsilon_{cr} = \frac{(t/b)^2}{2(1+\mu)}$, the term in length now being omitted.

The same quantities which were computed under "Elliptic Function Solution" may now be expressed once more in terms of the approximate solution for γ_b .

Rotation of flange.—The approximate rotation will be the integral of the approximate value of γ_b , or

$$\phi = \sqrt{\frac{15}{2}} \sqrt{\epsilon_{av} - \epsilon_{cr}} \left(\frac{x}{L} \right) \left(\frac{L}{b} \right) \quad \left(\frac{1}{2} \geq \frac{x}{L} \geq 0 \right)$$

and

$$\phi = \sqrt{\frac{15}{2}} \sqrt{\epsilon_{av} - \epsilon_{cr}} \left(1 - \frac{x}{L} \right) \left(\frac{L}{b} \right) \quad \left(1 \geq \frac{x}{L} \geq \frac{1}{2} \right)$$

A reference to figure 2 shows that the distribution of the angle ϕ is nearly linear for large rotations.

The maximum value of ϕ is $\frac{1}{2} \sqrt{\frac{15}{2}} \sqrt{\epsilon_{av} - \epsilon_{cr}} \left(\frac{L}{b} \right)$ or

$$\phi_{max} = 1.37 \frac{L}{b} \sqrt{\epsilon_{av} - \epsilon_{cr}} \quad (\text{A40})$$

A second approximation, which contains a small correction term to equation (A40), may be found from the relations

$$\lim_{k \rightarrow 1} \cosh^{-1} \frac{1}{\sqrt{1-k^2}} = \log \frac{2}{\sqrt{1-k^2}}$$

and

$$\lim_{k \rightarrow 1} K = \log \frac{4}{\sqrt{1-k^2}}$$

Since

$$\log \frac{2}{\sqrt{1-k^2}} = \log \frac{4}{\sqrt{1-k^2}} - \log 2$$

as $k \rightarrow 1$,

$$\cosh^{-1} \frac{1}{\sqrt{1-k^2}} = K - \log 2$$

The exact rotation at the middle of the column is given by equation (A35):

$$\phi_{max} = \sqrt{5} \frac{t}{b} \cosh^{-1} \frac{1}{\sqrt{1-k^2}}$$

therefore, as $k \rightarrow 1$,

$$\begin{aligned} \phi_{max} &= \sqrt{5} \frac{t}{b} (K - \log 2) \\ &= \sqrt{5} \frac{t}{b} \left(\frac{mL}{\sqrt{2} 4t} - \log 2 \right) \\ &= 1.37 \frac{L}{b} \sqrt{\epsilon_{av} - \epsilon_{cr}} - 1.55 \frac{t}{b} \end{aligned} \quad (\text{A41})$$

This corrective term $1.55 \frac{t}{b}$ is always a small part of ϕ_{max} .

Variation of middle-surface strain over width of flange.—The approximate strain distribution is obtained from equation (A12) by using the approximate value of γ_b from equation (A39):

$$\epsilon_x = \epsilon_{av} + \frac{5}{4} (\epsilon_{av} - \epsilon_{cr}) \left(1 - 3 \frac{z^2}{b^2} \right) \quad (\text{A42})$$

This result holds over most of the length of the flange but is in error near the ends and the middle where $\text{sn} \left(\frac{4Kx}{L} \right)$ has a value different from unity.

Relationship between the hinge-line, average, and critical strains.—Along the hinge line $z=0$, so that, approximately

$$(\epsilon_x)_{z=0} = \frac{9}{4} \epsilon_{av} - \frac{5}{4} \epsilon_{cr} \quad (\text{A43})$$

Fractional shortening.—The approximate shortening is

$$e = \frac{1}{L} \int_0^L \left(\frac{9}{4} \epsilon_{av} - \frac{5}{4} \epsilon_{cr} \right) dx = \frac{9}{4} \epsilon_{av} - \frac{5}{4} \epsilon_{cr} \quad (\text{A44})$$

and therefore is identical with ϵ_x along the hinge line $z=0$.

APPENDIX B

MAXIMUM STRENGTH OF A CRUCIFORM-SECTION COLUMN

The deformation theory of plasticity used here states that a relation exists between the stress intensity σ_i and the strain intensity e_i which is of the following form:

for loading (e_i increasing)

$$\sigma_i = E_{\text{sec}} e_i$$

for unloading (e_i decreasing)

$$d\sigma_i = E de_i$$

where

$$\sigma_i = \sqrt{\sigma_x^2 + \sigma_z^2 - \sigma_x \sigma_z + 3\tau^2}$$

$$e_i = \frac{2}{\sqrt{3}} \sqrt{\epsilon_x^2 + \epsilon_z^2 + \epsilon_x \epsilon_z + \frac{\gamma^2}{4}}$$

σ_x, ϵ_x stress and strain in the x -direction

σ_z, ϵ_z stress and strain in the z -direction

τ, γ shear stress and strain

In the case of a cruciform-section column compressed beyond the buckling stress σ_{cr} , the value of σ_x is the stress in the x -direction and is larger than σ_{cr} over most of the flange width. Also $\sigma_z = 0$, and with Poisson's ratio equal to $1/2$,

$$\epsilon_z = -\frac{1}{2} \epsilon_x; \text{ so that the fundamental stress-strain relation for}$$

increasing σ_i reduces to

$$\sqrt{\sigma_x^2 + 3\tau^2} = E_{\text{sec}} \sqrt{\epsilon_x^2 + \frac{\gamma^2}{3}}$$

in which

$$\sigma_x = E_{\text{sec}} \epsilon_x$$

$$\tau = \frac{E_{\text{sec}}}{3} \gamma$$

The value of ϵ_x at any point (x, z) of a cruciform flange is assumed from appendix A to be as in equation (A36c)

$$\epsilon_x = \frac{(t/b)^2}{2(1+\mu)} + \frac{m^2}{12} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \left(1 - 3 \frac{z^2}{b^2}\right) \sin^2 \left(\frac{4Kx}{L}\right)$$

where k^2 is a parameter lying between 0 and 1 which specifies the amount of twist,

$$K = \int_0^{\pi/2} \frac{d\alpha}{\sqrt{1 - k^2 \sin^2 \alpha}}$$

$$m^2 = 12 \left[\epsilon_{av} - \frac{(t/b)^2}{2(1+\mu)} \right] = K^2 (1 + k^2) \left(\frac{4t}{L} \right)^2$$

As soon as a value is assigned to k^2 corresponding to a certain amount of twist, the quantities K and m^2 are fixed and ϵ_x may be computed.

Over most of the length of the column, $\sin \left(\frac{4Kx}{L} \right) \approx 1$ and,

therefore, the variation of ϵ_x with x may be neglected by taking

$$\epsilon_x = \frac{(t/b)^2}{2(1+\mu)} + \frac{m^2}{12} + \frac{5}{24} \frac{k^2 m^2}{1+k^2} \left(1 - 3 \frac{z^2}{b^2}\right)$$

The shear strain γ arises from the twist $\frac{d\phi}{dx}$ of the flange after buckling and is proportional to the distance r away from the center line of the cross section:

$$\gamma = 2r \frac{d\phi}{dx}$$

However for insertion into the formula for strain intensity, a value of γ^2 is desired which is independent of r . Such a value may be obtained by taking the average value of γ^2 over the thickness. The mean value of γ^2 over the cross section is

$$\bar{\gamma}^2 = \frac{1}{t} \int_{-t/2}^{t/2} 4r^2 \left(\frac{d\phi}{dx} \right)^2 dr = \frac{t^2}{3} \left(\frac{d\phi}{dx} \right)^2 = \frac{\gamma_0^2}{3} \left(\frac{t}{b} \right)^2$$

From the theory of appendix A (equation (A31)),

$$\gamma_b = \frac{\sqrt{5}}{2} \frac{km}{\sqrt{1+k^2}}$$

over most of the section for which $\sin\left(\frac{4Kx}{L}\right) \approx 1$. Hence

$$\overline{\gamma^2} = \frac{5}{12} \left(\frac{t}{b}\right)^2 \frac{k^2 m^2}{1+k^2}$$

and thus the strain intensity $\sqrt{\epsilon_z^2 + \frac{\gamma^2}{3}}$ is completely de-

termined as soon as a value of the parameter k^2 is selected.

From the stress-strain relation the value of the stress intensity and of course E_{sec} is determined by the value of the strain intensity. (The elastic modulus E is used if the strain intensity is decreasing.) The stress σ_x may then be computed by the relation $\sigma_x = E_{sec}\epsilon_x$ as a function of the z -coordinate across the flange. The average value of σ_x across the width of the flange is then

$$\sigma_{av} = \frac{1}{b} \int_0^b \sigma_x dz$$

and is the average stress that would be determined from a testing machine at the value of k^2 selected.

In the actual calculations, the width b of the flange was divided into ten equal strips and the value of σ_{av} was found by a numerical summation. As the twist of the flange varies from zero to infinity, the parameter k^2 varies from zero to 1. The value of σ_{av} may be investigated as a function of k^2 and will have a maximum at some value of k^2 . This maximum value of σ_{av} multiplied by the total area gives the maximum load for the cruciform flange under consideration.

REPORT 1030

INVESTIGATION OF SEPARATION OF THE TURBULENT BOUNDARY LAYER¹

By G. B. SCHUBAUER and P. S. KLEBANOFF

SUMMARY

An investigation was conducted on a turbulent boundary layer near a smooth surface with pressure gradients sufficient to cause flow separation. The Reynolds number was high, but the speeds were entirely within the incompressible flow range. The investigation consisted of measurements of mean flow, three components of turbulence intensity, turbulent shearing stress, and correlations between two fluctuation components at a point and between the same component at different points. The results are given in the form of tables and graphs. The discussion deals first with separation and then with the more fundamental question of basic concepts of turbulent flow.

INTRODUCTION

In 1944 an experimental investigation was begun at the National Bureau of Standards with the cooperation and financial assistance of the National Advisory Committee for Aeronautics to learn as much as possible about turbulent-boundary-layer separation. Considering that previous experimentation had been limited to mean speeds and pressures, it was decided that the best way to bring to light new information was to investigate the turbulence itself in relation to the mean properties of the layer. Since little was known about turbulent boundary layers in large adverse pressure gradients, the investigation was exploratory in nature and was pursued on the assumption that whatever kind of measurements that could be made on turbulence and turbulent processes would carry the investigation in the right direction.

The investigation was therefore long range, there being no natural stopping point as long as there remained unknowns and means for investigating them. The decision to stop came when it was decided that the more basic properties of turbulent motions, such as production, decay, and diffusion, which form the subject of modern theories, could better be investigated first without the effect of pressure gradient. The experimental work on separation was therefore halted after a certain fund of information had been obtained on turbulence intensity, turbulent shearing stress, correlation coefficients, and the scale of turbulent motions.

Use was made of the results from time to time as they could be made to serve a particular purpose. Certain of the results have appeared therefore in references 1 to 3. It is now felt that the results should be presented in their entirety for what they contribute to the separation problem and to the understanding of turbulent flow, even though they leave many questions unanswered.

The authors wish to acknowledge the active interest and support of Dr. H. L. Dryden during this investigation and the assistance given by Mr. William Squire in the taking of observations and the reduction of data.

SYMBOLS

x	distance along surface from forward stagnation point
y	distance normal to surface measured from surface
z	direction perpendicular to xy -plane
U	mean velocity in boundary layer
U_1	mean velocity just outside boundary layer
U_m	mean velocity just outside boundary layer at $x=17\frac{1}{2}$ feet, used as reference velocity
V	y -component of mean velocity in boundary layer
u, v, w	x -, y -, and z -components of turbulent-velocity fluctuations
u', v', w'	root-mean-square values of u, v , and w
ρ	density of air
ν	kinematic viscosity of air
p	pressure
q_1	free-stream dynamic pressure $\left(\frac{1}{2}\rho U_1^2\right)$
q_m	free-stream dynamic pressure at $x=17\frac{1}{2}$ feet $\left(\frac{1}{2}\rho U_m^2\right)$
τ	turbulent shearing stress $(-\rho\overline{uv})$
$\overline{uv}$	mean value of product of u and v
$C_{\tau 1}, C_{\tau m}$	coefficients of turbulent shearing stress $\left(C_{\tau 1}=\tau/\frac{1}{2}\rho U_1^2, C_{\tau m}=\tau/\frac{1}{2}\rho U_m^2\right)$
τ_o	skin friction
C_f	coefficient of skin friction $\left(\tau_o/\frac{1}{2}\rho U_1^2\right)$
δ	boundary-layer thickness
δ^*	boundary-layer displacement thickness $\left(\int_0^\infty \left(1-\frac{U}{U_1}\right)dy\right)$
θ	boundary-layer momentum thickness $\left(\int_0^\infty \frac{U}{U_1}\left(1-\frac{U}{U_1}\right)dy\right)$
H	boundary-layer shape parameter (δ^*/θ)
L_x, L_y	scales of turbulence

and x_2)

APPARATUS AND TEST PROCEDURE

The setup for the investigation was arranged with two things in mind: (1) The Reynolds number was to be as high as possible and (2) the boundary layer was to be thick enough to permit reasonably accurate measurements of all components of the turbulence intensity and shearing stress by hot-wire techniques which were known to be reliable. Since this required a large setup, the 40-foot open-air wind tunnel at the National Bureau of Standards was chosen, and a wall of airfoil-like section shown in figures 1 and 2 was constructed in the center of the test section. The wall was 10 feet high, extending from floor to ceiling, and was 27.9 feet long. It was constructed of $\frac{1}{4}$ -inch Transite on a wooden frame, and the surface on the working side was given a smooth finish by sanding and varnishing and, finally, waxing and polishing. The profile was chosen so that the adverse pressure gradient on the working side would be sufficient to cause separation and yet have sufficiently small curvature to make the pressure changes across the layer negligible.

Since the separation point was found to be very close to

FIGURE 1.—Front view of "boundary-layer wall" in NBS 10-foot open-air wind tunnel.

FIGURE 2.—Sectional drawing of "boundary-layer wall."

the trailing edge, a blister was constructed on the tunnel wall to move the separation point upstream to the location shown in figure 2. At the outset there was troublesome secondary flow from premature separation near the floor and, to a lesser degree, near the ceiling. A vent in the floor allowing air to enter the tunnel and blow away the accumulated dead air afforded a satisfactory remedy. The flow was then two-dimensional over the central portion of the wall from the leading edge to the separation point.

A steeply rising pressure, caused by the small radius of curvature of the leading edge and the induced angle of attack, produced transition about 2 inches from the leading edge. The boundary layer was therefore turbulent over practically the whole of the surface and, over the region of major interest, ranged in thickness from $2\frac{3}{8}$ inches at the $17\frac{1}{2}$ -foot position to 9 inches at the separation point. All measurements were made with a free-stream speed of about 160 feet per second at the $17\frac{1}{2}$ -foot position. The boundary-layer thickness at $17\frac{1}{2}$ feet was equivalent to that on a flat plate 14.3 feet long with fully turbulent layer and no pressure gradient, and the flat-plate Reynolds number corresponding to 160 feet per second was 14,300,000. The speed was always adjusted for changes in kinematic viscosity from day to day to maintain a fixed Reynolds number throughout the entire series of measurements. The turbulence of the free stream of the tunnel was about 0.5 percent.

All measurements were made at the midsection of the wall, where the flow most closely approximated two-dimensionality, and on the side labeled "Working side" in figure 2. While the measurements extended over a considerable period of time, there was no evidence from pressure and mean-velocity distributions that the geometry of the wall changed. There was, however, considerable scatter in the turbulence measurements from day to day, some of which was due to inherent inaccuracies associated with hot-wire measurements, and some of which may have been caused by actual changes in the flow. The results therefore do not lend themselves to a determination of differential changes in the x -direction with high accuracy. It was the intention to obtain results applicable to a smooth surface; therefore the surface was frequently polished and kept clean at all times. However, because of the texture of the Transite, the surface could not be given a mirrorlike finish equal to that of a metal surface.

Considerable emphasis was placed on the precise determination of the position of separation. A method was finally evolved whereby the line of separation and the direction of

the flow at the surface in the neighborhood of this line could be found. This consisted of pasting strips of white cloth on the surface with a starch solution. Small crystals of iodine were then stuck to the strips. Blue streaks on the starched cloth then showed the direction of the air flow. By this means separation could be located with an accuracy of ± 2 inches. Initially the line of separation was nowhere straight, but, after the removal of some of the reversed flow near the floor by the vent previously mentioned, the line was made straight for a distance of 2 feet in the center and was located 25.7 ± 0.2 feet from the leading edge.

The pressure distribution was measured with a static-pressure tube 0.04 inch in diameter, constructed according to the conventional design for such a tube. Mean dynamic pressure was obtained by adding a total-pressure tube of the same diameter but flattened on the end to form a nearly rectangular opening 0.012 inch wide.

The hot-wire equipment used in the investigation of turbulence has been fully described in reference 1, and it suffices here merely to call attention to the manner of operation and the performance of the equipment. The thick boundary layer made it possible to obtain essentially point measurements without having to construct hot-wire anemometers on a microscopic scale. The several types used are shown in figure 3. The $\frac{1}{16}$ -inch scale shows the high magnification of types A, B, C, and D. A complete holder is shown by E with the inch scale above. Heads of type A were used for measuring u' , those of type B or C were used for measuring turbulent shearing stresses, and those of type D were used for measuring v' and w' . In use the prongs pointed directly into the mean wind.

When the head of type C was used for measuring shearing stress, an observation of the mean-square signal from each of the wires was necessary. A similar pair of observations

FIGURE 3.—Types of hot-wire anemometers and complete holder used in investigation

was necessary when using type B, but with only one wire the head had to be rotated through 180° . Since it was usually difficult to execute this rotation by remote control, most of the measurements of shearing stress were made with the head of type C.

The hot-wires themselves, shown at the tips of the prongs, were tungsten 0.00031 inch in diameter. Platinum wire could not be used because the air was taken into the tunnel from outdoors and platinum wires were broken by flying dirt particles. The diameter of 0.00031 inch was the smallest obtainable in tungsten at the time, and the length could not be reduced below about $\frac{1}{16}$ inch and still maintain the required sensitivity. In all cases the boundary-layer thickness was at least 25 times the wire length.

The uncompensated amplifier had a flat response from 2 to 5,000 cycles per second and an amplification decreasing above 5,000 cycles per second to about 50 percent at 10,000 cycles per second. The time constant of the wires ranged from 0.001 to 0.003 second, depending on operating conditions, and the over-all response of wire and amplifier could be made equal to that of the uncompensated amplifier by means of the adjustable compensation provided in the amplifier. However, with this relatively high time constant, the background noise level was high and had to be subtracted from the readings in order to obtain the true hot-wire signal.

The methods of determining u' , v' , w' , $\overline{uv}$, and $\overline{uv}/u'v'$ are fully described in reference 1. The determination of R_y and R_x involved the use of a pair of heads of type A, separated by known distances normal to the surface for R_y and along the tangent to the surface for R_x . The "sum-and-difference" method described in reference 4 was used, account being taken of the inequality of u' at the two wires and the differences in sensitivity.

The several measuring heads were mounted on various types of traversing equipment designed for convenience, rigidity, and a minimum of interference at the point where a measurement was being made.

TEST RESULTS

The results of the measurements are given in tables 1 to 8 and figures 4 to 14. Figures 15 to 22 repeat certain of the results to aid in the analysis.

The tabulation is made to present all of the detail contained in the measurements and to make the results readily available to any style of plotting that suits the reader's needs. Figures 4 to 14 are summary plots intended to show an over-all picture rather than detail.

PRESSURE DISTRIBUTION

The values given in table 1 and figure 4 were obtained from measurements of pressure with a small static-pressure tube placed $\frac{1}{4}$ inch from the surface at various positions along the midspan. The tube was also traversed in the y -direction, from which it was found that changes in pressure across the boundary layer were barely detectable in the region from $x=18$ to 23 feet and were not measurable elsewhere. The

pressure is therefore regarded as constant across the boundary layer, and all of the information on pressure gradient is given by the variation of q_1/q_m with x .

FIGURE 4.—Distribution of velocity and dynamic pressure just outside boundary layer.

FIGURE 5.—Contour plot of mean velocities.

MEAN-VELOCITY DISTRIBUTION

Mean velocities were obtained from dynamic-pressure measurements made at various distances y . No correction was made for the effect of turbulence. The distributions of mean velocity are given in table 2 and summarized by the contour plot shown in figure 5. From these data were derived the values of δ^* , θ , and H given in table 3 and figure 6.

FIGURE 6.—Boundary-layer parameters.

 FIGURE 7.—Variation of U/U_1 with H for various values of y/θ .

 FIGURE 8.—Contour plot of u' .

 FIGURE 9.—Contour plot of v' .

 FIGURE 10.—Contour plot of w' .

FIGURE 12.—Contour plot of $\overline{uv}$ -correlation coefficient.

FIGURE 13.—Transverse correlation coefficient.

FIGURE 14.—Longitudinal correlation coefficient.

The distribution of mean velocity is plotted in figure 7 in the manner suggested by Von Doenhoff and Tetervin in reference 5. If H is a universal parameter specifying the boundary-layer profile, the curves of figure 7 should agree in all detail with those of figure 9 in reference 5. The agreement is good, although there are systematic differences slightly greater than the experimental dispersion.

TURBULENCE INTENSITIES

The turbulence intensities are given in table 4 in terms of u'/U_1 , v'/U_1 , and w'/U_1 . They are summarized in figures 8 to 10 in terms of u'/U_m , v'/U_m , and w'/U_m in order to show changes in the absolute magnitude of the fluctuations. As desired, u' , v' , and w' may be expressed in relation to any

of the mean velocities U , U_1 , or U_m by the aid of tables 1 and 2.

COEFFICIENT OF TURBULENT SHEARING STRESS AND $\overline{uv}$ -CORRELATION COEFFICIENT

The directly observed quantity $\overline{uv}$ has been expressed nondimensionally in terms of a coefficient of turbulent shearing stress

$$C_{\tau 1} = \frac{2\overline{uv}}{U_1^2}$$

$$C_{\tau m} = \frac{2\overline{uv}}{U_m^2}$$

The choice of coefficients is arbitrary, and $C_{\tau 1}$ is tabulated in table 5 while contour plots for $C_{\tau m}$ are given in figure 11. The choice of $C_{\tau m}$ for the figure was made because it was desired to show an over-all picture of variations in τ independent of variations in mean velocity.

The values of the correlation coefficient $\overline{uv}/u'v'$ are given in table 6 and figure 12.

CORRELATION COEFFICIENTS R_y AND R_z

The correlation coefficients R_y and R_z express the correlation between values of u at the same instant at two different points. This correlation between points separated by distances in the direction of the local normal to the surface is expressed by R_y , and the correlation between points separated by distances in the direction of the local tangent to the surface is expressed by R_z . These directions were normal and tangential to streamlines only when the local mean direction of the flow was tangent to the surface. Where the boundary layer was thickening rapidly, as near the separation point, the flow in the outer portion of the boundary layer had a greater radius of curvature than the surface and the direction was not tangent to the surface. In such regions, therefore, R_y and R_z do not conform strictly to the conventional definition of such coefficients.

Values of R_y are given in table 7 and values of R_z are given in table 8. Figures 13 and 14 show representative correlation curves in order to give an idea of the distances over which u is correlated compared with the boundary-layer thickness.

It will be noted that a correlation exists over much of the boundary-layer thickness. With the region near separation excluded, fluctuations at the center of the layer are related to those everywhere else in the same section. Under such conditions a small negative correlation is found between points in the layer and those outside, as shown in figure 13. Subsequent measurements in a boundary layer with approximately one-tenth of the free-stream turbulence have shown no effect of the free-stream turbulence on the magnitude of the negative correlation. An explanation of this negative correlation on the basis of continuity requirements is offered in reference 3.

From tables 7 and 8 one may calculate integral scales, defined by

$$L_y = \int_0^{\infty} R_y dy$$

$$L_x = \int_0^{\infty} R_x dx$$

These are not given here because it is felt that the qualitative concept of scale obtained from figures 13 and 14 conveys about as much physical significance to scale as is possible at present.

DISCUSSION OF RESULTS

MECHANICS OF SEPARATION

The separation point is defined as the point where the flow next to the surface no longer continues to advance farther in the downstream direction. This results from a failure of the medium to have sufficient energy to advance farther into a region of rising pressure. Certain characteristics of the mean flow serve as a guide to the imminence of separation. For example, the shape factor H can be expected to have a value greater than 2. In the present experiment H was found to have the value 2.7 at the separation point, comparing well with the value of 2.6 given in reference 5.

The empirical guides, however, give little insight into the physical factors involved. Separation is a natural consequence of the loss of energy in the boundary layer, and the burden of explanation rests rather with the question as to why separation does not occur at all times at a pressure minimum. At the surface the kinetic energy of the flow is everywhere vanishingly small. At a pressure minimum the potential energy is a minimum, and the air at the surface, having a vanishing amount of kinetic energy to draw upon, could never advance beyond a pressure minimum without receiving energy from the flow farther out. The necessary transfer is effected by the shearing stresses.

It is a well-known fact that viscous shearing stresses are so small that laminar flow can advance but a little distance beyond a pressure minimum. In contrast with this, turbulent shearing stresses can prevent separation entirely if the rate of increase of pressure is not too great. This emphasizes an important fact; namely, that when separation has not occurred, or has been delayed to distances well beyond the pressure minimum, as in the present experiment, viscous stresses play an insignificant role in the prevention or delay of separation.

Turbulent shearing stresses also determine the magnitude of shearing stresses in the laminar sublayer by forcing there a high rate of shear. This, in fact, gives boundary-layer profiles the appearance of near slip flow at the surface. Thus, turbulent stresses dominate all parts of the boundary layer. Viscous effects in the laminar sublayer and elsewhere still play an important role in determining the existing state of the turbulence. However, in dealing with the effects of turbulence, and not with the origin of turbulence, effects of viscosity can be neglected.

At the high Reynolds numbers of the present experiment the laminar sublayer was extremely thin and was never approached in any of the measurements. At the 17½-foot position at 0.1 inch from the surface the turbulent shearing stress was 190 times the viscous shearing stress. Considering the low order of magnitude of the viscous stresses compared with that of the turbulent stresses, the equations of motion may be closely approximated by including only the Reynolds stresses, and may be written

$$U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} - \frac{\partial \bar{u}^2}{\partial x} - \frac{\partial \bar{u}v}{\partial y} \quad (1)$$

$$U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial y} - \frac{\partial \bar{u}v}{\partial x} - \frac{\partial \bar{v}^2}{\partial y} \quad (2)$$

While all terms in equations (1) and (2) have been measured, they have not been measured with sufficient accuracy to test the adequacy of the equations. The relative importance of the terms involving Reynolds stresses depends on location in the boundary layer. The normal stresses $\rho \bar{u}^2$ and $\rho \bar{v}^2$ are pressures and their gradients make merely small contributions to $\partial p / \partial x$ and $\partial p / \partial y$. Among the Reynolds stresses the shearing stress is the more important quantity and, accordingly, attention is devoted to it.

It is easy to see qualitatively on physical grounds how the shearing stress must be distributed across the boundary layer. The shearing stress is always in such a direction that fluid layers farther out pull on layers farther in. When the pressure is either constant or falling, all pull is ultimately exerted on the surface. Therefore the shearing stress must be at least as high at the surface as it is elsewhere, and it would be expected to be a maximum there, as it must fall to zero outside the boundary layer. When the pressure is rising, part of the pull must be exerted on the fluid near the surface that has insufficient energy of its own to advance to regions of higher pressure. In other words, the fluid in such layers must be pulled upon harder than it pulls upon the layer next nearer the surface. This means that the shearing stress must have a maximum away from the surface in regions of adverse pressure gradient.

Representative observed distributions are shown in figure 15. It will be seen that the maximum shear stress develops first near the surface and move progressively outward. The region between the surface and the maximum is receiving energy from the region beyond the maximum, the rate per unit volume at each point being $U \frac{\partial \tau}{\partial y}$. Thus the fall in the shearing stress toward the surface, producing a positive slope, is evidence that the shearing stress is acting to prevent separation. It is clear then that a falling to zero, as for example the curve at $x=25.4$ feet, is not the cause of separation. It is rather an indication that the velocity gradient is vanishing at the surface. This means that the velocity in the vicinity of the surface is vanishing and that a condition is developing in which no energy can be

FIGURE 15.—Distribution of coefficient of turbulent shearing stress across boundary layer.

received. When this condition is fulfilled, the fluid can move no farther and separation has occurred.

The initial slope of the curves in figure 15 is given by equation (1), which becomes, when $y=0$:

$$\frac{\partial p}{\partial x} = \frac{\partial \tau}{\partial y} \quad (3)$$

A theory of the distribution of shearing stress based on the inner boundary conditions $\partial^2 \tau / \partial y^2 = 0$ and equation (3) and on the outer boundary conditions $\tau = 0$ and $\partial \tau / \partial y = 0$ at $y = \delta$ has been given by Fediaevsky (reference 6). The agreement between Fediaevsky's theory and experimental values from the present investigation was fair at the 17½-foot position and excellent at the 25-foot position, but elsewhere was poor. Two examples of the agreement are given in figure 16. The Fediaevsky theory, which defines merely how the curves shall begin and end, either loses control over the middle portion or ignores other controlling factors.

Since equation (3) specifies the initial slope, it is an aid in finding the skin friction by the method of extrapolating the distribution curves to $y=0$. The values found in this way are given in figure 17. As would be expected, the skin friction falls to zero at the separation point. The lack of agreement with values calculated by the Squire-Young formula (reference 7) is to be expected, as this formula does not include the effect of pressure gradient.

FIGURE 16.—Experimental values for coefficient of turbulent shearing stress compared with curves from Fediaevsky theory.

FIGURE 17.—Experimental values for coefficient of skin friction compared with values calculated with Squire-Young formula.

The foregoing discussion has simply described the shearing stress in the light of the present experiment and pointed out the role of shearing stress as an energy-transferring agent. While these phenomena are characteristic in every adverse pressure gradient, the form of the shearing stress and also the velocity profiles will be different for different pressure distributions. The present experiment gives merely one example.

ORIGIN OF TURBULENCE AND TURBULENT SHEARING STRESS

The discussion of origin of turbulence and turbulent shearing stress will be based on concepts that have superseded the older mixing-length theories. Unfortunately, experiments have not kept pace with ideas and the concepts have not yet been fully verified.

In recent years definite ideas have taken shape regarding the decay of turbulence. These stem from an observation made by Dryden (reference 8), namely, that the rates of decay of different frequency components in isotropic tur-

bulence require that the higher-frequency components gain energy at the expense of the lower-frequency components. It has now become generally accepted that decay involves a transfer of energy from larger eddies to smaller eddies by Reynolds stresses when the Reynolds number characteristic of the eddies is sufficiently high. This idea forms the physical basis for modern theories of isotropic turbulence (for example, references 9 to 15).

Information about turbulent flow points more and more to the conclusion that the concept is basic and may be carried over to shear flow. (See, for example, Batchelor's discussion of Kolmogoroff's theory, reference 9, and Townsend's discussion, reference 16.) The general idea may be expressed as follows: The highest Reynolds number is associated with the mean flow, and here the mean Reynolds stresses transfer energy to the flow system comprising the next smaller spatial pattern, for example, the largest eddies. This second system involves other Reynolds stresses which in turn transfer energy to smaller systems and so on through a spectrum of turbulence until the Reynolds number gets so low that the dissipation is completed by the action of viscosity alone. The evolution of heat by the action of viscosity is small for the larger systems and gets progressively greater as the systems get smaller and smaller, with a weighting depending on some Reynolds number characterizing the whole system, say, a Reynolds number based on the outside velocity and the boundary-layer thickness. The higher the Reynolds number the more is the action of viscosity confined to the high-frequency end of the spectrum. Thus at sufficiently high Reynolds numbers the action of viscosity is not only removed from the mean flow but also from all but the smaller-scale components of the turbulence. An exception must, of course, be made for the laminar sublayer, and the likelihood that this is a valid picture increases with distance from the surface.

These ideas then might be regarded as describing a tentative model of a turbulent boundary layer to be examined in the light of experiment. The model is, of course, conceived only in general outline and should not be assumed the same for all conditions.

The rate of removal of kinetic energy per unit volume from the mean flow by Reynolds stresses is given by:

$$\rho \left[\bar{u}^2 \frac{\partial U}{\partial x} + \bar{v}^2 \frac{\partial V}{\partial y} + \bar{u}v \left(\frac{\partial V}{\partial x} + \frac{\partial U}{\partial y} \right) \right] \quad (4)$$

This energy goes directly into the production of turbulence.

The term $\bar{u}v \frac{\partial U}{\partial y}$ will generally outweigh the others, but in order to see the relative magnitudes near separation the terms in expression (4) were calculated for the 24.5-foot position. The term $\bar{u}v \frac{\partial V}{\partial x}$ was found to be negligible. The other terms within the brackets together with their sum are

FIGURE 18.—Rate of production of turbulence and mean energy of turbulence at $x=24.5$ feet. Right ordinate scale to be used only for top curve.

shown in figure 18 divided by U_m^3 . It is seen that the term $\bar{u}v \frac{\partial U}{\partial y}$ is still the largest, and therefore remains the most important contributor to turbulence.

The distribution of turbulence energy is also given in figure 18. This shows a maximum energy content where the rate of production is the greatest; otherwise the comparison has no particular significance. Such coincidence is not required and is not found farther upstream. Data are not available for establishing the balance between production, diffusion, convection, and dissipation of turbulence energy.

It is clear that the turbulence exists because of the Reynolds stresses, and it is self-evident that the normal stresses $\rho \bar{u}^2$ and $\rho \bar{v}^2$ exist because of the turbulence, but the source of the shearing stress $\rho \bar{u}v$ is not apparent without further examination.

Since

$$\tau = -\rho \bar{u}v = -\rho \frac{\bar{u}v}{u'v'} u'v' \quad (5)$$

where $\bar{u}v/u'v'$ is the correlation coefficient, it is seen that τ depends on the correlation and intensity of u and v . If a flow is turbulent without a gradient in mean velocity, there can be no mean shearing stress and therefore no mean correlation between u and v . It is apparent then that a gradient is necessary to produce a correlation, and one might expect to find $\bar{u}v/u'v'$ proportional to dU/dy . From figure 12 it appears that $\bar{u}v/u'v'$ shows too little variation across the boundary layer to be proportional to the local value of the mean-velocity gradient. To apply a more direct test, $\bar{u}v/u'v'$ was plotted in figure 19 against the mean local gradient. Obviously $\bar{u}v/u'v'$ cannot be regarded as proportional to $(\theta/U_1) (dU/dy)$, and, what is more, it becomes independent of the local gradient for a wide range of values of $(\theta/U_1) (dU/dy)$.

FIGURE 19.—Relation between $\overline{uv}$ -correlation coefficient and local mean-velocity gradient.

Assuming the correctness of the concept of transfer of energy from larger to smaller flow regimes, it is seen that energy flows into turbulence mainly by way of the largest eddies, and it is then mainly these that account for the average shearing stress. Returning to figure 13, it is seen by the curves of R_v that the turbulent motions are correlated over much of the boundary-layer thickness up to the position $X=23$ feet and are still correlated over a considerable portion of the thickness at larger values of x . The extent of the R_v -correlation is roughly a measure of the extent of the largest eddies. This means that the correlation coefficient $\overline{uv}/u'v'$ arises from those components of the turbulence that extend over much of the boundary-layer thickness, and the correlation between u - and v -components of such a motion would be expected to depend on the mean-velocity gradient as a whole rather than upon the local gradient at any one point. Large mean gradients exist near the surface without producing correspondingly large correlation coefficients in the same locality, and it appears that the correlations here are very likely fixed by some over-all effect. If an over-all velocity gradient is represented at each position by U_1/U_m divided by δ , and this is used as the independent variable in figure 20 to cross-plot values of $\overline{uv}/u'v'$ taken from the flat portion of the curves in figure 19, a definite proportionality between these two quantities is found. This bears out the foregoing argument.

Figure 21 was originally prepared to test one of the equations of state in Nevzgljadov's theory (reference 17), which expresses the shearing stress as proportional to the turbulent energy per unit volume and the mean-velocity gradient. The theory is not supported by the results for the same reason as that mentioned in connection with figure 19. In fact, shearing stress per unit energy is much like the correlation coefficient and would be two-thirds of $\overline{uv}/u'v'$ if u' , v' , and w' were all equal. The similarity between figures 19 and 21 is therefore not surprising. The hairpin loops in the curves in these two figures apparently result from the distribution

FIGURE 20.—Relation between $\overline{uv}$ -correlation coefficient near surface and general mean-velocity gradient.

FIGURE 21.—Relation between shearing stress per unit energy of turbulence and local mean-velocity gradient.

of shearing stress imposed by the adverse pressure gradient.

Figure 22 emphasizes the great difference between turbulent shear flow and laminar shear flow. In laminar flow the shearing stress is directly proportional to the local velocity gradient. In turbulent flow, shown in figure 22, the shearing stress may rise abruptly for scarcely any change in the local velocity gradient and again fall with increasing velocity gradient. This illustrates the difficulty of adopting the concepts of viscous flow in turbulent flow. The difference probably arises because turbulent phenomena, unlike molecular phenomena, are on a scale of space and velocity of the same order as that of the mean flow.

FIGURE 22.—Relation between coefficient of shearing stress and local mean-velocity gradient.

The tentative picture in the form of the model previously described is still speculative and probably oversimplified. It has, however, received support in the present experiment, perhaps as much as could be expected from over-all measurements embracing the entire frequency spectrum. Observations of these same quantities as a function of frequency would be much more informative, but unfortunately the experimental conditions in an open-air wind tunnel discouraged work of this sort. Other types of hot-wire measurements, such as those described by Townsend in reference 16, would be of as great value in probing for the true picture of a turbulent boundary layer as they were in bringing to light phenomena in the turbulent wake of a cylinder.

The present model is but an extension of the concepts required to explain the spectrum and decay of isotropic turbulence. However, in going from the relative simplicity of isotropic turbulence to boundary-layer turbulence many new factors are introduced. Distance from transition point, pressure gradient, curvature, and surface roughness doubtless affect details and may have profound influences. It must be left to future experiments and theory to fill in the gaps, and when this has been done perhaps the data given herein will have more meaning than they have at

present. It is with this thought in mind that the data are given in tables, in which form they are the more readily available for new uses.

CONCLUDING REMARKS

Certain measured characteristics of a separating turbulent boundary layer have been presented. The average characteristics are mean velocity, pressure, and the derived parameters, displacement thickness, momentum thickness, and shape factor. The turbulent characteristics comprise intensities, shearing stresses, transverse correlations, longitudinal correlations, and correlations between two fluctuation components at a point.

The results have been discussed, first, in connection with what they reveal about separation and, second, in connection with what they reveal about the nature of turbulent boundary layers. The modern concept of energy transfer through a spectrum was extended to the turbulent boundary layer. The resulting model of a turbulent boundary layer was supported by the results. This together with the support from theory and experiment in isotropic turbulence makes it appear that the model may be a very useful one for guiding future experiments.

It is seen that the investigation of separation of the turbulent boundary layer had to go beyond the mere investigation of separation. The real problem is the understanding of the mechanics of turbulent shear flow under the action of pressure gradient. The solution of this problem depends on the understanding of the mechanics of turbulence, and in this only rudimentary beginnings have been made.

REPORT 1031

A STUDY OF THE USE OF EXPERIMENTAL STABILITY DERIVATIVES IN THE CALCULATION OF THE LATERAL DISTURBED MOTIONS OF A SWEEP-WING AIRPLANE AND COMPARISON WITH FLIGHT RESULTS¹

By JOHN D. BIRD and BYRON M. JAQUET

SUMMARY

An investigation was made to determine the accuracy with which the lateral flight motions of a swept-wing airplane could be predicted from experimental stability derivatives determined in the 6-foot-diameter rolling-flow test section and 6- by 6-foot curved-flow test section of the Langley stability tunnel. In addition determination of the significance of including the nonlinear aerodynamic effects of sideslip in the calculations of the motions was desired. All experimental aerodynamic data necessary for prediction of the lateral flight motions are presented along with a number of comparisons between flight and calculated motions caused by rudder and aileron disturbances.

In general, the agreement between the calculated and measured motions of the airplane considered was good when the effects of all control movements were taken into account. The greatest disagreement occurred at lift coefficients where Reynolds number effects on the experimental derivatives would be expected to be high, which for the case considered was for lift coefficients above about 0.8 when wing slots were used. The nonlinear effects of sideslip for this airplane were not very significant for the motions considered, which generally involved sideslip angles less than 10° .

INTRODUCTION

For the past few years, numerous investigations have been made in the Langley stability tunnel to determine the effects of geometric variables on the static-, rolling-, yawing-, and pitching-stability derivatives of various airplane configurations. (See references 1 to 4.) In the past, however, none of the experimental data have been compared with data obtained in flight to determine its relative worth. The purpose of the present report is to determine the applicability of the experimental stability derivatives to the prediction of the lateral disturbed motions of an airplane in flight. The equations used for calculating the motions are given in the appendix.

A $\frac{1}{8}$ -scale model of a swept-wing version of a conventional fighter airplane, which was selected because of the large amount of flight data available (see references 5 and 6), was tested in the 6-foot-diameter rolling-flow test section and 6- by 6-foot curved-flow test section of the Langley stability tunnel to determine all the stability derivatives which are

usually considered necessary to calculate the lateral motions arising from a disturbance caused by the rudder or the ailerons. Comparisons have been made between the flight and calculated lateral motions for a wide range of conditions in gliding flight.

A few calculations have been made to determine the effects of nonlinear variations of the aerodynamic forces and moments with the angle of sideslip.

COEFFICIENTS AND SYMBOLS

The results of the wind-tunnel tests are presented as standard NACA coefficients of forces and moments. Moment coefficients are referred to a center of gravity located at 21.8 percent of the mean aerodynamic chord. The wind-tunnel data and motion calculations are referred to the stability axes, which are a system of axes having their origin at the center of gravity and in which the Z -axis is in the plane of symmetry and perpendicular to the relative wind, the X -axis is in the plane of symmetry and perpendicular to the Z -axis, and the Y -axis is perpendicular to the plane of symmetry. The positive directions of the stability axes and of angular displacements of the airplane and control surfaces are shown in figure 1.

FIGURE 1.—System of stability axes. Arrows indicate positive forces, moments, and angular displacements.

¹ Supersedes NACA TN 2013, "A Study of the Use of Experimental Stability Derivatives in the Calculation of the Lateral Disturbed Motions of a Swept-Wing Airplane and Comparison with Flight Results" by John D. Bird and Byron M. Jaquet, 1950.

The coefficients and symbols are defined as follows:

C_L	lift coefficient ($Lift/qS$)
$C_{L_{max}}$	maximum lift coefficient
C_X	longitudinal-force coefficient (X/qS)
C_Y	lateral-force coefficient (Y/qS)
C_l	rolling-moment coefficient (L/qSb)
C_n	yawing-moment coefficient (N/qSb)
$C_{Y_\psi} = \frac{\partial C_Y}{\partial \psi}$	
$C_{l_\psi} = \frac{\partial C_l}{\partial \psi}$	
$C_{n_\psi} = \frac{\partial C_n}{\partial \psi}$	
$C_{l_\beta} = \frac{\partial C_l}{\partial \beta}$	
$C_{n_\beta} = \frac{\partial C_n}{\partial \beta}$	
$C_{Y_p} = \frac{\partial C_Y}{\partial \frac{pb}{2V}}$	
$C_{l_p} = \frac{\partial C_l}{\partial \frac{pb}{2V}}$	
$C_{n_p} = \frac{\partial C_n}{\partial \frac{pb}{2V}}$	
$C_{Y_r} = \frac{\partial C_Y}{\partial \frac{rb}{2V}}$	
$C_{l_r} = \frac{\partial C_l}{\partial \frac{rb}{2V}}$	
$C_{n_r} = \frac{\partial C_n}{\partial \frac{rb}{2V}}$	
I_{X_0}	moment of inertia about longitudinal principal axis
I_{Y_0}	moment of inertia about spanwise principal axis
I_{Z_0}	moment of inertia about normal principal axis
X	longitudinal force along X -axis
Y	lateral force along Y -axis
Z	normal force along Z -axis ($Lift = -Z$)
L	rolling-moment about X -axis
N	yawing-moment about Z -axis
$pb/2V$	wing-tip helix angle, radians
$rb/2V$	yawing-velocity parameter, radian measure
p	rolling angular velocity about X -axis
r	yawing angular velocity about Z -axis
v	linear velocity of airplane along Y -axis
V	free-stream velocity along X -axis
V_c	calibrated airspeed, based on sea-level density of air
β	angle of sideslip; $\beta = -\psi$ in wind-tunnel tests ($\tan^{-1} \frac{v}{V}$)
α_R	angle of attack of wing root chord line

α	angle of attack of thrust line ($\alpha_R - 1.2^\circ$)
ψ	angle of yaw, degrees
i_t	angle of incidence of stabilizer with respect to thrust line, positive when trailing edge is down
δ	control-surface deflection, measured in a plane perpendicular to hinge axis
Λ	angle of sweepback, degrees
q	free-stream dynamic pressure ($\frac{1}{2} \rho V^2$)
S	wing area
b	wing span
A	aspect ratio (b^2/S)
ρ	mass density of air
T	time
$T_{1/2}$	time to damp to half amplitude
P	period
l	tail length
Subscripts:	
a	aileron
r	rudder
f	flap
v	vertical tail

WIND-TUNNEL TESTS

APPARATUS AND MODEL

The experimental static-lateral-stability derivatives, rolling-stability derivatives, and yawing-stability derivatives were determined from tests conducted in the Langley stability tunnel in which rolling or curved flight is simulated by rolling or curving the air stream about a rigidly mounted model.

The tests were made on a conventional six-component balance system with the model mounted at the flight center of gravity which is at 21.8 percent of the mean aerodynamic chord of the wing.

The full-scale airplane (a swept-wing version of a conventional fighter) had the quarter-chord line of the wing, just outboard of the intake ducts, swept back 35° . Some of the pertinent airplane characteristics are given in table I. More details of the airplane may be obtained from references 5 and 6.

The $\frac{1}{9}$ -scale model shown in figure 2 and in the photographs of figures 3 to 6 was constructed of laminated mahogany, finished in clear lacquer, and all surfaces were highly polished. The model propeller had three metal blades set at an angle of 28° at the 0.75 radius. All propeller-on tests were made with windmilling propeller. The model wing had a removable leading edge so that slats of 0 percent, 40 percent, and 80 percent of the swept span could be used interchangeably to simulate those of the full-scale airplane. The top surfaces of the slats were cast to the contour of the airfoil and the slats were extended by means of metal brackets which also act as fences to reduce spanwise flow along the slot. A cross section through the slot and slat is shown in reference 5.

The wing had a plain trailing-edge flap with a chord of 15.1 percent of the wing chord measured perpendicular to the hinge axis. The gap was sealed for all tests. As in the case of the airplane the main wheels of the model were fixed for all tests; whereas the nose wheel and nose-wheel doors were removed for all flaps-up tests.

Shown in figure 2 are the two ventral fins tested on the model. The large ventral fin was used for all tests except a few with the 80-percent-span slot configuration for which the small ventral fin was used.

TEST AND TEST CONDITIONS

Trim tests.—Model trim lift coefficients of 0.33, 0.55, 0.76, and 0.95 were selected as representative of those obtained in flight tests. The angle of incidence of the horizontal tail was measured with respect to the thrust line.

In order to determine the trim angles of the horizontal tail for the previously mentioned lift coefficients, tests were made through the angle-of-attack range with the horizontal tail set at -5° , -3° , and 1° incidence. From these tests the trim angles of the horizontal tail were determined. (See table II.)

Static tests.—In order to determine the static-stability derivatives C_{l_p} , C_{n_p} , and C_{Y_p} , the model was tested at $\psi = \pm 5^\circ$ through an angle-of-attack range of $\alpha = -2^\circ$ to $\alpha = 23^\circ$ for the flaps up (trim $C_L = 0.33$) and $\alpha = -2^\circ$ to $\alpha = 18^\circ$ for the flaps down (trim $C_L = 0.76$) for each of the slot configurations. Tests were also made at all selected test trim lift coefficients through an angle-of-yaw range of $\psi = \pm 20^\circ$ to determine the variations of C_l , C_n , and C_Y with ψ for all slot configurations.

Tare tests were made for the 40-percent-span slot configuration (flaps up and down). The effect of the slots on the tares was assumed to be small; therefore, the tares for the 40-percent-span slot configuration were applied to all configurations. The Mach and Reynolds numbers for the tests were 0.17 and 1.01×10^6 , respectively.

Rolling-flow tests.—Tests were conducted in the 6-foot-diameter rolling-flow test section of the Langley stability tunnel, wherein rolling flight of the model was simulated by rotating the air stream. The model was mounted rigidly on a conventional support strut. Details of this test procedure are given in reference 1.

All slot configurations were tested through the angle-of-attack range with the flaps up (trim $C_L = 0.33$) and with the flaps down (trim $C_L = 0.76$) at helix angles $pb/2V$ of 0, ± 0.0253 , and ± 0.0757 radian. The slopes of C_l , C_n , and C_Y plotted against $pb/2V$ are the derivatives C_{l_p} , C_{n_p} , and C_{Y_p} . The 40-percent-span slot configuration (flaps up and down) was tested at the selected trim lift coefficients for the previously mentioned values of $pb/2V$ from $\psi = 0^\circ$ to $\psi = 20^\circ$ to determine the variation of C_{l_p} , C_{n_p} , and C_{Y_p} with ψ . The Mach number and Reynolds number for the rolling-flow tests were 0.17 and 1.01×10^6 , respectively.

Yawing-flow tests.—Yawing-flow tests were conducted in the 6- by 6-foot curved-flow test section of the Langley stability tunnel. In this section, curved flight is simulated

approximately by directing the air in a curved path about a fixed model.

All slot configurations were tested in curved flow through the angle-of-attack range with the flaps up (trim $C_L = 0.33$) and with the flaps down (trim $C_L = 0.76$) at values at $rb/2V$ of 0, -0.039 , -0.082 , and -0.108 . The slopes of C_l , C_n , and C_Y plotted against $rb/2V$ are the derivatives C_{l_r} , C_{n_r} , and C_{Y_r} .

The 40-percent-span slot configuration (flaps up and down) was tested through an angle-of-yaw range of $\psi = \pm 20^\circ$ for values of $rb/2V$ of 0, -0.039 , -0.082 , and -0.108 at the previously mentioned trim lift coefficients to determine the variation of C_{l_r} , C_{n_r} , and C_{Y_r} with ψ . The values presented herein are the average of the results at corresponding positive and negative angles of yaw.

The 40-percent-span slot configuration (flaps up) was tested at a trim lift coefficient of 0.33 through the angle-of-yaw range with the propeller off.

The yawing-flow tests were made at a Mach number of 0.13 and a Reynolds number of 0.8×10^6 .

CORRECTIONS

Approximate jet-boundary corrections based on methods derived for unswept wings were applied to the angle of attack, longitudinal-force coefficient, and rolling-moment coefficient, and a blocking correction of 1.01 was applied to the dynamic pressure.

Corrections for the effect of the support strut have been applied to C_X , C_L , C_l , C_n , C_Y , C_{l_p} , C_{n_p} , and C_{Y_p} . In rolling flow and curved flow, accurate tares were difficult to obtain; and, as a result, the derivatives C_{l_p} , C_{n_p} , C_{Y_p} , C_{l_r} , C_{n_r} , and C_{Y_r} are not corrected for the effects of the support strut.

The derivative C_{l_p} was corrected for the effective pitching velocity, which exists when the model is tested at an angle of yaw, by the following equation:

$$C_{l_p} = C_{l_p}' \cos \psi + f(A, \Lambda, \psi)$$

where C_{l_p}' is measured about the wind axis, and $f(A, \Lambda, \psi)$, which is small as compared with $C_{l_p}' \cos \psi$, is a function determined by use of the methods of reference 4. Corresponding effective pitching corrections were not applied to the derivatives C_{n_p} and C_{Y_p} .

A correction was also applied to the derivative C_{Y_r} to account for the error caused by the cross-tunnel static-pressure gradient which is associated with curved flow.

EXPERIMENTAL RESULTS

The experimental data are discussed briefly with reference to the effects of the slots and angle of yaw on the aerodynamic characteristics of the model, because the effects of these variables on the rotary derivatives have not been investigated extensively to date. The figures which present the results obtained in the present investigation are listed in table III.

The basic lift and longitudinal-force data of figures 7 and 8 are generally in good agreement with larger scale tests of another model of the same airplane, as given in reference 7.

The main effect of the slots is to extend the linear range of those stability derivatives which are largely contributed by the wing to higher lift coefficients in a manner similar to the effect of slots on the lift curve of a wing. (See figs. 7 to 10 and 12, 13, 15, and 16.) One significant effect of the slots is on the damping in yaw C_{n_r} , which increased as the slot span is increased. When the 80-percent-span slots are used C_{n_r} is increased (over that of the unslotted configuration) by about 25 percent at $C_L=0$. (See fig. 15 (a).) When the flaps are deflected (fig. 15 (b)), the effects of the slots on the yawing-stability derivatives are not as great as when the flaps are retracted.

A comparison of figures 11(a) to 11(f) shows that C_{n_y} varies to some extent through the yaw range, C_{Y_ψ} is approximately constant, and for any given lift coefficient C_{l_y} is

approximately constant between $\psi=-10^\circ$ and $\psi=10^\circ$. As the angle of yaw is increased (fig. 14 (a)), C_{Y_ψ} tends to decrease, C_{n_r} remains approximately constant, and C_{l_y} decreases slightly. The variations are similar when the flaps are deflected. (See fig. 14 (b).)

The tests for the determination of the variation of C_{Y_r} , C_{n_r} , and C_{l_r} with ψ were made for negative values of $rb/2V$ only. Results for positive values of $rb/2V$ and positive ψ were obtained by assuming that the model was essentially symmetrical about the XZ -plane and by utilizing the results for the corresponding opposite angles of yaw and $rb/2V$ with regard for signs. This procedure amounted to averaging the derivatives for corresponding positive and negative angles of yaw.

In general, as the angle of yaw is increased from 0° to 20° , the damping in yaw C_{n_r} is increased by about 15 percent, and C_{Y_r} and C_{l_r} are decreased slightly (fig. 17 (a)). Deflection of the flaps or removal of the propeller does not appreciably

FIGURE 7.—Variation of longitudinal-force coefficient and angle of attack with lift coefficient for three slot configurations. Large ventral fin on; propeller on; $\psi=0^\circ$; $R=1.01 \times 10^6$.

change the variations of the yawing-stability derivatives with angle of yaw. (See fig. 17.)

Because C_{n_r} is largely dependent on the size of the vertical tail it is approximately true throughout the yaw range that

$$C_{n_r} = -\frac{2l_v}{b} C_{n_{\beta}}$$

Substitution of the proper values of the span, $C_{n_{\beta}}$, and the tail length l_v indicates that the trend of the variation of C_{n_r} with ψ shown in figure 17 is reasonable.

FIGURE 8.—Variation of longitudinal-force coefficient and angle of attack with lift coefficient for two slot configurations. Trim $C_L=0.33$; $\psi=0^\circ$; $\delta_r=0^\circ$; $R=1.01 \times 10^6$.

The relative constancy of C_{Y_p} , C_{l_p} , C_{n_p} , C_{Y_r} , C_{l_r} , and C_{n_r} with angle of yaw as indicated by figures 14 and 17 and the linearity of the curves of C_{Y_r} , C_{l_r} , and C_{n_r} plotted against ψ for angles of yaw up to approximately 10° (fig. 11) were factors which indicated that nonlinearities were not of first-order importance for this airplane in the calculation of motions involving reasonably small variations in ψ . Consequently, most of the motion calculations neglect the effect of ψ on the stability derivatives.

The results of unpublished tests of swept wings at Reynolds numbers to 8.0×10^6 in the Langley 19-foot pressure tunnel indicate that the linear part of the curve of C_{l_p} plotted against C_L is increased by an increase in Reynolds number. The curves of C_{l_p} against C_L given herein agree well with those obtained in flight (references 5 and 6) and in tests of a $\frac{1}{4.5}$ -scale model (reference 7) except at lift coefficients above $C_L=0.8$ where the magnitude of the present test values decreases for the slotted-wing configurations. The linear parts of the curves of the rolling- and yawing-stability derivatives are believed to be extended similarly to higher lift coefficients if the Reynolds number is increased.

MOTION CALCULATION METHODS

The lateral disturbed motions of the test airplane were calculated from the aerodynamic data obtained from the tests described in the section entitled "Wind-Tunnel Tests." The mass and dimensional characteristics of the airplane are given in table I, and a tabulation of the flight conditions for which lateral disturbed motions were calculated for comparison with the flight motions is given in table IV. Most of the calculations involved dynamic derivatives which were constant for a given lift coefficient as is usually employed in the theory of small disturbances used in lateral-stability calculations.

Solutions of the lateral equations of motion, given in the appendix, were obtained for unit step disturbances in roll and yaw by the method described in reference 8. The aileron and rudder deflections during the flight motion under investigation were then approximated by a series of step functions usually at $\frac{1}{2}$ -second intervals. The motion arising from the control movements was then calculated by

$$\beta_n, p_n, \text{ or } r_n = \sum_{n=0}^m \left[(\delta_{m-n})_{\text{rudder}} (B_n)_{\text{yaw}} + (\delta_{m-n})_{\text{aileron}} (B_n)_{\text{roll}} \right]$$

where B_n is the value of the unit solution caused by $\Delta C_n=1$ or $\Delta C_l=1$ at a time $T=kn$, and δ_{m-n} is the fraction of the unit disturbance applied by the rudder or aileron at a time $T=k(m-n)$. The rudder and aileron effectiveness were

obtained from reference 7. This procedure is essentially an approximate evaluation of Duhamel's integral and was considered sufficiently accurate for these calculations. Reference 8 gives a more exact graphical evaluation of this integral. The yawing moment caused by aileron deflection and the rolling moment caused by rudder deflection were not considered of enough significance to warrant their inclusion in these calculations. In some cases, however, these factors may be of greater significance.

In a few cases, unit solutions to the equations of motion were obtained by a Laplace transform procedure which has been adapted for use with automatic digital computers. The results were, of course, identical with those presented in this report.

Calculations of the lateral motions for a few cases employing a nonlinear variation of rolling-moment and yawing-moment coefficients with angle of sideslip and a variation of C_{n_r} with angle of sideslip were carried out by use of the Kutta three-eighths rule for solving the lateral equations of motion. (See reference 9.) All lateral-motion calculations were made on an automatic digital computing machine.

CALCULATED LATERAL MOTIONS

GENERAL

The flight records corresponding to the motions calculated for this report showed that the motions resulting from right and left control movements were not exactly of opposite magnitude. This result indicates that there was some asymmetry in the characteristics of the airplane, although the

FIGURE 9.—Variation of lateral static-stability derivatives with lift coefficient for three slot configurations. Large ventral fin on; propeller on; $\psi = 0^\circ$; $R = 1.01 \times 10^6$.

wind-tunnel test results indicated no marked asymmetry in the model characteristics. Part of the differences in the flight motions to the right and left are undoubtedly due to variation in the thrust conditions. Although the flight tests were made under approximately zero thrust, no convenient means of obtaining this condition was available, and thus this requirement was left to the judgement of the pilot. Some small part of the difference in the motions to the left and right should be attributable to instrument error as the film record frequently contained considerable hash which, of course, tended to obscure the actual motion record. The differences between the motions to the right and left were resolved in the present report by presenting both records with the sign of one reversed so that the motions were superimposed. The shaded areas in the lateral-motion plots (figs. 18 to 23 and 25 to 35) represent the difference between the motions to the right and left. The flight motions corresponding to the calculated motions were obtained from references 5 and 6 and related tests. The figures which present the results of the lateral-motion calculations are listed in table III.

FIGURE 10.—Variation of lateral static-stability derivatives with lift coefficient for two slot configurations. Trim $C_L=0.33$; $\psi=0^\circ$; $\delta_f=0^\circ$; $R=1.01 \times 10^6$.

LATERAL OSCILLATIONS

Lateral oscillations were initiated by abruptly deflecting the rudder of the airplane and returning it to neutral equally as rapid a moment later. Some aileron waggle caused by the floating tendency of the ailerons occurred and was accounted for in the calculations by the procedure given in the calculation methods.

The calculated and flight motions are generally in good agreement for all motions calculated (figs. 18 to 23) except for the condition at $C_L=0.977$. (See fig. 23.) A comparison of the flight and calculated periods and time to damp to half amplitude (fig. 24) also indicate fairly good agreement except for the motions at lift coefficients of 0.977 and 1.169.

The values of C_{l_p} used for the calculation of the lateral motions were obtained from the curves of C_l plotted against ψ (fig. 11) wherever possible rather than the curves of C_{l_p} obtained from tests made at $\psi=\pm 5^\circ$ (figs. 9 and 10) because this procedure is believed to be more accurate. Although the difference between the two methods is generally small, such is not always true; and in some cases the calculated rate of damping was found to be appreciably affected by the difference in C_{l_p} .

At the higher lift coefficients, the experimental stability derivatives deviate appreciably from their initial trends. This tendency previously has been referred to as a Reynolds number effect and is probably the cause for the lack of agreement at high lift coefficients between the flight and calculated results. References 5 and 6 which present flight tests for this airplane show no reduction in C_{l_p} up to the maximum test lift coefficient. The rotary derivatives of the airplane presumably behave similarly. Evidence of the deviation of the experimental stability derivatives from their true variation with lift coefficient is observed in figure 20 which presents results for a lateral oscillation occurring at $C_L=0.759$. The calculated result indicates an excessive response in sideslip, yaw, and roll.

A few additional calculations of the period and time to damp, made for other high lift coefficients in flight, indicate increasingly poor agreement between the flight and calculated times to damp to one-half amplitude with increasing lift coefficient. The relatively good agreement between the periods of the flight and calculated motions for all lift coefficients, however, indicates that the experimental values of $C_{n\beta}$ are fairly close to the correct values. The period of the motion is primarily a function of the directional-stability parameter $C_{n\beta}$. (See reference 10.) An extrapolation of the curves of the derivatives plotted against lift coefficient—which amounted to selecting the value of the derivative just previous to the break in the curves occurring at maximum lift coefficient—was employed for one case at $C_L=1.17$ but failed to yield a satisfactory result. A linear extrapolation of the curves in the region preceding the departure from the theoretical or linear trend is expected to be more satisfactory.

FIGURE 11.—Continued.

FIGURE 11.—Continued.

RUDDER KICKS

Rudder kicks were initiated by abruptly deflecting the rudder of the airplane and holding this deflection as the airplane responded. The records of the flight motions were short, usually covering 5 seconds. As in the case of the lateral oscillations discussed previously, some slight aileron waggle that occurred was accounted for in the calculated motions. The agreement between the flight and calculated motions is, in general, quite good (figs. 25 to 31). Agreement is best at the lower lift coefficients; however at a lift coefficient of 0.919 (fig. 28), good agreement is shown between flight and calculated angles of sideslip and rolling velocities.

The flight tests reported in reference 5 showed that at low lift coefficients the airplane rolled in response to a rudder kick as if the airplane had a decided negative dihedral

effect. Figure 31 indicates that this peculiar response was largely caused by the slight aileron waggle which occurred during the motion. In general, for all configurations investigated, it was found necessary to account for any slight aileron movements in order to predict satisfactorily the lateral motions of the airplane.

The motions at $C_L=0.794$ (fig. 30) give evidence of departure of the experimental derivatives from the true variation with lift coefficient. This result again is the Reynolds number effect previously discussed. The flight and calculated periods of the lateral oscillation caused by the rudder kicks are in very good agreement which indicates again that the values of C_{n_p} used in the calculations were reasonably accurate.

FIGURE 15.—Variation of yawing-stability derivatives with lift coefficient for three slot configurations. Large ventral fin on; propeller on; $\psi=0^\circ$; $R=0.8 \times 10^6$.

AILERON ROLLS

Aileron rolls were initiated by abruptly deflecting the aileron control of the airplane and holding the deflected position as the airplane responded. The rudder control was held as near neutral as possible. The records of motion were necessarily short because of the large angles of bank assumed by the airplane after a short period of time.

Comparison of the flight and calculated aileron rolls indicates fairly good agreement (figs. 32 to 35) except for the high-lift-coefficient condition without nose slots. The stability derivatives for the unslotted configuration show a departure at fairly low lift coefficient from the initial trend of the variation of the derivatives with lift coefficient. As previously mentioned, this result is not obtained at the flight Reynolds numbers. The calculations for this high lift coefficient were carried out with two sets of stability deriva-

tives. One set was obtained by a linear extrapolation of the curves of the derivatives plotted against lift coefficient and the second set, by selecting for the value of the derivative that value just previous to the final break in the curves of the derivatives plotted against lift coefficient. The second procedure was necessary because the flight lift coefficient was greater than the maximum experimental lift coefficient. The linear extrapolation produces the better result, but it can be seen that neither set of derivatives was very satisfactory although it would appear logical to believe, in view of the Reynolds number effects indicated previously, that the linear extrapolation of the derivatives would have given fairly good results. The aileron roll for the 80-percent-span slot configuration with flaps down at $C_L=1.169$ (fig. 35) shows fair agreement between the flight and calculated motions so that a beneficial effect of the slots in maintaining an unseparated

FIGURE 16.—Variation of yawing-stability derivatives with lift coefficient for two slot configurations. Trim $C_L = 0.33$; $\psi = 0^\circ$; $\delta_f = 0^\circ$; $R = 0.8 \times 10^6$.

flow over the wing to a fairly high lift coefficient is indicated.

The effects of elasticity of the wing were not considered in the calculations of the aileron rolls because of lack of knowledge of the flexibility of the wing. Rough estimates of the effect of elasticity on the rolling velocity for the results of figure 33 indicate that the discrepancies shown between flight and calculated results would be reduced by about 50 percent or more.

A comparison has been made of the maximum rolling velocities obtained by calculation for conditions duplicating those in flight, by flight tests, and by calculations for a coordinated maneuver in which the yawing velocity and angle of sideslip are maintained at zero. For this last case, the rolling velocity becomes

$$p = \frac{-\Delta C_l}{C_{l_p}} \frac{2V}{b}$$

The results are presented in the following table:

Figure	Maximum rolling velocities from figures			$\left \frac{\Delta C_l}{C_{l_p}} \right \frac{2V}{b}$
	Calculated	Flight (left)	Flight (right)	
32	0.62	0.44	---	2.67
33	.77	.60	0.53	1.11
34	.78	---	.67	1.13
35	.34	.33	.30	.68

The comparison indicates that a marked difference may be obtained in the maximum rolling velocity by eliminating the degrees of freedom of sideslip and yaw. This last method of calculation is used frequently in comparing the relative merits of various forms of ailerons.

NONLINEAR CALCULATIONS

Calculations, in which the curves of C_l and C_n against ψ , were represented not by a single slope but by a series of tangents to the curves and in which the variation of C_n with ψ was included, were made for two motions to illustrate the effect of these nonlinearities. The results are given in figures 36 and 37 along with the flight motion and the calculations made for linear slopes and constant damping derivatives. The effect of the aileron waggle was small and was taken to be the same as for the linear calculation. These figures indicate that for the angles of sideslip encountered in these motions little is to be gained by going to the additional effort required to make the calculations for the nonlinear case. The nonlinear calculations required approximately ten times as long to complete as the linear calculations. Motions at large angles of sideslip or motions for a configuration having more pronounced nonlinearities than for the airplane considered herein would undoubtedly show the nonlinearities to be of greater significance.

SUMMARY OF RESULTS

The investigation indicated that the lateral disturbed motions of the airplane considered herein may be generally calculated with good accuracy by the use of experimental-scale-model data up to lift coefficients where any appreciable effects of the difference in Reynolds number between the scale and flight conditions begin to be apparent. This effect is usually evidenced by a departure of the scale results from a gradual variation with lift coefficient and, for the case investigated, corresponds to a lift coefficient of 0.8 for the slotted-wing configurations. At higher lift coefficients the accuracy in calculating flight motions is progressively

FIGURE 17.—Variation of yawing-stability derivatives with angle of yaw. Large ventral fin on; 40-percent-span slots; $R=0.8 \times 10^6$.

poorer, especially in the time to damp to half amplitude where errors as much as 100 percent or more may be encountered. For the airplane of this investigation, at these high lift coefficients, the calculated time to damp to half amplitude was generally higher than the flight value. In most cases the period of the motion could be calculated to within 5 percent of that obtained in the flight motion. In order to obtain good accuracy in predicting flight motions, proper consideration of all control movements must be made.

For most cases, the nonlinear variation of the directional-stability parameter, the effective dihedral parameter, and the variation of the damping in yaw with angle of yaw could

be neglected. If, however, the flight motions reach a sufficiently large amplitude for a long period of time, as in an aileron roll for example, greater accuracy in the calculated motions should result if the nonlinearities in the variation of yawing-moment coefficient, rolling-moment coefficient, and damping in yaw with angle of yaw are included in the calculations.

APPENDIX

LATERAL EQUATIONS OF MOTION

The lateral equations of motions used for most of the calculations of this report consider the fluctuation of the aerodynamic forces to be directly proportional to the component angular and translational velocities associated with the axis system as is customary in classical stability theory. The modification to these equations to account for the nonlinear effects of sideslip is discussed in the text. The equations used herein contain the necessary product of inertia and control terms and are given as follows:

Roll

$$C_{l_{\delta_r}} \delta_r + C_{l_{\delta_a}} \delta_a + C_{l_{\beta}} \beta + \frac{1}{2} C_{l_p} D\varphi + \frac{1}{2} C_{l_r} D\psi = 2\mu \left\{ \left[\left(\frac{k_{x_0}}{b} \right)^2 \cos^2 \eta + \left(\frac{k_{z_0}}{b} \right)^2 \sin^2 \eta \right] D^2 \varphi + \left[\left(\frac{k_{z_0}}{b} \right)^2 - \left(\frac{k_{x_0}}{b} \right)^2 \right] \cos \eta \sin \eta D^2 \psi \right\}$$

Yaw

$$C_{n_{\delta_r}} \delta_r + C_{n_{\delta_a}} \delta_a + C_{n_{\beta}} \beta + \frac{1}{2} C_{n_p} D\varphi + \frac{1}{2} C_{n_r} D\psi = 2\mu \left\{ \left[\left(\frac{k_{z_0}}{b} \right)^2 \cos^2 \eta + \left(\frac{k_{x_0}}{b} \right)^2 \sin^2 \eta \right] D^2 \psi + \left[\left(\frac{k_{z_0}}{b} \right)^2 - \left(\frac{k_{x_0}}{b} \right)^2 \right] \cos \eta \sin \eta D^2 \varphi \right\}$$

Sideslip

$$C_{Y_{\delta_r}} \delta_r + C_{Y_{\delta_a}} \delta_a + C_{Y_{\beta}} \beta + \frac{1}{2} C_{Y_p} D\varphi + \frac{1}{2} C_{Y_r} D\psi + C_L \varphi + C_L \psi \tan \gamma = 2\mu (D\beta + D\psi)$$

REPORT 1032

A COMPARISON OF THEORY AND EXPERIMENT FOR HIGH-SPEED FREE-MOLECULE FLOW¹

By JACKSON R. STALDER, GLEN GOODWIN, and MARCUS O. CREAGER

SUMMARY

A comparison is made of free-molecule-flow theory with the results of wind-tunnel tests performed to determine the drag and temperature-rise characteristics of a transverse circular cylinder.

The model consisted of a 0.0031-inch-diameter cylinder constructed of butt-welded iron and constantan wires. Temperatures were measured at the center and both ends of the model. The cylinder was tested under conditions where the Knudsen number of the flow (ratio of mean-free-molecular path to cylinder radius) varied between 4 and 185. The molecular speed ratio (ratio of stream speed to the most probable molecular speed) varied from 0.5 to 2.3. In terms of conventional flow parameters, these test conditions correspond to a Mach number range from 0.55 to 2.75 and a Reynolds number range from 0.005 to 0.90.

The measured values of the cylinder center-point temperature confirmed the salient point of the heat-transfer analysis which was the prediction that an insulated cylinder would attain a temperature higher than the stagnation temperature of the stream.

Good agreement was obtained between the theoretical and the experimental values for the drag coefficient. As predicted, theoretically, the drag coefficient was independent of Knudsen (or Reynolds number) variation and depended primarily upon the molecular-speed ratio.

INTRODUCTION

The various phenomena connected with the high-speed flows of rarefied gases have recently been the subject of several analytic investigations (references 1, 2, 3, and 4). Interest in this phase of aerodynamics and thermodynamics has been aroused primarily because of the necessity of being able to compute forces on and heat transfer to missiles which may fly at great altitudes at high speed. In another analytic exploration of this field, simplified concepts of aerodynamic and thermodynamic phenomena occurring at high altitudes have been used by Whipple (reference 5) in an investigation of the properties of the upper atmosphere by means of measurements of the brightness and deceleration of meteors.

Experimental work in the field of high-speed rarefied gas flows has been practically nonexistent up to this point. The pioneer work of Epstein (reference 6) on the drag of spheres

in a rarefied gas was concerned only with very low-speed motions. Consequently, the purpose of the present investigation was twofold: (1) to obtain experimental data that could be compared with the predictions of an analytic treatment of aerodynamic and thermodynamic processes occurring at very high altitudes; and (2) as a means to this end, to develop a wind-tunnel and related instrumentation that would permit testing of models under simulated conditions of high-altitude high-speed flight. In connection with the second objective—the development of a wind tunnel and instrumentation—it should be pointed out that a low-density wind tunnel is being developed concurrently at the University of California and the authors wish to acknowledge the assistance they have received from the reports issued by this group, as well as the stimulus received from conversations with the University of California personnel.

At the beginning of the experimental work, it was decided that the initial model tests in the low-density wind tunnel should be confined to the free-molecule-flow regime despite the fact that this regime is probably of less technical importance than the slip-flow and intermediate regimes. This decision was reached because the free-molecule regime is susceptible to analysis; whereas the slip-flow and intermediate regimes have not yet been adequately treated (cf., reference 2). In view of the many uncertainties connected with the development of entirely new types of wind-tunnel instrumentation, it was thought to be essential to test in a field where the experimental work could be guided by a theoretical background.

The selection of the test body was governed both by the requirement that free-molecule flow be obtained and by the practical considerations arising from tunnel size and instrumentation. The former condition required that the significant body dimension be small compared to the mean-free-molecular path.

A cylinder with axis perpendicular to the stream was chosen as the body which most nearly fulfilled the requirements of the test. The radius of the cylinder could be made small compared with the mean-free path. In addition, since it was desired to measure both aerodynamic forces and body temperature, the cylinder had the virtue of being doubly symmetrical so that only drag force had to be measured. The problem of temperature measurement could

¹ Supersedes NACA TN 2244, "A Comparison of Theory and Experiment for High-Speed Free-Molecule Flow" by Jackson R. Stalder, Glen Goodwin, and Marcus O. Creager, 1950.

be solved by constructing the model from dissimilar metals so that the model itself formed a thermocouple.

The present investigation is a first step toward an attempt to gain an understanding of the comparatively new and unexplored field of high-speed low-density flows. The experiments reported herein were made to provide a comparison with some important results of free-molecule-flow theory and to facilitate the solution of problems connected with the design, operation, and instrumentation of a low-density wind tunnel. The tests were conducted in the Ames low-density wind tunnel.

ANALYSIS

The general problem of the calculation of aerodynamic forces and heat transfer to a body in a free-molecule-flow field is amenable to solution by application of the simpler concepts of the kinetic theory of gases. The simplification arises from the assumption that the motions of molecules that strike the body are in no way affected by collisions with molecules that have struck the body and have returned to the main stream of gas. This basic postulate allows the molecular motions of the oncoming stream to be treated as having the classical Maxwellian velocity distribution superimposed on a uniform mass velocity. Hence, the severe complication of dealing with a nonuniform-gas is avoided. Of course, this assumption does not imply that returning molecules do not collide with oncoming molecules since collisions do occur, on the average, at a distance from the body equal to one mean free path. However, if this mean free-path length is large compared with the body dimensions, it can be seen from geometrical considerations that the probability is small that the impinging molecules that do collide with returning molecules will strike the body without first having had their original Maxwellian velocity restored by collisions with other impinging molecules. It would seem probable, also, that a high value of mass velocity compared with the random thermal velocity of the gas would favor free-molecule flow because the re-emitted molecules would tend to be swept along with the stream away from the zone of influence of the body.

In general, the mechanism of energy and momentum transfer for free-molecule flow are inseparable. In effect, this means that the drag on a body is affected by the surface temperature of the body. This state of affairs arises because of the fact that a portion of the momentum imparted to the body is due to the emission of molecules from the surface and the velocity of emission depends upon the temperature of the body. This phenomenon will be discussed in detail later.

Because of the assumption that the motions of the oncoming and re-emitted molecules can be treated independently, the computation of the drag on and heat transfer to a cylinder can be broken down into separate parts—the part due to impact by impinging molecules and a part due to re-emission of the molecules from the surface. By the use of this basic principle, it is possible to calculate the drag and heat-transfer characteristics of a transverse cylinder in a free-molecule-flow field.

HEAT TRANSFER TO A TRANSVERSE CYLINDER IN A FREE-MOLECULE-FLOW FIELD

The calculation of the heat-transfer or energy-exchange process between the cylinder and the gas is made by using the basic method described in reference 4. The general equations of reference 4 are expressed in Cartesian coordinate form and can be summarized as follows:

The translational molecular energy incident upon the front side of an elemental plane area dA inclined at an angle θ with respect to the stream mass velocity U is, for a monatomic gas,

$$dE_i = n \left(\frac{mU^2}{2} + \psi kT \right) dA \quad (1)$$

where n , the number of molecules striking unit surface area per second, is given by

$$n = \frac{Nv_m}{2\sqrt{\pi}} \chi \quad (2)$$

For the rear side of the elemental area, similar expressions apply.

$$dE_i' = n' \left(\frac{mU^2}{2} + \psi' kT \right) dA \quad (3)$$

$$n' = \frac{Nv_m}{2\sqrt{\pi}} \chi' \quad (4)$$

The total molecular energy incident upon the front and rear sides of dA is, for a monatomic gas, given by equations (1) and (3), respectively, since only translational energies are involved. However, for a diatomic gas, the expression for the incident energy contains an additional term due to the rotational component of the molecular internal energy, and this component must be added to the translational component. The rotational energy per molecule of a gas composed of rigid dumbbell molecules is

$$E_R = kT \quad (5)$$

Then, the total incident molecular energy on the front side of dA is, for a diatomic gas, given by the following expression:

$$dE_i = dE_i + nE_R dA = n \left[\frac{mU^2}{2} + (\psi + 1)kT \right] dA \quad (6)$$

and, for the rear side of dA ,

$$dE_i' = dE_i' + n'E_R dA = n' \left[\frac{mU^2}{2} + (\psi' + 1)kT \right] dA \quad (7)$$

The method of calculation of the energy transported from the elemental area by re-emitted molecules is shown in appendix A. The result derived therein can be applied to the calculation of the energy transport by a monatomic gas from the front side of the area by combining equations (A1) and (A12) to yield

$$dE_r = dE_i(1 - \alpha) + 2\alpha n k T_c dA \quad (8)$$

and, for the energy transport by a diatomic gas, as

$$dE_r = (dE_i + n k T dA)(1 - \alpha) + 3\alpha n k T_c dA \quad (9)$$

Parallel equations can be written for the rear side of the area, dA .

The net radiant energy exchange is (assuming gray-body radiation)

$$\epsilon \sigma (T_c^4 - T_i^4) dA \quad (10)$$

where T_i is the effective temperature of the surroundings to which the area dA is radiating. This expression implies that the body of which dA is a part is small in comparison with the surrounding volume.

The problem now becomes one of applying the foregoing equations, which were derived for a plane area placed at an

arbitrary angle with respect to the stream, to a specific body—in this case a cylinder with axis perpendicular to the stream velocity. For a cylinder of length L , the elemental area may be written as

$$dA = rLd\theta \quad (11)$$

$$2\alpha rL \left[\int_0^{\pi/2} n \left(\frac{mU^2}{2} + \psi kT \right) d\theta + \int_0^{\pi/2} n' \left(\frac{mU^2}{2} + \psi' kT \right) d\theta \right] - 4\alpha rLkT_c \left(\int_0^{\pi/2} n d\theta + \int_0^{\pi/2} n' d\theta \right) + 2\pi rL \left[Q - \epsilon \sigma (T_c^4 - T_i^4) \right] = 0 \quad (12)$$

For a diatomic gas, a similar equation applies

$$2\alpha rL \left\{ \int_0^{\pi/2} n \left[\frac{mU^2}{2} + (\psi + 1)kT \right] d\theta + \int_0^{\pi/2} n' \left[\frac{mU^2}{2} + (\psi' + 1)kT \right] d\theta \right\} - 6\alpha rLkT_c \left(\int_0^{\pi/2} n d\theta + \int_0^{\pi/2} n' d\theta \right) + 2\pi rL \left[Q - \epsilon \sigma (T_c^4 - T_i^4) \right] = 0 \quad (13)$$

The reduction of the integrals appearing in equations (12) and (13) is a straightforward but lengthy procedure. The methods used to evaluate these integrals are given in appendix B. The final results are written here, for a monatomic gas, as

$$\begin{aligned} & 2 \frac{T_c}{T} (Z_1 + Z_2) - \left[Z_1 (s^2 + 2) + Z_2 \left(s^2 + \frac{5}{2} \right) \right] + \\ & \frac{2\pi^{3/2}}{pv_m \alpha} \left[\epsilon \sigma (T_c^4 - T_i^4) - Q \right] = 0 \end{aligned} \quad (14)$$

and, for a diatomic gas, as

$$\begin{aligned} & 3 \frac{T_c}{T} (Z_1 + Z_2) - \left[Z_1 (s^2 + 3) + Z_2 \left(s^2 + \frac{7}{2} \right) \right] + \\ & \frac{2\pi^{3/2}}{pv_m \alpha} \left[\epsilon \sigma (T_c^4 - T_i^4) - Q \right] = 0 \end{aligned} \quad (15)$$

In order to facilitate computation, values of the dimensionless groups,

$$\begin{aligned} f(s) &= Z_1 (s^2 + 3) + Z_2 \left(s^2 + \frac{7}{2} \right), \\ g(s) &= 3(Z_1 + Z_2), \\ f^o(s) &= Z_1 (s^2 + 2) + Z_2 \left(s^2 + \frac{5}{2} \right), \end{aligned}$$

and

$$g^o(s) = 2(Z_1 + Z_2),$$

appearing in equations (14) and (15), are tabulated in the table of appendix B.

Equations (14) and (15) then completely describe energy transfer occurring between a transverse cylinder and its surroundings in terms of the cylinder temperature, static gas temperature and pressure, molecular-speed ratio, accommodation coefficient, the effective temperature of the surroundings to which the cylinder is emitting radiation, the emissivity of the cylinder surface, and the internal energy input to the cylinder. The equations are subject to the following restrictions:

1. The surface temperature of the cylinder is assumed to be constant, circumferentially.

2. The cylinder receives and emits radiant energy as a gray body; that is, the emissivity is independent of wave length. Also, the cylinder is assumed to be small compared to the surrounding volume.

3. The internal energy of the gas stream in which the cylinder is located has the value $(3/2) kT$ for a monatomic gas and $(5/2) kT$ for a diatomic gas.

Then, if internal energy input to the cylinder per unit area is denoted as Q (in the usual experimental arrangement this would be electrical energy), an equation can be written which expresses an energy balance on the cylinder. For a monatomic gas, the energy-balance equation is

DRAG ON A TRANSVERSE CYLINDER IN A FREE-MOLECULE-FLOW FIELD

The general problem of aerodynamic forces acting on bodies in free-molecule flow has been treated by several authors (references 1, 2, and 3). The basic method of calculation was identical in each case. The method consists of the assumption of a gas with a Maxwellian velocity distribution superimposed upon an arbitrary mass velocity. The number of molecules having specified velocities that impinge upon an elemental area inclined at an arbitrary angle to the stream mass velocity is computed and, from this calculation, the force due to the transmitted momentum is obtained. To this momentum due to molecular impingement, however, must be added the momentum imparted to the surface by molecules emitted from the surface. The magnitude and direction of the force imparted by emitted molecules depends, among other things, on the type of emission that is assumed to occur. A condensed discussion of the several possible types of surface emission can be found in reference 4. An extensive treatment of the subject is given in reference 7.

In order to determine the total aerodynamic force on a body of arbitrary shape, the differential momentum imparted to an element of the body surface is computed, as outlined in the preceding paragraph, and the total momentum obtained by integration over the body surface. Also, since the impinging and re-emitted momenta can be added linearly, the resulting total momentum can be calculated for any desired type of re-emission.

In this paper, completely diffuse scattering of the incident molecular stream from an insulated surface is assumed. By this assumption it is meant that (a) the molecules that are scattered from the surface are emitted with a Maxwellian distribution of speed, (b) the direction of molecular emission from the surface is controlled by the Knudsen cosine law (cf., references 7 and 8), (c) the body temperature is assumed to be uniform over the surface, and further (d) that conservation of number of molecules is maintained for each element of the body surface. These assumptions seem to be in accord with physical fact, as discussed in reference 6.

The specific problem of the aerodynamic drag on a transverse cylinder has been treated in references 1 and 3. The reason for repetition of the calculation here is that the results have been obtained in a compact closed form which is amenable to easy calculation and, further, that a solution for the re-emission drag is obtained which involves measurable physical quantities. Appendices A and C contain the

details of the calculations and only the final results are presented here. The results of the computations are as follows: The total drag acting on an insulated transverse circular cylinder of radius r and length L is given by

$$D = \frac{\rho U^2}{2} (2rL)(C_{D_i} + C_{D_r}) \quad (16)$$

where C_{D_i} and C_{D_r} are the drag coefficients associated with impinging and re-emitted momenta. The value of C_{D_i} is shown in appendix C to have the value

$$C_{D_i} = \frac{\pi^{1/2} e^{-s^2/2}}{s} \left\{ I_0(s^2/2) + \left(\frac{1+2s^2}{2} \right) \left[I_0(s^2/2) + I_1(s^2/2) \right] \right\} \quad (17)$$

and the value of C_{D_r} for an insulated cylinder is shown in appendix A to be, for a monatomic gas,

$$C_{D_r} = \frac{\pi^{3/2}}{4s} \sqrt{\frac{Z_1(s^2+2) + Z_2\left(s^2 + \frac{5}{2}\right)}{2(Z_1 + Z_2)}} \quad (18)$$

and, for a diatomic gas,

$$C_{D_r} = \frac{\pi^{3/2}}{4s} \sqrt{\frac{Z_1(s^2+3) + Z_2\left(s^2 + \frac{7}{2}\right)}{3(Z_1 + Z_2)}} \quad (19)$$

APPARATUS AND TEST METHODS

THE WIND TUNNEL

The Ames low-density wind tunnel, in which the present tests were conducted, is an open-jet nonreturn-type tunnel. A sketch showing the major components of the wind tunnel is shown in figure 1. The test gas, from a bottled source, is throttled into a settling chamber and then passes through an axially symmetric nozzle which discharges a free jet into an 18-inch cubical test chamber. The test chamber is connected through a surge chamber to four booster-type oil-diffusion pumps which continuously evacuate the system. The diffusion pumps are connected in parallel and are backed by a mechanical vacuum pump which discharges to the atmosphere. Valves are provided at the inlet to each diffusion pump in order to allow the pumping system to be isolated when the test chamber is opened to the atmosphere.

A traversing mechanism is installed in the test chamber which permits three degrees of motion relative to the gas stream. The mechanism is used to position models and instrumentation in the desired location within the gas stream.

The nozzles used in the tests were axially symmetric with an outlet diameter of 2 inches and were machined from clear plastic. The nozzle contours were determined by the method outlined in reference 9. No boundary-layer correction was applied to the nozzle contours.

After the system was evacuated, the flow rate of the test gas into the settling chamber was adjusted until the stagnation pressure, as measured by a McLeod gage, reached the desired value.

The static pressure in the test chamber was read on another McLeod gage and, if the resulting pressure ratio was that

required to establish flow at the particular Mach number desired for the run, the tunnel was considered ready for tests. In order to match tunnel conditions of static pressure and pressure ratio with those that existed at an earlier time, it was sometimes necessary to alter the amount of throttling at the pump inlets due to a slight variation of pumping speed from day to day.

The pressure level in the tunnel was varied by increasing or decreasing the flow of the test gas into the system. The static and stagnation pressures were again checked to determine if sufficient pressure ratio was available to establish flow at the desired Mach number. This procedure was somewhat complicated by the fact that at the lower pressure levels the boundary layer in the nozzle would tend to thicken, thus causing a decrease in the Mach number compared with that obtained at the higher pressure levels.

The wind tunnel could be operated through a range of test-section pressures of from 20 to 135 microns of mercury for a given nozzle and over a range of Mach numbers from 0.5 to 2.75 by using several nozzles.

INSTRUMENTATION AND THE TEST MODEL

The static pressures which existed in the wind tunnel were, in general, too low to be measured with a conventional manometer or Bourdon-type pressure gage; therefore, two types of gages widely used in high-vacuum work were utilized, namely, the McLeod and Pirani gages. For a complete description of these gages the reader is referred to any standard text on high-vacuum technique (e. g., reference 10); however, some of the special features of the gages used will be described.

The McLeod gage used as a primary standard in these tests had an initial volume of 146 milliliters connected to a closed tube of 1.95-millimeter diameter. This arrangement gave a scale length of 51.4 centimeters for a pressure range of 0 to 3000 microns. (For the sake of brevity, the term micron is used throughout as a unit of pressure rather than the term microns of mercury.) The diameter of the closed tube was measured by the mercury pellet method to within ± 0.01 millimeter and the difference in height of the mercury columns could be read to the nearest 0.1 millimeter by use of a micrometer scale. At a pressure of 100 microns, this gage could be read to within 1 percent with ease.

The gage was connected to the test chamber with an 18-millimeter-diameter glass tube to insure a short time lag between equalization of the system and the gage pressures. A dry-ice and acetone cold trap was provided between the gage and the test chamber to prevent condensable vapors from reaching the gage.

In general, it is difficult to obtain a completely independent method of checking the accuracy of pressure measurements made with a McLeod gage for pressures below about 1 millimeter of mercury. Above 1 millimeter of mercury a U-tube manometer, filled with a very low-vapor-pressure oil and having a high-vacuum system (of the order of 10^{-5} mm of Hg) connected to one leg, may be used. The McLeod gage used in the tests was checked in this manner and the agreement between the oil manometer and the McLeod gage was within ± 3 percent.

FIGURE 1.—Ames low-density wind tunnel.

An indication of the accuracy of the McLeod gage used in the tests in the pressure range below 200 microns was obtained by comparing the pressures indicated by the test McLeod gage with those obtained with a laboratory-type McLeod gage having a range of 0 to 200 microns, which has been calibrated against a laboratory standard McLeod gage at the manufacturer's plant. The agreement between the test gage and the laboratory-type gage was within ± 3 percent at a pressure of 100 microns.

The Pirani gage used in the tests consisted of an open glass tube, which contained a heated filament. The gas pressure in the tube determined the temperature and thus the resistance of the filament. A temperature-compensating tube of identical construction was sealed off at a very low pressure. The measuring and compensating tube filaments formed two legs of a Wheatstone bridge; and the unbalance of the Wheatstone bridge circuit, as indicated by a self-balancing potentiometer, was a measure of the pressure in the open leg of the gage. The Pirani gage was calibrated against the 0- to 3000-micron-range McLeod gage as a standard.

A drift of the calibration of the Pirani gage with time was noted and for this reason the Pirani gage was calibrated

before and after every test run. A typical calibration curve is shown in figure 2.

Examination of figure 2 reveals that the sensitivity of the Pirani gage used was nearly constant from a pressure of 10 microns to a pressure of 80 microns. Above about 200 microns this Pirani gage becomes too insensitive to be usable as a pressure-measuring instrument.

FIGURE 2.—Typical calibration of Pirani gage in nitrogen gas.

FIGURE 3.—Impact-pressure-measuring system.

Whenever a pressure-measuring device is connected to a vacuum system by a tube or small orifice, two troublesome effects are present—time lag and gassing. The time lag of the pressure gage is due to the fact that, as the pressure in the main part of the system is changed, a volume of gas must flow out of or into the pressure gage and its connecting tubing. At the low pressures encountered during the tests, this time lag may be of the order of hours if the gage volume and connecting tubing are not properly proportioned. Gassing, that is, gas being given up or adsorbed by the surface of the pressure gage and its connecting tubing, has the effect of causing the pressure gage to indicate a different pressure than that which exists in the main part of the system. Outgassing effects can be reduced materially by proper cleaning of the surface and by heating the surface under a vacuum to drive off water vapor and other materials which cling to ordinary surfaces.

Schaaf, Mann, and Cyr (references 11 and 12) have investigated this problem in considerable detail, and show that, if the assumption is made that gassing is a function of surface area only, there exists an optimum geometry of gage volume and connecting tubing which will result in minimum time lags. References 11 and 12 were used as guides in the design of the impact and static-pressure-measuring devices which were used in the tunnel calibration tests, and, in addition, the time lag of these pressure-measuring systems was measured.

The impact pressures encountered during the wind-tunnel-calibration tests were too high to be measured with a Pirani gage and, because of the difficulty of obtaining a suitable flexible tube which would have a small time lag, the McLeod gage could not be used. These impact pressures, therefore, were measured with a glass U-tube manometer filled with a low-vapor-pressure oil. The manometer was located inside

the test chamber with one leg of the manometer open and the other end fastened with a glass connection to a 1/8-inch-diameter spherical-head impact tube. Figure 3 shows a diagrammatic sketch of this arrangement. The difference in oil level between the two legs, as read by a coordinate-type cathetometer located outside the tunnel, was the difference between the test-chamber static pressure and the impact pressure. The test-chamber static pressure was measured by the 0- to 3000-micron McLeod gage described earlier.

The time lag of the system shown in figure 3 was measured by setting the pressure in the test chamber at approximately 3 millimeters of mercury and then evacuating the chamber to approximately 10 microns as quickly as possible. The time required for the oil level in the two legs to equalize was approximately 15 seconds. This indicates a very short time lag for the practical case as the rate of pressure change encountered in the wind-tunnel calibration was small compared to that measured during the time-lag test. The procedure used in the wind-tunnel-calibration tests was to continue to take readings of the oil level until steady state was established.

The static pressure of the gas stream from the nozzle was measured with a 0.10-inch-diameter ogival probe connected directly to a Pirani gage as shown in figure 4. Three 0.0225-inch-diameter holes spaced 120° apart were located at a point on the ogive where the pressure is equal to free-stream pressure as calculated by the method given in reference 13. The position along the probe where the surface pressure is equal to free-stream pressure varies somewhat with Mach number; however, this variation is

FIGURE 4.—Static-pressure-measuring system.

not large and static pressures measured by this probe agreed with pressures measured with a 4° cone.

No boundary-layer correction was applied to the ogive, or cone contour; consequently, it is possible that some error in the measurement of static pressure existed. Figure 5 shows the main dimensions of the static-pressure probe used.

In order that the Pirani gage shown in figure 4 could be calibrated against the McLeod gage, which was connected to the test chamber, a 4-millimeter-bore stopcock was glass-welded to the Pirani gage to allow calibration with a relatively large opening and attendant short time lag. As the stream static pressures were measured with the stopcock closed, the following tests were conducted to measure the order of magnitude of the time lag of the system. The test chamber was pressurized to 165 microns and suddenly evacuated to approximately 5 microns. The rate of pressure change as measured by the Pirani gage with the stopcock open and with the stopcock closed is shown in figure 6. The procedure was repeated with a rising pressure and the results are also shown in figure 6.

It can be seen from figure 6 that the two curves, representing the runs with the stopcock open and closed, are essentially congruent after 70 seconds for decreasing pressure and after 50 seconds for the increasing pressure runs. With the stopcock open, the time lag of the Pirani gage should be very small (references 11 and 12) and the curve of pressure as a function of time includes the time required for the pumping equipment to evacuate the test chamber, the time lag in the self-balancing potentiometer, and the thermal lag in the Pirani filaments. The curve of pressure as a function of time for the stopcock closed includes all these factors plus the additional time lag imposed by the small holes in the static probe. The pressure variation during the time-lag tests was much more severe than any encountered during the static survey tests; therefore it can be concluded that, by waiting for at least 2 minutes before recording data, all errors due to time lag would be eliminated.

The test model.—The model tested was a 0.0031-inch-diameter right-circular cylinder fabricated from iron and constantan wires and had an exposed length of $1\frac{1}{2}$ inch.

FIGURE 5.—Static-pressure probe used in the tests.

FIGURE 6.—Time response of the static-pressure-measuring system.

The iron and constantan wires were electrically butt-welded together to form a thermocouple junction. Figure 7 shows a microphotograph of the model. It can be seen that the welding operation did not appreciably alter the shape of the model. The butt-welded junction was located in the center of the model and a 0.0031-inch iron wire was silver soldered to the constantan side of the model at a distance of $\frac{1}{16}$ inch from the center junction. A 0.0031-inch-diameter constantan wire was similarly fastened to the iron side of the model. These two auxiliary thermocouple junctions were used to measure the temperature at the ends of the model.

The entire model was covered with fine-grain soot obtained from an acetylene flame in order that the emissivity would be constant over the total model length and so that an established value of emissivity of 0.95 could be used to evaluate the heat loss by radiation.

Thermocouple voltages from the center and end thermocouples were read on a null-type laboratory potentiometer having a least count of 0.01 millivolt.

The drag balance.—A specially constructed microbalance shown in figures 8 (a) and 8 (b) was used to measure the drag of the model tested. The balance consisted of a beam mounted upon an agate knife-edge which rested in a steel V-block, as shown diagrammatically in figure 9. The model was mounted between two arms extending down from either side of the beam. Electrical leads were transferred from the moving beam to the balance frame through mercury pools.

A drag force on the model caused an unbalance of the beam which was counteracted by a magnetic-restoring force produced by an armature located in a magnetic field produced by an alternating-current coil. An optical lever approximately 2 feet long was used to determine the zero position of the balance.

FIGURE 7.—Micro-photograph of model showing weld at junction of iron and constantan. Enlarged 60 times.

The magnitude of the drag force in terms of magnetizing current was determined by hanging known weights on a lever arm attached to the balance beam and measuring the current necessary to restore the balance to zero position. Figure 10 shows a typical calibration of the drag balance.

The model was mounted between the extension arms of the drag balance and was shielded over all but the center $1\frac{1}{2}$ inch, as shown in figures 8 (a) and 8 (b). A check was made on the effectiveness of the shielding on the supporting members. A small shield was mounted to the center main shield (extension arms) covering the center portion of the model (normally exposed). The completely shielded model was then placed in the gas stream. No drag forces were detected.

It was found that the balance exhibited an erratic calibration shift from day to day, which necessitated calibration of the balance before and after each drag determination.

CALIBRATION OF THE WIND TUNNEL

The purpose of the calibration of the wind tunnel was to determine the Mach number and static-pressure distributions of the stream in the plane at which the model was

(a) Front view.

(b) Rear view.

FIGURE 8.—Photograph of drag balance showing force shields.

FIGURE 9.—Diagrammatic sketch of drag balance.

located— $\frac{1}{4}$ inch downstream of the exit plane of the various nozzles used.

The method used was to survey the stream with the impact- and static-pressure probes described earlier. These impact- and static-pressure probes, together with their pressure-measuring gages, were mounted 2 inches apart upon a common support from the traversing mechanism and readings were taken at $\frac{1}{16}$ -inch intervals from the center to the edge of the stream. This method of mounting allowed both the impact and static pressures to be measured during the course of one run, thus obviating the necessity of matching tunnel conditions on separate runs.

Table I lists the nozzles tested, their design Mach number, and the tunnel conditions for which the surveys were made.

The static pressure varied across the stream issuing from each of the nozzles tested. For most of the nozzles, the pressure was somewhat higher near the center portion of the stream than was the pressure of the quiescent gas in the test chamber. Certain of these nozzles, however, did

¹ Average Mach number over center half inch of stream.

FIGURE 10.—Typical calibration curve for drag balance.

not show this general trend. In these nozzles the pressure first decreased, then increased, as the probe was moved from the nozzle wall to the center of the stream. Figures 11 and 12 show this effect. In general, the static-pressure variation across the stream was not large. The average change over the center $\frac{1}{2}$ inch of the stream amounted to 2 percent, while the maximum deviation was only 5 percent.

The impact-pressure surveys of all the nozzles had one common characteristic; that is, the impact pressure increased from a minimum value at the edge of the nozzle wall to a maximum value near the center of the stream. The area of the stream which had a constant, or nearly constant, impact pressure varied somewhat from nozzle to nozzle, and also to some extent with pressure level. The average variation of impact pressure over the center $\frac{1}{2}$ inch of the stream for all nozzles tested was 7 percent with a maximum variation

FIGURE 11.—Variation of impact and static pressure with nozzle radius for nozzle number 1 using nitrogen gas.

in some cases of 14 percent. Figures 11 and 12 show the variation of impact pressure across the stream for one nozzle using two gases, nitrogen and helium.

The Mach number of a gas stream can be computed from measured values of the stagnation and static pressure of the stream, provided that the flow is isentropic between the points of pressure measurement. However, if the static and impact pressures are measured at the same point in the stream, no assumption regarding the nature of the flow need be made in order to compute the local stream Mach number. For an inviscid flow, the Mach number can be calculated from Rayleigh's equation, the use of which involves the assumption of a normal shock wave ahead of the impact-pressure tube and isentropic compression of the gas in the subsonic flow behind the shock wave to the stagnation point on the impact-pressure tube. In a low-density flow, however, viscous effects are present in the flow about a stagnation region, thus invalidating the assumption of isentropic compression behind the normal shock wave. Chambré (reference 14) computed the viscous correction to be applied to spherical-head impact tubes in a low-density flow, and figure 13 shows the Mach number distribution of nozzle 1 as computed by the Rayleigh equation (inviscid) and as computed by Chambré's equation. The Mach numbers calculated from the stagnation and local static pressures were,

FIGURE 12.—Variation of impact and static pressure with nozzle radius for nozzle number 1 using helium gas.

FIGURE 13.—Comparison of Mach number distribution in nozzle number 1 as calculated with and without viscous correction, test gas, nitrogen.

in all cases, higher than those computed using local values of impact and static pressure, thus indicating that the flow through the nozzle was nonisentropic due to viscous effects. Chambré's equation was used to compute Mach number from measured static and impact pressures for the tests described herein.

The variation of impact and static pressure across the stream resulted in a stream in which the Mach number was not constant. Figures 13 and 14 show this effect and are generally representative of all nozzles tested. If only the center $\frac{1}{2}$ inch of the nozzles is considered, the average variation in Mach number amounted to 5 percent; however, at certain pressure levels in some of the nozzles the variation was as much as 14 percent.

In order to determine if shock waves were present in the center $\frac{1}{2}$ inch of the gas stream, the nitrogen-glow-discharge technique of flow visualization was used to examine the flow qualitatively. This technique was originally described in reference 15. The method used to generate the glow discharge was to pass the test gas through a screen which was connected to a pulsed direct-current power supply. The screen was located at the entrance plane to the nozzle and was pulsed to a negative peak potential of 1000 volts. The pulsation frequency was 1000 cycles per second.

Figure 15 shows the gas stream from nozzle 1 at a static pressure of 114 microns. A 5° half-angle wedge was placed in the stream to generate a relatively weak shock wave which could be used as a yardstick to evaluate the strength of the nozzle shocks, if present. No shock waves were

FIGURE 14.—Comparison of Mach number distribution in nozzle number 1 as calculated with and without viscous correction, test gas, helium.

observed in the gas stream at this pressure level if the wedge was removed. As the static-pressure level was lowered, the shock wave from the wedge became too indistinct to be photographed. Observation of the nitrogen glow did not indicate the presence of strong shock waves in the nozzles.

DRAW AND HEAT TRANSFER TESTS

The test procedure used in the drag and heat-transfer experiments was to calibrate the drag balance with the tunnel shut down and then to set tunnel conditions corresponding to those obtained during tunnel-calibration tests by matching the stagnation and test chamber static pressures. As extremely close control over tunnel conditions was difficult to attain, the pressure level during certain test runs

FIGURE 15.—Shock wave from 5° half-angle wedge at pressure of 114 microns as seen with nitrogen glow discharge.

varied approximately 5 percent from those obtained during the tunnel-calibration tests. Examination of the results of the tunnel-calibration tests showed that Mach number variation is small for small changes in the pressure level; therefore, the Mach number obtained during nozzle-calibration tests was applied to the heat-transfer and drag tests without correction. The Mach number used in plotting the data (which was converted numerically to molecular-speed ratio by means of the relation $s = M \sqrt{\gamma/2}$) was the average value obtained from a graphical integration of the Mach number distribution across the center $1\frac{1}{32}$ inch of the stream.

After stable operating conditions had been attained, the drag force, model temperatures, and other pertinent data were recorded. Table II lists the recorded data. It will be noted that, in the column listing the recorded drag force, two values occur on some of the runs. The different values were due to separate drag measurements during the course of one run or resulted from small shifts in the calibration of the drag balance as determined before and after each run. In the figures which are later presented, showing drag coefficients, the points correspond to those calculated using the average of the two values listed in table II.

To determine if the model surface conditions were changing with time, the model drag and temperature were measured at $\frac{1}{2}$ -hour intervals over a period of 6 hours for one particular test condition. Figures 16 and 17 show the results of these tests and it can be seen that the drag coefficient and temperature ratio remained essentially constant, thus indicating that the accommodation coefficient and tunnel conditions were constant over this period of time.

The reproducibility of the data was checked by repeating the above-described run on separate days. The reproducibility was found to be within the accuracy of the drag and temperature measurements described above.

RESULTS AND DISCUSSION

A DISCUSSION OF THE ASSUMPTIONS AND RESULTS OF THE THEORETICAL ANALYSIS

An examination of the heat-transfer equations (14) and (15) for a monatomic and a diatomic gas, respectively, reveals several interesting features. If an adiabatic case is considered, that is, if both internal-energy input to the cylinder and radiant-energy exchange are considered absent, it can be seen that the ratio of cylinder temperature to free-stream static temperature is a unique function of the molecular-

FIGURE 17.—Variation of the ratio of model to free-stream temperature, T_c/T with time.

speed ratio. The values of the temperature ratio computed from equations (14) and (15) are shown in figure 18. For comparison, curves of the temperature ratio for continuum flow are also shown. These latter curves were computed for the case where the total stream energy is recovered—in other words, the temperature recovery factor was considered to be unity. Several remarkable conclusions can be drawn from an examination of this figure. It can be seen that an insulated cylinder in a free-molecule-flow field will attain a higher temperature at a given value of molecular-speed ratio (or Mach number) than will be obtained in a continuum flow field. Since the continuum curves also represent the temperature ratio of a gas that has been accelerated adiabatically from rest to any value of molecular speed ratio, it may be inferred that an insulated cylinder located in a low-density wind tunnel under free-molecule-flow conditions will attain a temperature which exceeds the total temperature of the gas stream. This result, of course, is in direct contrast to the corresponding phenomenon which occurs under con-

FIGURE 18.—Variation of the ratio of cylinder temperature to free-stream static temperature with molecular speed ratio for an adiabatic cylinder in free-molecule flow.

FIGURE 16.—Variation of measured drag coefficient with time.

tinuum-flow conditions where an insulated body can have, at most, a temperature equal to the stream stagnation temperature and normally does not even attain this temperature due to outward heat flow in the boundary layer. The anomaly can be explained, however, by a consideration, in the case of free-molecule flow, of the magnitudes of the incident and re-emitted molecular energy. The incident molecular energy is computed using the total velocity resulting from combination of the stream mass velocity and the random thermal velocities. When the total velocity term is squared there results a term, which is twice the scalar product of the vector mass velocity and the vector thermal velocity. This scalar product term effectively increases the apparent internal energy of the gas from the continuum value of $3/2 kT$ per molecule to a value varying from $2 kT$ to $5/2 kT$ depending upon the speed and orientation of the body. The apparent internal energy becomes $5/2 kT$ for high speeds and body angles of attack greater than zero. This is just equal to the internal plus potential energy per molecule of a cube of continuum gas. Therefore, the energy incident on the body in free-molecule flow becomes equal to that of a continuum for large values of the molecular speed ratio for surfaces inclined at angles of attack greater than zero. The molecular energy which is re-emitted from the surface is assumed to be equal to the energy of a stream issuing effusively from a Maxwellian gas, in equilibrium at some yet unspecified temperature, into a perfect vacuum. For the case of an insulated body, the temperature of this gas is that of the body. The energy of the re-emitted stream calculated in this manner is equal to $2 kT_w$ per molecule. The corresponding energy for a continuum gas at the same temperature is $5/2 kT_w$ per molecule if both thermal and potential energies are considered. For a given re-emitted stream temperature, a smaller amount of energy per molecule is transported from a body for the case of free-molecule flow than is transported in the case of continuum flow. It is clear that, if the same total amount of energy, namely the incident energy, is to be removed in each case, the effusive stream temperature and, hence, the body temperature for an insulated body must be higher for free-molecule flow than for continuum flow.

It is seen from figure 18, that, theoretically, a higher cylinder temperature is predicted for the case of a monatomic gas than for a diatomic gas. The explanation lies in the additional energy which the diatomic gas is able to remove from the cylinder by virtue of the internal energy component due to molecular rotation. Of course, the impinging diatomic gas transmits more energy to the cylinder due to the rotational energy component; however, the rotational component is a smaller fraction of the total impinging energy than of the total re-emitted energy.

An examination of the equations for the drag coefficient of an insulated cylinder (equations (17) and (18)) shows that the total drag coefficient, $C_D = C_{D_i} + C_{D_r}$, is a function only of the molecular-speed ratio. A plot of the total drag coefficient as a function of the molecular-speed ratio for an insulated cylinder is shown in figure 19. It is notable that the drag coefficient approaches infinity as the molecular-speed ratio approaches zero. Hence, if the expression for total drag is written in the conventional drag-coefficient

FIGURE 19.—The total drag coefficient for an insulated transverse cylinder in a free-molecule flow as a function of the molecular speed ratio, s .

form, it can be shown from equations (17) and (18) that C_D becomes inversely proportional to the speed ratio as s approaches zero. It is also notable that the drag coefficient approaches a constant value as the speed ratio becomes large. This means, simply, that the effect of the random thermal motions becomes negligible as the speed of the cylinder relative to the gas becomes high.

HEAT-TRANSFER TEST RESULTS

The salient point of the analysis concerning heat transfer to a cylinder in a free-molecule field was the prediction that an insulated model would attain a temperature in excess of the tunnel stagnation temperature. This result was observed in all runs. The maximum rise of the model center-point temperature above the tunnel stagnation temperature was 65° F , using nitrogen as the test gas, and 147° F , using helium as the test gas.

The results of the heat-transfer tests are shown in figures 20 and 21 in which the ratio of the cylinder-center temperature to the free-stream static temperature is plotted as a function of the molecular-speed ratio for the nitrogen and helium runs, respectively. The stream-static temperature was computed from the adiabatic relationship, using the measured value of Mach number (or molecular-speed ratio) corresponding to the nozzle pressure ratio as determined from the nozzle-calibration tests. The temperature-ratio curve for continuum flow assuming a temperature-recovery factor of unity is shown for comparison. It will be noted that in all cases the temperature ratio exceeded the maximum which could be attained under continuum-flow conditions. It can be seen that, in general, the test points indicate that the cylinder did not attain the full temperature rise that was predicted by the free-molecule analysis. This result may be ascribed to heat losses occurring from radiation and from conduction along the wire to the end supports.

FIGURE 20.—Variation of the ratio of model temperature to free-stream static temperature with molecular speed ratio for a diatomic gas.

The fact that a large temperature gradient existed along the length of the wire due to end losses is clearly shown by the cylinder-end temperatures which are listed, together with the cylinder center-point temperature, in table II.

DRAG TEST RESULTS

The measured drag force on the cylinder was reduced to conventional dimensionless drag-coefficient form by means of the equation

$$C_D = \frac{D}{\gamma L r p M^2} = \frac{D}{2 L r p s^2} \quad (20)$$

The data points obtained from equation (20) are shown in figure 22. For comparison, the theoretical curves of drag coefficient as a function of molecular-speed ratio for an insulated cylinder, taken from figure 19, are shown as a solid line. It can be seen that agreement between theory and experiment is good considering the limitations of the theory and the difficulties attendant with the measurement of drag forces from 1 to 20 milligrams. The experimental values for the drag coefficient tend to fall below the theoretical values at molecular-speed ratios above about 1.0 and to be higher than the theoretical values at speed ratios below 1.0. The former characteristic may be due to a tendency toward specular reflection at the higher speed ratios while the latter characteristic, at subsonic values of speed ratio, may have been caused by interference with the flow caused by the shields at the ends of the model.

The major premise of the existence of free-molecule flow was borne out by several factors in addition to the good agreement between the calculated and experimental values

FIGURE 21.—Variation of the ratio of model temperature to free-stream static temperature with molecular speed ratio for a monatomic gas.

of drag coefficient. One of the basic assumptions of the drag analysis is that the drag coefficients are independent of Reynolds number or Knudsen number. In contrast, the continuum- and slip-flow regimes are characterized by the dependence of drag coefficients both upon Reynolds number and Mach number (cf., reference 16). Although it was not

FIGURE 22.—Variation of total drag coefficient with molecular speed ratio.

FIGURE 23.—The range of Knudsen numbers and molecular speed ratios covered in the tests. Knudsen number based upon model radius.

experimentally possible to vary the Knudsen number independently of the speed ratio for one test gas, the use of both nitrogen and helium gave overlapping values of speed ratio with an approximate 2:1 variation of Knudsen number. The variation of Knudsen number covered by the tests with molecular-speed ratio is shown in figure 23. No trend is noticeable in the drag coefficients obtained in each case; consequently, it can be concluded that free-molecule flow existed.

A comparison between measured drag coefficient and the drag coefficient calculated by methods as given by Lamb (reference 17) illustrates the inapplicability of continuum theory in the free-molecule regime. A sample calculation made by Lamb's continuum method for conditions of molecular-speed ratio equal to 0.5 and a Knudsen number of 185 (based on cylinder radius) gave a drag coefficient of 390. The corresponding experimental value was 14.6.

CONCLUSIONS

The following conclusions may be drawn from a comparison of the test results with free-molecule-flow theory shown in this report:

1. The salient point of the heat-transfer analysis, which was the prediction that an insulated cylinder would attain a temperature higher than the stagnation temperature of the stream, was confirmed by the test results.

2. Drag coefficients, calculated from free-molecule-flow theory, agreed well with the measured drag coefficients. As predicted theoretically, the measured drag coefficients were independent of the Reynolds and Knudsen numbers and depended primarily upon the molecular-speed ratio.

APPENDIX A

THE MOMENTUM AND ENERGY EXCHANGE PROCESSES ACCOMPANYING MOLECULAR EMISSION FROM A SURFACE

For the case of diffuse scattering of a stream of molecules from a surface, all directional history of the impinging stream is erased upon impact with the surface. The impinging stream is assumed to be scattered in a random manner which will be described in detail later. The energy and momentum carried by the scattered stream depends upon the velocity of emission which can be related to the energy (or temperature) level that the stream has. The effective temperature or energy of the scattered stream depends upon the efficiency of the energy-exchange process that occurs between the solid surface and the impinging stream. This efficiency can be described by introduction of the accommodation coefficient which is defined as

$$\alpha = \frac{E_i - E_r}{E_i - E_w} \quad (\text{A1})$$

where the symbols have the following definitions:

E_i rate of incident molecular energy

E_r rate of re-emitted molecular energy

E_w rate of re-emitted molecular energy that would be carried by the scattered stream if it were a stream issuing from a gas in equilibrium at the surface temperature, T_w

It is assumed that the emitted stream has a Maxwellian distribution of speed corresponding to a gas in equilibrium at an unspecified temperature, T_r . This fictitious gas has, also, an unspecified number of molecules per unit volume, N_r . Now, as shown in reference 8, page 62, the number of molecules scattered from unit surface area per second that have speeds in the range dv and that are moving in a direction that makes an angle lying in the range $d\Omega$ with the normal to the surface is given by

$$dn_r = 2\pi N_r A_r v^3 e^{-\beta_r v^2} \sin \Omega \cos \Omega dv d\Omega \quad (\text{A2})$$

Then, the normal component of force imparted to the surface by this group of molecules is

$$dG_r = 2\pi N_r A_r m v^4 e^{-\beta_r v^2} \sin \Omega \cos^2 \Omega dv d\Omega dA \quad (\text{A3})$$

and the translational energy carried by this group is

$$dE_r = \pi N_r A_r m v^5 e^{-\beta_r v^2} \sin \Omega \cos \Omega dv d\Omega dA \quad (\text{A4})$$

By integration of these expressions with respect to Ω and v , the following values are obtained for the total momentum and energy carried by the scattered stream from dA :

$$dG_r = 2\pi N_r A_r m dA \int_0^\infty v^4 e^{-\beta_r v^2} dv \int_0^{\pi/2} \sin \Omega \cos^2 \Omega d\Omega = \frac{N_r m}{4\beta_r^2} dA \quad (\text{A5})$$

$$dE_r = \pi N_r A_r m dA \int_0^\infty v^5 e^{-\beta_r v^2} dv \int_0^{\pi/2} \sin \Omega \cos \Omega d\Omega = \frac{N_r m}{2\sqrt{\pi}\beta_r^3} dA \quad (\text{A6})$$

In order to obtain a value for N_r in terms of known variables, the number of molecules scattered from the surface is equated to the number of molecules striking the surface. The number of molecules per second scattered from unit area is

$$n_r = 2\pi N_r A_r \int_0^\infty v^3 e^{-\beta_r v^2} dv \int_0^{\pi/2} \sin \Omega \cos \Omega d\Omega = \frac{N_r}{2\sqrt{\pi}\beta_r} \quad (\text{A7})$$

and the number of molecules striking unit area per second is shown in reference 4 to be given by

$$n = \frac{N\chi}{2\sqrt{\pi}\beta} \quad (\text{A8})$$

The value of N_r is obtained by equating n_r and n from equations (A7) and (A8), thus,

$$N_r = N\chi \frac{\beta_r}{\beta} \quad (\text{A9})$$

By substitution of this value of N_r in the momentum and energy equations, the following is obtained:

$$dG_r = \frac{Nm\chi}{4\beta\beta_r} dA \quad (\text{A10})$$

$$dE_r = \frac{Nm\chi}{2\sqrt{\pi}\beta\beta_r^2} dA \quad (\text{A11})$$

An identical analysis yields a value for E_w of

$$dE_w = \frac{Nm\chi dA}{2\sqrt{\pi}\beta\beta_w^2} = 2nkT_w dA \quad (\text{A12})$$

For the case of a diatomic gas where the expression for the re-emission energy per molecule contains an additional term having the value kT_w , which accounts for the rotational energy per molecule, the total re-emission energy has the value $3nkT_w dA$.

Equation (A10) describes the normal re-emission pressure on the front side of a unit inclined area. In order to obtain the net drag force (or pressure) in the direction of the mass velocity U , the pressure on the rear side of the inclined area must be taken into account. The computation of the pressure on the rear side of the area is made in a similar manner to the computation of the pressure on the front side of the area and leads to an expression

$$dG_r' = \frac{Nm\chi'}{4\beta\beta_r} dA \quad (\text{A13})$$

Then, the net drag force due to re-emission pressure in the direction of U , the mass velocity, is

$$dG_r - dG_r' = \frac{Nm \sin \theta}{4\beta\beta_r} (\chi - \chi') dA \quad (\text{A14})$$

Replacing χ and χ' by their values, equation (A14) becomes

$$dG_r - dG_r' = \frac{\sqrt{\pi} N m s \sin^2 \theta}{2\beta\beta_r} dA \quad (\text{A15})$$

This expression can be put into drag-coefficient form by use of the following substitutions: $Nm = \rho$, $s/\beta = U$. Equation (A15) then becomes

$$dG_r - dG_r' = \left(\frac{\rho U^2}{2}\right) \frac{\sqrt{\pi} \sin^2 \theta}{s_r} dA \quad (\text{A16})$$

where s_r is the molecular-speed ratio of the re-emitted stream. Then the re-emission drag coefficient, based on the total area of one side of the plane area, is

$$C_{D_r} = \frac{\sqrt{\pi} \sin^2 \theta}{s_r} \quad (\text{A17})$$

In order to obtain an expression for s_r which contains measurable or calculable physical quantities it is necessary to write an equation expressing an energy balance on the body in question. For the case of an insulated cylinder, if radiant energy exchange is neglected, only molecular energies are involved and the incident molecular energy can be equated to the re-emitted molecular energy. To write an energy balance equation for a transverse cylinder, it is assumed that the energy balance is maintained for the cylinder as a whole and not for individual elements of the cylinder. This means, essentially, that the cylinder has a uniform temperature, circumferentially. The total incident molecular energy on the cylinder is, for a monatomic gas,

$$E_i = \frac{2rL\rho}{4\sqrt{\pi}\beta^3} \left[\int_0^{\pi/2} \chi(s^2 + \psi) d\theta + \int_0^{\pi/2} \chi'(s^2 + \psi') d\theta \right] \quad (\text{A18})$$

The total molecular energy emitted from the cylinder surface is

$$E_r = \frac{2rL\rho}{2\sqrt{\pi}\beta\beta_r^2} \left(\int_0^{\pi/2} \chi d\theta + \int_0^{\pi/2} \chi' d\theta \right) \quad (\text{A19})$$

The values of the integrals are shown in appendix B to be

$$\begin{aligned} \int_0^{\pi/2} \chi d\theta &= \frac{Z_1 + Z_2}{2} + \sqrt{\pi} s \\ \int_0^{\pi/2} \chi' d\theta &= \frac{Z_1 + Z_2}{2} - \sqrt{\pi} s \\ \int_0^{\pi/2} \chi\psi d\theta &= Z_1 + \frac{5}{4} Z_2 + \frac{5}{2} \sqrt{\pi} s \\ \int_0^{\pi/2} \chi'\psi' d\theta &= Z_1 + \frac{5}{4} Z_2 - \frac{5}{2} \sqrt{\pi} s \end{aligned}$$

When E_i and E_r are equated from equations (A18) and (A19) and the values of the integrals are substituted, the following result is obtained:

$$\frac{1}{4\beta^3} \left[s^2(Z_1 + Z_2) + \frac{4Z_1 + 5Z_2}{2} \right] = \frac{1}{2\beta_r^2\beta} (Z_1 + Z_2) \quad (\text{A20})$$

Therefore,

$$\beta_r = \beta \sqrt{\frac{2(Z_1 + Z_2)}{Z_1(s^2 + 2) + Z_2\left(s^2 + \frac{5}{2}\right)}} \quad (\text{A21})$$

A similar analysis for the case of a diatomic gas where the incident molecular energy is

$$E_i = \frac{rL\rho}{2\sqrt{\pi}\beta^3} \left[(s^2 + 1) \int_0^{\pi/2} \chi d\theta + (s^2 + 1) \int_0^{\pi/2} \chi' d\theta + \int_0^{\pi/2} \chi\psi d\theta + \int_0^{\pi/2} \chi'\psi' d\theta \right] \quad (\text{A22})$$

and the re-emission energy is

$$E_r = \frac{3rL\rho}{2\sqrt{\pi}\beta\beta_r^2} \left(\int_0^{\pi/2} \chi d\theta + \int_0^{\pi/2} \chi' d\theta \right) \quad (\text{A23})$$

gives a value of β_r of

$$\beta_r = \beta \sqrt{\frac{3(Z_1 + Z_2)}{Z_1(s^2 + 3) + Z_2\left(s^2 + \frac{7}{2}\right)}} \quad (\text{A24})$$

Now, the total re-emission drag force acting on dA has been shown (cf., equation (A16)) to be

$$dG_r - dG_r' = \left(\frac{\rho U^2}{2}\right) \frac{\sqrt{\pi} \sin^2 \theta}{s_r} dA$$

To obtain the total re-emission drag on a cylinder, equation (A16) must be integrated over the cylinder surface, thus,

$$G_r - G_r' = \left(\frac{\rho U^2}{2}\right) (2rL) \frac{\sqrt{\pi}}{s_r} \int_0^{\pi/2} \sin^2 \theta d\theta = \left(\frac{\rho U^2}{2}\right) (2rL) \frac{\pi^{3/2}}{4s_r} \quad (\text{A25})$$

Then, the re-emission drag coefficient based on the projected cylinder area is

$$C_{D_r} = \frac{\pi^{3/2}}{4s_r} \quad (\text{A26})$$

The final equation for the re-emission drag coefficient for an insulated cylinder in a monatomic gas stream is obtained by using the relation $s_r = U\beta_r$ and taking β_r from equations (A21) and (A24).

$$C_{D_r} = \frac{\pi^{3/2}}{4s} \sqrt{\frac{Z_1(s^2 + 2) + Z_2\left(s^2 + \frac{5}{2}\right)}{2(Z_1 + Z_2)}} \quad (\text{A27})$$

and, for an insulated cylinder in a diatomic gas stream, as

$$C_{D_r} = \frac{\pi^{3/2}}{4s} \sqrt{\frac{Z_1(s^2 + 3) + Z_2\left(s^2 + \frac{7}{2}\right)}{3(Z_1 + Z_2)}} \quad (\text{A28})$$

APPENDIX B

HEAT TRANSFER TO A TRANSVERSE CIRCULAR CYLINDER IN FREE-MOLECULE FLOW

It has been shown (see Analysis) that an energy balance on a cylinder located in a stream of monatomic gas flowing with a velocity U perpendicular to the cylinder axis is expressed by

$$2\alpha r L \left[\int_0^{\pi/2} n \left(\frac{mU^2}{2} + \psi k T \right) d\theta + \int_0^{\pi/2} n' \left(\frac{mU^2}{2} + \psi' k T \right) d\theta \right] - 4\alpha r L k T_c \left(\int_0^{\pi/2} n d\theta + \int_0^{\pi/2} n' d\theta \right) + 2\pi r L [Q - \epsilon \sigma (T_c^4 - T_i^4)] = 0 \quad (B1)$$

Equation (B1) can be simplified by dividing through by $2\pi r L$ and replacing n and n' by their values from equations (2) and (4), thus,

$$\frac{N v_m \alpha}{4\pi^{3/2}} (mU^2 - 4kT_c) \left(\int_0^{\pi/2} \chi d\theta + \int_0^{\pi/2} \chi' d\theta \right) + \frac{\alpha k T N v_m}{2\pi^{3/2}} \left(\int_0^{\pi/2} \chi \psi d\theta + \int_0^{\pi/2} \chi' \psi' d\theta \right) - \epsilon \sigma (T_c^4 - T_i^4) + Q = 0 \quad (B2)$$

The integrals to be evaluated are

$$\int_0^{\pi/2} \chi d\theta \quad (B3)$$

$$\int_0^{\pi/2} \chi' d\theta \quad (B4)$$

$$\int_0^{\pi/2} \chi \psi d\theta \quad (B5)$$

$$\int_0^{\pi/2} \chi' \psi' d\theta \quad (B6)$$

If the value of χ in equation (B3) is replaced by its definition (from list of symbols), equation (B3) becomes

$$\int_0^{\pi/2} [e^{-s^2 \sin^2 \theta} + \sqrt{\pi} s \sin \theta + \sqrt{\pi} s \sin \theta \operatorname{erf}(s \sin \theta)] d\theta \quad (B7)$$

The first term of this integral can be evaluated by setting

$$s = 2x \text{ and } \cos 2\theta = z$$

Then, $d\theta = -\frac{dz}{2 \sin 2\theta}$ and the limits become

$$z = 1 \text{ when } \theta = 0$$

$$z = -1 \text{ when } \theta = \frac{\pi}{2}$$

Thus we can write

$$\int_0^{\pi/2} e^{-s^2 \sin^2 \theta} d\theta = \frac{e^{-z}}{2} \int_{-1}^1 \frac{e^{xz}}{\sqrt{1-z^2}} dz \quad (B8)$$

Now, by definition (cf., equation (11), p. 46, reference 18), the modified Bessel function of order n can be written as

$$I_n(x) = \frac{1}{\sqrt{\pi} \Gamma[n + (1/2)]} \left(\frac{x}{2} \right)^n \int_{-1}^1 e^{\pm xz} (1-z^2)^{n-1/2} dz \quad (B9)$$

Then

$$I_0(x) = \frac{1}{\sqrt{\pi} \Gamma(1/2)} \int_{-1}^1 \frac{e^{xz}}{\sqrt{1-z^2}} dz$$

and since

$$\Gamma\left(\frac{1}{2}\right) = \sqrt{\pi}$$

the first term of integral (B3) becomes

$$\frac{\pi}{2} e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) \quad (B10)$$

The second term (cf., equation (B7)) is

$$\sqrt{\pi} s \int_0^{\pi/2} \sin \theta d\theta = \sqrt{\pi} s \quad (B11)$$

The third term of equation (B7) is

$$\sqrt{\pi} s \int_0^{\pi/2} \sin \theta \operatorname{erf}(s \sin \theta) d\theta$$

which can be integrated by parts. Let

$$\operatorname{erf}(s \sin \theta) = u$$

and

$$\sin \theta d\theta = dv$$

Then

$$du = \frac{2s}{\sqrt{\pi}} e^{-s^2 \sin^2 \theta} \cos \theta d\theta$$

and

$$v = -\cos \theta$$

Then, the integral becomes

$$\sqrt{\pi} s \left[-\cos \theta \operatorname{erf}(s \sin \theta) \right]_0^{\pi/2} + 2s^2 \int_0^{\pi/2} \cos^2 \theta e^{-s^2 \sin^2 \theta} d\theta \quad (B12)$$

The bracketed term of equation (B12) is zero, leaving the second term yet to be evaluated. Make the substitutions

$$\cos^2 \theta = \frac{1 + \cos u}{2}$$

$$\sin^2 \theta = \frac{1 - \cos u}{2}$$

$$s^2 = 2x$$

Then

$$d\theta = \frac{du}{2}$$

and, replacing limits

$$\theta = 0 \quad u = 0$$

$$\theta = \frac{\pi}{2} \quad u = \pi$$

there results

$$2s^2 \int_0^{\pi/2} \cos^2 \theta e^{-s^2 \sin^2 \theta} d\theta = \frac{s^2}{2} \int_0^{\pi} (1 + \cos u) e^{-z(1 - \cos u)} du$$

$$= \frac{s^2 e^{-z}}{2} \int_0^{\pi} e^{+z \cos u} du + \frac{s^2 e^{-z}}{2} \int_0^{\pi} \cos u e^{z \cos u} du \quad (\text{B13})$$

Integral (B13) becomes, when substituting $z = \cos u$ and changing limits,

$$\frac{s^2 e^{-z}}{2} \int_{-1}^1 \frac{e^{zz}}{\sqrt{1-z^2}} dz + \frac{s^2 e^{-z}}{2} \int_{-1}^1 \frac{z e^{zz}}{\sqrt{1-z^2}} dz$$

$$= \frac{\pi s^2}{2} e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B14})$$

which is obtained by integrating the second term of (B14) by parts and substituting equation (B9). Then, the final value for integral (B3) is

$$\int_0^{\pi/2} \chi d\theta = \frac{\pi}{2} e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) + \sqrt{\pi} s + \frac{\pi s^2}{2} e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B15})$$

Now, integrals (B4), (B5), and (B6) contain only terms which can be evaluated by the methods shown above by which integral (B3) was evaluated. The results are

$$\int_0^{\pi/2} \chi' d\theta = \frac{\pi}{2} e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) - \sqrt{\pi} s + \frac{\pi s^2}{2} e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B16})$$

$$\int_0^{\pi/2} \chi \psi d\theta = \pi e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) + \frac{5}{2} \sqrt{\pi} s + \frac{5}{4} \pi s^2 e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B17})$$

$$\int_0^{\pi/2} \chi' \psi' d\theta = \pi e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) - \frac{5}{2} \sqrt{\pi} s + \frac{5}{4} \pi s^2 e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B18})$$

In order to eliminate an excessive amount of writing, new variables are defined as follows:

$$Z_1 = \pi e^{-s^2/2} I_0\left(\frac{s^2}{2}\right) \quad (\text{B19})$$

$$Z_2 = \pi s^2 e^{-s^2/2} \left[I_0\left(\frac{s^2}{2}\right) + I_1\left(\frac{s^2}{2}\right) \right] \quad (\text{B20})$$

Values of the dimensionless variables Z_1 and Z_2 were computed from the tables of Bessel functions in reference 19. Then, equation (B21) is obtained by substitution of equations (B15) to (B20) into equation (B2).

$$\frac{N v_m \alpha}{4 \pi^{3/2}} (m U^2 - 4 k T_c) (Z_1 + Z_2) + \frac{\alpha k T N v_m}{2 \pi^{3/2}} \left(2 Z_1 + \frac{5}{2} Z_2 \right) - \epsilon \sigma (T_c^4 - T_i^4) + Q = 0 \quad (\text{B21})$$

If $m v_m^2/2 = k T$, $k T N = p$, and $s = U/v_m$ are substituted into equation (B21), the following equation results:

$$2 \frac{T_c}{T} (Z_1 + Z_2) - \left[Z_1 (s^2 + 2) + Z_2 \left(s^2 + \frac{5}{2} \right) \right] + \frac{2 \pi^{3/2}}{p v_m \alpha} [\epsilon \sigma (T_c^4 - T_i^4) - Q] = 0 \quad (\text{B22})$$

which is the final energy exchange equation for a monatomic gas. An identical treatment of equation (13) for a diatomic gas gives

$$3 \frac{T_c}{T} (Z_1 + Z_2) - \left[Z_1 (s^2 + 3) + Z_2 \left(s^2 + \frac{7}{2} \right) \right] + \frac{2 \pi^{3/2}}{p v_m \alpha} [\epsilon \sigma (T_c^4 - T_i^4) - Q] = 0 \quad (\text{B23})$$

The groups $f(s) = Z_1 (s^2 + 3) + Z_2 (s^2 + \frac{7}{2})$, $g(s) = 3 (Z_1 + Z_2)$, $f^0(s) = Z_1 (s^2 + 2) + Z_2 (s^2 + \frac{5}{2})$, and $g^0(s) = 2 (Z_1 + Z_2)$ are tabulated in the following table:

s	$f(s)$	$g(s)$	$f^0(s)$	$g^0(s)$

APPENDIX C

THE DRAG DUE TO IMPINGING MOMENTUM ON A TRANSVERSE CYLINDER IN FREE-MOLECULE FLOW

The differential momentum imparted, by the impact of impinging molecules, to the front and rear sides of a body located in a free-molecule flow field is (cf., references 1, 2, and 3)

$$dG_i = \frac{\beta^3 m N}{\pi^{3/2}} \left\{ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_0^{\infty} (l_x c_x + l_y c_y + l_z c_z) c_x e^{-\beta^2[(c_x - U_x)^2 + (c_y - U_y)^2 + (c_z - U_z)^2]} dc_x dc_y dc_z - \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_0^0 (l_x c_x + l_y c_y + l_z c_z) c_x e^{-\beta^2[(c_x - U_x)^2 + (c_y - U_y)^2 + (c_z - U_z)^2]} dc_x dc_y dc_z \right\} dA \quad (C1)$$

In equation (C1), l_x, l_y, l_z are the cosines of the angle between the coordinate axes and the direction of the momentum force. Now let θ be the angle of attack of the element, that is, the angle between the mass velocity U and the plane of the plate. Then the drag force is in the direction of U and the following relations can be derived:

$$\left. \begin{aligned} U_x &= U \sin \theta & l_x &= \sin \theta \\ U_y &= -U \cos \theta & l_y &= -\cos \theta \\ U_z &= 0 & l_z &= 0 \end{aligned} \right\} \quad (C2)$$

Then, integration of equation (C1) and substitution of the relations of equation (C2) yield

$$dG_i = \frac{\rho U^2}{2} \left[\frac{2}{\pi^{1/2}} \frac{e^{-s^2 \sin^2 \theta}}{s} + 2 \sin \theta \operatorname{erf}(s \sin \theta) \left(1 + \frac{1}{2s^2} \right) \right] dA \quad (C3)$$

It is remarkable that a purely analytic solution for this type flow leads to a simple equation of the type of (C3) in which the bracketed term is a dimensionless function of molecular speed ratio and which may be interpreted as an ordinary drag coefficient.

In order to obtain the drag force on a transverse cylinder due to impinging momentum, equation (C3), which was derived for an elemental plane area, must be integrated over the surface of the cylinder. To this end, dA is written as

$$dA = r L d\theta \quad (C4)$$

Then, for the cylinder, the impinging drag force is

$$G_i = 2rL \left(\frac{\rho U^2}{2} \right) \int_0^{\pi/2} \left[\frac{2e^{-s^2 \sin^2 \theta}}{\pi^{1/2}s} + 2 \sin \theta \operatorname{erf}(s \sin \theta) \left(1 + \frac{1}{2s^2} \right) \right] d\theta \quad (C5)$$

This integral can be evaluated by the methods shown in appendix B. The final value for the drag force due to impinging molecules is

$$G_i = 2rL \left(\frac{\rho U^2}{2} \right) \frac{\pi^{1/2} e^{-s^2/2}}{s} \left\{ I_0 \left(\frac{s^2}{2} \right) + \left(\frac{1+2s^2}{2} \right) \left[I_0 \left(\frac{s^2}{2} \right) + I_1 \left(\frac{s^2}{2} \right) \right] \right\} \quad (C6)$$

Thus, there results from equation (C6) an impinging drag coefficient based on the projected area of the cylinder, which has the value

$$C_{Di} = \frac{\pi^{1/2} e^{-s^2/2}}{s} \left\{ I_0 \left(\frac{s^2}{2} \right) + \left(\frac{1+2s^2}{2} \right) \left[I_0 \left(\frac{s^2}{2} \right) + I_1 \left(\frac{s^2}{2} \right) \right] \right\} \quad (C7)$$

REPORT 1033

COMPARISON BETWEEN THEORY AND EXPERIMENT FOR WINGS AT SUPERSONIC SPEEDS¹

By WALTER G. VINCENTI

SUMMARY

In this paper, a critical comparison is made between experimental and theoretical results for the aerodynamic characteristics of wings at supersonic flight speeds. As a preliminary, a brief, nonmathematical review is given of the basic assumptions and general findings of supersonic wing theory in two and three dimensions. Published data from two-dimensional pressure-distribution tests are then used to illustrate the effects of fluid viscosity and to assess the accuracy of linear theory as compared with the more exact theories which are available in the two-dimensional case. Finally, an account is presented of an NACA study of the over-all force characteristics of three-dimensional wings at supersonic speed. In this study, the lift, pitching moment, and drag characteristics of several families of wings of varying plan form and section were measured in the wind tunnel and compared with values predicted by the three-dimensional linear theory. The regions of agreement and disagreement between experiment and theory are noted and discussed.

INTRODUCTION

The aerodynamics of wings at supersonic flight speeds is currently the subject of much research and discussion. As a result of many recent investigations, based on the earlier work of Prandtl, Ackeret, Busemann, and von Kármán, the theory of the subject is well advanced, both as applied to airfoil sections in two-dimensional flow and to complete, three-dimensional wings. Experimental knowledge is, by contrast, considerably less extensive, particularly with regard to the three-dimensional case. There are, however, sufficient experimental data in hand to permit a reasonably systematic comparison between theory and experiment. It is the purpose of this paper to present such a comparison insofar as the current availability of experimental results will allow.

THEORETICAL CONSIDERATIONS

To provide background for those who are unacquainted with the fundamentals of supersonic wing theory, it may be useful to review briefly the assumptions and findings of work in this field. (For a more complete discussion of the theory

and a bibliography of pertinent references, the reader is referred to the Tenth Wright Brothers Lecture by Theodore von Kármán, reference 1.)

In the solution of problems in supersonic wing theory, the following assumptions are usually made concerning the flow field which surrounds the wing:

- (a) The fluid medium is continuous and homogeneous.
- (b) The fluid has the thermodynamic characteristics of a perfect gas with constant specific heats.
- (c) Viscosity and thermal conductivity are vanishingly small.
- (d) External forces (such as gravity) are negligible.

For flight at ordinary altitudes and air temperatures, the most drastic of these assumptions is that of vanishingly small viscosity and thermal conductivity. This assumption allows the effects of fluid friction and heat transfer to be disregarded except as they are necessary to explain the existence of shock waves and vortices within the flow field. The assumption thus retains the essential features of supersonic flow as it is known to occur away from the immediate vicinity of the wing surface. It results, however, in the omission of the friction drag and of any changes in pressure distribution caused by growth or separation of the boundary layer.

On the basis of the foregoing assumptions, it is possible to obtain explicit relations for the sudden changes in flow which occur across a shock wave as well as a differential equation for the gradual changes which take place in the regions between such waves. When expressed with the geometrical coordinates as the independent variables, the differential equation governing the flow in the region between shock waves is nonlinear. It is therefore difficult to apply rigorously to most problems of practical interest.

Fortunately, in the special case of an airfoil section in a two-dimensional supersonic stream, results can be obtained with a high degree of mathematical rigor despite the nonlinearity of the governing differential equation. For reasons of mathematical practicality, it has been usual to restrict the solutions to instances in which the local velocity in the flow field is everywhere supersonic. This limits the solutions to airfoils with a sharp leading edge and to angles of attack and free-stream Mach numbers such that the shock wave from the leading edge is attached to the airfoil and the flow on

¹ Paper presented at the Second International Aeronautical Conference, Institute of the Aeronautical Sciences and The Royal Aeronautical Society, New York City, May 24-27, 1949. Supersedes NACA TN 2100, "Comparison Between Theory and Experiment for Wings at Supersonic Speeds" by Walter G. Vincenti, 1950.

the downstream side of the wave is supersonic. (It has also been customary to neglect the rotation of the fluid particles which will exist aft of the leading-edge wave in those cases in which the wave is curved, although this approximation is not essential.) Within these restrictions, section characteristics can be calculated to a high degree of precision for sections of even appreciable thickness. The method of computation reduces in practice to a stepwise application of the known relations for the compression through a shock wave and for the expansion around a convex corner. The procedure has therefore been termed the "shock-expansion" method (see, for example, reference 2). For rapid calculations, more restricted methods, such as Ackeret's linear theory (references 3 and 4) and Busemann's second-order theory (references 5, 6, and 7), can be obtained by means of series approximation to the complete equations for the shock wave and the expansion.

In the more practical case of a complete, three-dimensional wing, the general mathematical problem is forbiddingly complex, and it is necessary to simplify the nonlinear differential equation at the outset in order to obtain a solution. To accomplish this, it is assumed that the local velocity at all points in the flow field differs only slightly in magnitude and direction from the velocity of the undisturbed stream. This implies, in effect, that the thickness, camber, and angle of attack of the wing are small. With this approximation, the complete, nonlinear differential equation reduces, through the omission of terms of higher than the first order in the flow disturbances, to a linear equation which can be solved by established mathematical methods. On the basis of this equation, an extensive body of theory has been formulated covering a wide range of practical wings. For the present it will suffice to mention certain general concepts and results of this theory. Examples of specific calculations will be presented in the course of the later discussion.

A fundamental result of the linear theory, well known by now, is the concept of the Mach cone. According to this concept, the effect of a given disturbance in a uniform supersonic stream is felt only within the interior of a circular cone with vertex located at the point of the disturbance and axis extending downstream parallel to the original flow. The geometry of the cone is determined by the requirement that the component of free-stream velocity normal to the surface of the cone is equal to the speed of sound in the undisturbed stream. It follows that the semivertex angle of the cone is a function of the free-stream Mach number only. These considerations apply not only to the effects of an isolated disturbance but to the region of influence of each disturbance in a distributed system as well.

The concept of the Mach cone has immediate implications with regard to the aerodynamic problems of three-dimensional wings. This is illustrated in figure 1, which shows certain features of the flow over three flat lifting surfaces of representative plan form. In the case of the rectangular plan form A, for example, it follows from the concept of the Mach cone that, to a first approximation, the effects of the finite span are confined to the regions of the wing lying within the cone from the leading edge of each tip. The flow over

FIGURE 1.—Flat lifting surfaces in supersonic flow (linear theory).

the remainder of the wing (shown shaded) is identical with the two-dimensional flow over a wing of infinite span. On the moderately swept plan form B, the flow over the shaded regions is, by the same reasoning, unaffected by the presence of either the tips or root of the wing. Within these regions the flow can be treated as essentially two-dimensional by evaluating the velocity and the deflection angle in the direction normal to the leading edge. On the highly swept plan form C, all of the wing is within the fields of influence of the root and tips, and no regions of purely two-dimensional flow are to be expected.

Carrying these considerations a step farther, we may also examine the effect which the relationship between the plan form and the Mach cones has upon the chordwise lift distribution for the three wings. On both wings A and B, where the leading edge lies ahead of the Mach cones from the corners of the plan form, the Mach number of the component of free-stream velocity normal to the leading edge is greater than one. For reasons just examined, the lift distribution at the spanwise stations for which it is shown will be the same as the distribution over a flat lifting surface in a two-dimensional supersonic stream. Characteristic features of this distribution are that the intensity of lift at the leading edge is finite and has zero gradient in the chordwise direction. On plan form C, where the leading edge is swept behind the Mach cone, the Mach number of the flow component normal to the leading edge is less than one. It develops from the theory that in this case the lift distribution near the edge resembles the theoretical distribution predicted by linear theory for a flat lifting surface in a purely subsonic flow—that is, the lift intensity tends to an infinite value at the leading edge and drops off rapidly along the chord toward the trailing edge.

The foregoing differences in lift distribution provide one example of a general principle, the significance of which was first noted by R. T. Jones (reference 8). This principle, which arises throughout the study of wings by the linear theory, can be stated as follows: When the component of free-stream velocity normal to a wing element (i. e., lead-

ing edge, ridge line, or trailing edge) is greater than the speed of sound, the theoretical flow in the vicinity of the element has the essential character of the two-dimensional supersonic flow about an element of the same geometric type; similarly, when the velocity component normal to the element is less than the speed of sound, the theoretical local flow resembles that which prevails in the two-dimensional subsonic case. Because of the utility of this general result, it has become customary to describe the wing elements themselves as either "supersonic" or "subsonic." To determine which category an element occupies, it is obviously sufficient, as in figure 1, to note whether it is swept ahead of or behind the Mach cone. It is apparent that a wing element may change from one classification to the other as its orientation relative to the Mach cone is changed. This can be brought about by variation in either the free-stream Mach number or the geometry of the wing.

As a result of the inherent differences in the flow about supersonic and subsonic elements, theoretical calculations for three-dimensional wings indicate marked and interesting changes in the flight characteristics with changes in Mach number or wing geometry. By studying these effects, wing shapes can be found which afford optimum aerodynamic characteristics for a given flight condition. The results of such studies, indeed, provide a valuable guidance to the aircraft designer. In anticipation of the experimental results to be presented later, however, a word of caution is in order here. As exemplified in figure 1, the differences in theoretical pressure distribution between a supersonic and subsonic element may be characterized by large differences in chordwise pressure gradient. These differences may, in a real, viscous medium, give rise to corresponding differences in boundary-layer flow and hence to aerodynamic effects which are beyond the scope of the inviscid theory. As a result, the true variation of the wing characteristics with change in Mach number or wing geometry may be considerably different from that predicted by the theory. The later experimental results with regard to the drag of triangular wings supply an excellent example of such an effect.

In anticipation of the experimental data, it should also be pointed out that the concepts and results of the linear theory, based as they are upon the assumption of small disturbances, constitute only a first-order approximation to the truth even for the supposedly inviscid gas. When disturbances of appreciable magnitude are considered, the previous concept of a Mach cone traversing the entire flow field is no longer tenable. On the contrary, a given disturbance in a supersonic stream is then confined, not to the interior of a cone, but to the interior of some more complex surface whose shape and position depend upon the magnitude of the disturbance as well as upon other conditions in the general flow field. It follows that the regions of influence of a wing tip or wing root are not strictly as shown in figure 1, and the previous distinction between a supersonic and subsonic element cannot be applied without qualification. The ideas of the linear theory with regard to pressure propagation, therefore, should not be taken literally nor should deductions based upon them be accepted without reservation.

It is apparent from these brief theoretical considerations that calculations by the linear theory may be expected to fall short of the truth for two primary reasons. These are

- (a) the omission from the theory of all viscous phenomena, and
- (b) the theoretical assumption that the flow disturbances are small.

The importance of these approximations cannot be assessed at present from purely theoretical knowledge. Some insight is provided, however, by the available experimental results.

PRESSURE-DISTRIBUTION MEASUREMENTS IN TWO DIMENSIONS

It is desirable to begin the comparison between theory and experiment by examining some typical pressure-distribution results for an airfoil section in a two-dimensional supersonic stream. Because of the availability in the two-dimensional case of theories of greater accuracy than the linear theory, it is possible here to distinguish between the effects of viscosity and the effects of the terms neglected through the assumption of small disturbances.

A typical two-dimensional pressure distribution is given in figure 2, which shows the calculated and measured results for a 10-percent-thick, symmetrical, biconvex section at a Mach number of 2.13 and an angle of attack of 10° . The local pressure coefficient is plotted as a function of the chordwise position on the airfoil, positive values being plotted below the horizontal axis and negative values above. The theoretical pressure distributions given by the linear and shock-

FIGURE 2.—Pressure distribution for symmetrical biconvex section.

expansion theories are shown by curves as noted. The individual circles indicate experimental points obtained from the results of Ferri (reference 9).

The data of figure 2 show that considerable accuracy is gained by going from the linear to the shock-expansion theory. Over most of the airfoil section, the linear theory predicts the correct sense for the pressure gradient, but the quantitative agreement between the curve given by this theory and the experimental points is poor compared with the excellent check given by the shock-expansion method. Over the rear 40 percent of the upper surface, neither of the theories agrees with the trend exhibited by experiment.

The discrepancy between the theoretical pressure distributions calculated by the linear and shock-expansion theories is of importance primarily for its effect upon the chordwise distribution of lift. Examination of figure 2 reveals that the total lift of the section, as approximated by the area between the curves for the upper and lower surfaces, is given almost identically by the two theories. This illustrates the fact that in the two-dimensional case the higher-order terms neglected in the linear theory have little effect upon the over-all lift of the section. They do, however, serve to concentrate the lift farther forward on the chord than the linear theory would predict. This effect is essentially a consequence of the airfoil thickness and diminishes as the thickness is reduced.

The failure of even the shock-expansion theory to predict the pressure variation over the rear part of the upper surface is due to shock-wave, boundary-layer interaction (reference 9). In the idealized, inviscid fluid, the two-dimensional flow over a lifting airfoil at supersonic speeds is characterized by an oblique compression wave originating on the upper surface at the trailing edge. In the real, viscous fluid, this flow pattern is modified by an interaction between the oblique wave and the viscous boundary layer on the airfoil surface. The boundary layer separates from the upper surface some distance forward of the trailing edge, with the formation of a weak compression wave at the separation point and a consequent increase in pressure between this point and the trailing edge. There is, as a result, a noticeable loss of lift over the rear of the airfoil.

The foregoing results, of course, imply certain deviations of the true aerodynamic coefficients from the curves predicted by the linear theory. For the reasons outlined, the higher-order pressure effects neglected in the linear theory have little influence upon the lift-curve slope, although they do result in a relatively forward shift of the center of pressure (or aerodynamic center). The interaction between the trailing shock wave and the viscous boundary layer acts both to decrease the lift-curve slope slightly and to displace the center of pressure still farther forward. Viscous friction, the effects of which are not visible in the pressure distribution, tends to increase the true drag relative to the calculated value, though this tendency is opposed here by the unpredicted increase in pressure near the trailing edge as the result of the shock-wave, boundary-layer interaction. All of these effects are apparent in the available force-test data for airfoils in two-dimensional flow (references 9 and 10). As will be seen, they are also observed in the results for three-

dimensional wings, at least for those cases in which the wing elements are predominantly supersonic.

FORCE TESTS IN THREE DIMENSIONS

The discussion to this point has been confined to theoretical considerations and to a comparison between theoretical and experimental results for a typical airfoil section in two-dimensional flow. The remainder of the paper will be concerned with a more general comparison between theory and experiment for complete, three-dimensional wings.

The results upon which this comparison is based were obtained in 1946 as part of an investigation of wing characteristics conducted at the Ames Aeronautical Laboratory of the NACA. The portion of the general investigation to be discussed here was concerned with force tests at supersonic speeds of approximately 30 wing models chosen to cover a wide range of geometric variables and to include examples with both supersonic and subsonic wing elements. The experimental work was performed in the Ames 1- by 3-foot supersonic wind tunnel No. 1, which is a continuous-flow, closed-return tunnel of approximately 10,000 horsepower.²

The wing models were supported in the wind tunnel on a slender body of revolution mounted directly ahead of a three-component, strain-gage balance as shown in figure 3. For the majority of the models, the airfoil section taken in the streamwise direction was a 5-percent-thick isosceles triangle, that is, a triangle with maximum thickness of 5 percent located at midchord. This cambered section was chosen primarily for ease of construction. The models were made of hardened, ground tool steel with the leading and trailing edges maintained sharp to less than a 0.001-inch radius, except for certain tests in which the leading edge was purposely rounded. The support body, which was the same for all models, was kept as small as possible consistent with the requirement that it could be used with a wide range of plan forms.

Because of the presence of the support body, the experimental results to be presented apply, strictly speaking, to wing-body combinations rather than to the wings alone. The theoretical curves are, on the other hand, for simple, isolated wings. A detailed examination of the interference problem indicates that, for the particular body used here, the effects of the body are small insofar as the lift and pitching moment are concerned. The influence on minimum drag may, however, be considerable. The measured values of the minimum drag coefficient must therefore be regarded as of primarily qualitative significance in comparison with theory.

Because of limitations of time and space, it is obviously impossible in a paper of this kind to discuss more than a small portion of the results obtained in the investigation. The data presented will therefore be chosen primarily for their value in illustrating certain general ideas or typical conclusions. This approach will result in the omission of

² As with most experimental investigations, many people contributed to the final results of the study. Particular credit is due, however, to Jack N. Nielsen, Milton D. Van Dyke, and Frederick H. Matteson, who participated in the analysis of the results, to Robert T. Madden, Richard Scherrer, and John A. Blackburn, who conducted the wind-tunnel tests, and to Albert G. Oswald, who was in charge of the wind-tunnel instrumentation.

(b) Swept wing.

FIGURE 3.—Typical wing models mounted on support body in Ames 1-by 3-foot supersonic wind tunnel.

many interesting items dear to the heart of the experimentalist, but it is hoped that an adequate over-all picture of the significant results will emerge. In all of the figures presented, the aerodynamic coefficients will be referred to the plan form area of the wing, including that portion of the plan form enclosed by the support body. All of the results are for a free-stream Mach number of 1.53 and a test Reynolds number of 0.75 million based upon the mean geometric chord of the wing. Unless stated otherwise, it may be assumed that the results were obtained using models with the cambered, isosceles-triangle section previously described.

In the discussion of the results, it is convenient to consider first the lift and pitching moment, since these charac-

teristics depend primarily upon the distribution of normal pressure over the surface of the wing. The consideration of drag, which depends upon the frictional forces as well, will be deferred until later.

LIFT AND PITCHING MOMENT

According to the linear theory, the lift and pitching-moment curves for any given wing are each a straight line. At a given Mach number, the slope of the line depends solely upon the plan form of the wing and is independent of the camber and thickness. The intercept—that is, the angle of zero lift or the moment at zero lift—is a function of both the camber and the plan form, but is independent of the wing thickness. Only the slope of the curves will be discussed here, since this is the characteristic of greatest practical importance.

Lift-curve slope.—The nature of the agreement between theory and experiment with regard to the lift-curve slope for unswept wings is illustrated in figure 4. Here $dC_L/d\alpha$ is plotted as a function of aspect ratio for a series of four unswept wings having a common taper ratio of 0.5. The wing corresponding to each test point is indicated by a small sketch, which shows also the trace of the Mach cones from the forwardmost point of the wing. On this and later figures, the variation predicted by the linear theory is shown over as wide a range as is practicable on the basis of existing computational methods.

The agreement between theory and experiment in figure 4 is seen to be excellent over the entire range of aspect ratios. The exact coincidence for aspect ratios from 2 to 6 is, in fact, too good to be absolutely true. It appears likely that the secondary effects of viscosity and support-body interference, which must certainly be present in some degree, are completely compensating for these wings. The decrease in lift-curve slope observed both experimentally and theoretically at the low aspect ratios is caused by a loss of lift within the Mach cones which originate at the leading edge of the wing tips. As the aspect ratio is reduced, a greater and greater percentage of the plan form is included within these Mach

FIGURE 4.—Effect of aspect ratio on lift-curve slope.

FIGURE 5.—Effect of sweep on lift-curve slope.

cones, with a resulting decrease in the lifting effectiveness of the wing.

The effect of wing sweep on the slope of the lift curve is illustrated in figure 5. Here $dC_L/d\alpha$ is shown as a function of the sweep angle at the midchord line for a series of seven wings also of taper ratio 0.5. The unswept wing of this series is identical with the aspect ratio 4 wing of the previous figure. In the design of the swept wings, the aspect ratio was made to decrease as the cosine of the angle of sweep, since wings of constant aspect ratio did not appear structurally feasible. The sweep angles were chosen to provide representative plan forms with both supersonic and subsonic leading and trailing edges. The wing of 43° sweepback was designed to have its leading edge coincident with the Mach cone, which has a sweep angle of 49.2° at the test Mach number of 1.53. Since the sweep angle of these wings is specified at the midchord line, a given swept-forward wing can be obtained from the corresponding swept-back wing by a simple reversal of the direction of motion.

The agreement between theory and experiment in figure 5 is almost exact over the range of sweep angles from 0° to 43° sweepforward, the forwardmost limit of the theoretical results. For all of the swept-back wings, the experimental slopes fall consistently below the theoretical values by from 8 to 10 percent. In both the swept-back and swept-forward direction, the experimental results exhibit a marked reduction in $dC_L/d\alpha$ as the edges of the plan form are swept increasingly farther behind the Mach cone. This trend is predicted by the theoretical curve in the swept-back case and would undoubtedly be confirmed for the swept-forward wings if complete theoretical results were available.³ It is interesting to note, incidentally, that the 43° swept-back wing, which has its leading edge coincident with the Mach cone, shows no departure from the general trend of the experimental results.

³ For the range of sweep angles from 43° to 60° sweepback, the shape of the theoretical curve is somewhat approximate. Strictly speaking, small discontinuities in the slope of the curve would be expected at approximately 43° and 55° where the leading edge and trailing edge of the plan form coincide, respectively, with the Mach cone. No attempt was made to determine these discontinuities, the theoretical curve being faired smoothly through the available calculated points.

FIGURE 6.—Effect of aspect ratio on moment-curve slope.

For the range of sweep angles between $\pm 43^\circ$, the theoretical curve of figure 5 is exactly symmetrical about the vertical axis. This means that, within this range, the theoretical lift-curve slope of a plan form of the present series is unchanged by a reversal of the direction of motion. Similar result has been obtained by several authors for other, more general classes of wings (see, for example, references 11 and 12), though the limits of generality have not, to the writer's knowledge, been completely established.⁴ The observed departure of the experimental results from the theoretical symmetry may be due to differences in aeroelastic deformation between corresponding swept-forward and swept-back wings or to asymmetry in the effects of other secondary factors such as viscosity and support body interference.

To summarize, we may say that the agreement between experiment and linear theory with regard to the lift-curve slope of three-dimensional wings is satisfactory for most practical purposes. In view of the situation previously observed in the two-dimensional case, however, it cannot be assumed that agreement in the integrated lift implies complete agreement in the details of the lift distribution.

Moment-curve slope.—Further indication that the details of the flow over the wings are, as in the two-dimensional case, somewhat different from the predictions of the linear theory is given by the pitching-moment data. Figure 6 shows the moment-curve slope as a function of aspect ratio for the series of unswept wings previously discussed. The moment coefficient is here taken about the centroid of plan-form area, with the mean aerodynamic chord as the reference length. The moment-curve slope is thus an approximate measure of the displacement of the aerodynamic center of the wing forward of the centroid of area, expressed as a fraction of the mean aerodynamic chord.

It can be seen from figure 6 that the linear theory predicts a progressively forward displacement of the aerodynamic center as the aspect ratio is reduced. As in the case of the

⁴ Since the present paper was written, the theoretical result observed here has been established with complete generality with regard to plan form by Clinton E. Brown of The Langley Aeronautical Laboratory of the NACA. (See Brown, Clinton E.: The Reversibility Theorem for Thin Airfoils in Subsonic and Supersonic Flow. NACA TN 1944, 1949.) According to Brown's proof, which is based upon previous work by Max M. Munk, the theoretical lift-curve slope of a given wing is, to the first order, invariant with respect to a reversal of the direction of motion, irrespective of the Mach number or shape of the plan form.

lift-curve slope, this variation is due to the loss of lift which occurs over the rear portion of the wing within the Mach cones from the tips. The trend of the experimental values is in agreement with the theoretical curve, but the forward displacement is uniformly greater than the theory predicts. The reason for this discrepancy becomes apparent if we imagine the wing series of figure 6 to be extended to indefinitely high aspect ratios. In the limit of infinite aspect ratio, the flow over the wing would be purely two-dimensional, and the theoretical characteristics would be simply those of the wing section. For the present isosceles-triangle section, the values of dC_m/dC_L given by the linear and shock-expansion theories are as indicated by the two horizontal lines to the right. The theoretical curve for the finite-span wings, of course, approaches the linear section value as an asymptote. If only nonviscous effects were important in the experiments, the measured curve would be expected to approach the section value predicted by the shock-expansion method. The fact that it seems to approach an asymptote above this latter value is consistent with the occurrence of shock-wave, boundary-layer interaction near the supersonic trailing edge as previously observed in the two-dimensional results (fig. 2). We may thus infer that the discrepancy between experiment and linear theory over the entire range of aspect ratios is due to a combination of both higher-order pressure effects and fluid viscosity.

The effect of sweep on the moment-curve slope is shown in figure 7 for the same series of wings used before. It is apparent that here experiment and theory agree neither quantitatively nor qualitatively. For the unswept wing, the observed discrepancy can be accounted for as explained in connection with figure 6. The disagreement in the variation with angle of sweep is, however, difficult to reconcile on the basis of present knowledge. In general, the effects of boundary-layer separation may be expected to have a major influence on the moment characteristics of swept wings, particularly in those cases in which the wing elements are predominately subsonic. The possible importance of the higher-order pressure effects should not be overlooked, however. It can be shown from quite general considerations that the calculation by the linear theory of the aerodynamic-center position for any given wing is subject to a possible error of the same order of magnitude as the percent thickness of the airfoil section. For this reason, the development of a rea-

FIGURE 7.—Effect of sweep on moment-curve slope.

FIGURE 8.—Effect of sweep on minimum drag.

sonably general, second-order wing theory may prove essential to a complete understanding of the pitching-moment problem.

DRAG

The calculation of wing drag by the linear theory leads to a parabolic curve of drag versus lift. The value of the minimum drag coefficient depends, for a given Mach number, upon the thickness, camber, and plan form of the wing, while the lift coefficient at which the minimum occurs is a function of the camber and plan form. The rise in drag as the lift coefficient departs from that for minimum drag depends, according to the linear theory, upon the geometry of the plan form only.

Minimum drag.—A typical illustration of the effect of change in plan form on the minimum drag is given in figure 8, which shows the variation in minimum drag coefficient for the previous series of swept wings. The theoretical curve shown is for the pressure drag only—that is, no attempt has been made to estimate the skin friction. Because of the mathematical complications introduced by camber when the edges of the wing are subsonic, it was not practicable here to extend the theoretical curve beyond 43° in either direction. Within these limits, the theoretical drag increases with increasing sweep. Extension of the curve to higher angles of sweep would be expected to show a marked decrease in the calculated drag, similar to the well-known results for uncambered wings swept behind the Mach cone.

The experimental curve of figure 8 follows the general trend indicated by theory. As the sweep increases from zero in either direction, the measured drag first rises to a maximum in the vicinity of the Mach cone and then decreases markedly with further increase in sweep. The large decrease in drag obtained by sweeping the wing behind the Mach cone has been observed by numerous investigators and need not be enlarged upon here. What is more interesting in the present results is the failure of the experimental values to rise as rapidly as does the theoretical curve in the lower range of sweep angles. For the wings of 0° and $\pm 30^\circ$ sweep, the displacement of the experimental points above the theoretical curve is consistent with a reasonable allowance for skin friction and support-body interference. For the wings of $\pm 43^\circ$ sweep, however, the experimental values are almost

coincident with the theoretical. This result suggests that the linear theory may be overly pessimistic regarding wing drag when the Mach number normal to the wing elements is near unity. Support for this conjecture is found in the work of Hilton and Pruden (reference 10), who report a similar situation in two-dimensional tests of an airfoil section at moderately supersonic speeds. It is likely that in both instances the results are due to transonic effects which are beyond the scope of the linear theory.

The symmetry of the curves of figure 8 is also worthy of note. It has been shown by several authors (see, for example, references 1 and 12) that, to the order of accuracy of the linear theory, the minimum pressure drag of a wing of any plan form is unchanged by a reversal of the direction of motion, provided the wing section is without camber. For cambered wings, the corresponding drag theorem is probably less general with regard to plan form, though, as in the case of the lift-curve slope, the limits of generality have not been defined. For the present wings, reversibility is readily proven over the range of sweep angles between $\pm 43^\circ$. As a result, the theoretical curve of figure 8 is, like the corresponding curve for $dC_L/d\alpha$ in figure 5, exactly symmetrical over this interval. In spite of the theoretical result, however, the almost perfect symmetry of the experimental curve of figure 8 comes as somewhat of a surprise. It might be expected that secondary differences between corresponding swept-forward and swept-back wings would cause an asymmetry here akin to that observed in the experimental values of lift-curve slope.

The most interesting results with regard to drag, however, are concerned with the effects of thickness distribution on the minimum drag of triangular wings. At about the time the present study was beginning, theoretical results by Puckett appeared (reference 13) which indicated that the minimum pressure drag of an uncambered triangular wing with a subsonic leading edge could be held to a relatively low value by proper location of the position of maximum thickness. To check these results, two triangular wings of aspect ratio 2 were included in the present study. Both wings had an uncambered double-wedge section with a thick-

ness ratio of 5 percent. In one case the maximum thickness was located at midchord, in the other at a position 20 percent of the chord aft of the leading edge.

The findings for these wings are summarized in figure 9, which shows the theoretical and experimental values of the minimum drag coefficient plotted as a function of the position of maximum thickness. The curve of theoretical pressure drag, which is representative of Puckett's results, is divided into two parts by a sharp break in slope, located in this instance at 42 percent of the chord. For points to the right of this break, the ridge line defined by the position of maximum thickness is supersonic, and the flow around the ridge resembles the supersonic flow around a convex corner. Under these conditions, there is little pressure recovery over the rear of the wing, and the drag is relatively high. For points to the left of the break, the ridge line is subsonic, and the local flow is of the characteristically subsonic type. Under these conditions, the pressure recovery over the rear of the wing is considerable, and the drag is correspondingly reduced. For the wings under consideration, the net result of moving the maximum thickness forward from the 50-percent to the 20-percent station is to reduce the computed pressure-drag coefficient from 0.0092 to 0.0054. Unfortunately, the measured values of the minimum drag, indicated by the two small circles, do not follow the theoretical trend. The apparent effect of the forward displacement is, in fact, to increase the drag slightly.

When this result was first noted, the experimental data were suspected of being in error. Repeated tests, however, gave identical results. It was next thought that support-body interference might be to blame. Estimates indicated, however, that such interference could hardly account for the large difference in the increments by which the measured total drag exceeded the computed pressure drag for the two wings. Consideration of the friction drag finally supplied the key to a possible explanation. To examine this possibility, curves of theoretical total drag were computed on the basis of the skin-friction coefficients corresponding to completely laminar and completely turbulent flow in the boundary layer. When this was done, it was found, as is apparent in the figure, that the experimental point for the wing with maximum thickness at 50 percent fell midway between the two resulting curves, while that for the wing with maximum thickness at 20 percent was slightly above the curve for completely turbulent flow. This suggested that the failure of the experimental points to follow the trend of the theoretical pressure drag might be due to a difference in the extent of laminar boundary-layer flow on the two wings.

To check this hypothesis, the liquid film method developed by Gray of the R.A.E. for the indication of transition at subsonic speeds (reference 14) was adapted for use in a supersonic stream. This method depends upon the fact that the rate of evaporation of a film of liquid on the surface of a model is, on the average, greater where the boundary layer is turbulent than where it is laminar. In applying this principle at the Ames Laboratory, the model is first coated with

FIGURE 9.—Effect of position of maximum thickness on minimum drag of triangular wings.

(a) Maximum thickness at 20-percent chord.
(b) Maximum thickness at 50-percent chord.

FIGURE 10.—Results of liquid-film tests on triangular wings at zero lift. Section: uncambered double wedge, 5-percent thick, $M_0 = 1.53$.

flat black lacquer and then, immediately prior to installation in the tunnel, with a liquid mixture containing glycerin. A run is then made at the desired test condition for a sufficient time to allow the liquid to evaporate completely in the turbulent region but remain moist over most of the laminar area. Upon removal from the tunnel, the model is dusted with talcum powder, which adheres to the laminar but not to the turbulent area, thus increasing the contrast for photographic purposes and providing a clear indication of the extent of the two types of boundary-layer flow.

The results of liquid film tests of the two triangular wings at zero lift are shown in figure 10. For the wing with maximum thickness at midchord, the region of turbulent flow, which appears as the dark region on the model, constitutes only about half of the surface area aft of the ridge line. For the wing with maximum thickness displaced forward, the turbulent region occupies almost all of the considerably

larger area which is aft of the ridge line on this wing.⁵ These results were repeated many times during the numerous tests necessary to perfect the liquid-film technique. Examination of calculated pressure distributions for the two wings shows in each case excellent correlation between the experimentally determined region of turbulent flow and the calculated region of adverse pressure gradient. Because of the effects of support-body interference, it is not possible to make a decisive comparison between the measured values of total drag and theoretical values calculated on the basis of the observed areas of laminar and turbulent flow. The evidence of the liquid-film tests, however, leaves little doubt as to the primary reason why forward displacement of the maximum thickness fails to produce the reduction in minimum drag predicted by the inviscid, linear theory.

The foregoing result has important implications with regard to the degree of drag reduction possible at supersonic speeds through the use of sweepback. The relatively high pressure drag of an unswept wing at speeds above the speed of sound is a direct result of an absence of pressure recovery over the rear of the wing. The high pressure drag is thus associated with a chordwise pressure gradient which is, for the most part, favorable to the boundary-layer flow. The reduction of pressure drag by means of sweepback depends, on the other hand, upon the presence of an appreciable pressure recovery, or in other words, upon the existence of a region of adverse gradient. If the region of such gradient occupies the major portion of the wing, then, as was seen in the case of the triangular wing with thickness forward, the detrimental effects upon the skin friction may more than offset the gains in pressure drag. This suggests that it may be desirable here, as in the case of the subsonic, low-drag airfoil, to look for wing shapes which have their pressure recovery confined to a relatively small part of the wing area. Wings of this type may, in fact, prove more practical at supersonic than at subsonic speeds, since there is indication (reference 15) that the boundary-layer phenomena at the higher speeds may be more conducive to long runs of laminar flow.

Drag rise and lift drag ratio.—The final question to be discussed is that of the variation in drag with change in lift. As previously mentioned, the theoretical curve of drag versus lift is, for any given wing, parabolic in shape. The rise in drag as the lift coefficient departs from that for minimum drag depends, for a given Mach number, on the wing plan form only and is independent of the camber and thickness. The shape of the theoretical parabola for a given wing is thus identical with that for a flat lifting surface of the same plan form as the wing in question.

In the case of a plan form with a supersonic leading edge, the determination of the rise of the theoretical parabola is relatively simple. In this case, which is exemplified by plan forms A and B of figure 1, the local pressure on the flat lifting surface is everywhere finite. The variation in drag with change in lift can thus be found by simple integration of

⁵The white streaks extending back into the otherwise dark turbulent area are streamers of excess liquid blown back from the laminar region. These streamers may at times be used as a valuable indication of the direction of flow within the boundary layer, particularly on highly swept wings.

the pressures acting on the top and bottom of the surface. For all of the wings of the present study having a supersonic leading edge, the shape of the drag curve given by the theoretical calculation shows good agreement with experiment.

In the case of a wing with a subsonic leading edge, the theoretical problem is more complex. In this case, exemplified by plan form C of figure 1, there is a singularity—that is, an infinite value—in the theoretical lift intensity at the leading edge of the equivalent flat surface. The effect of this singularity is to produce a finite suction force on the leading edge in the direction opposite to the free stream. This force—sometimes referred to simply as “leading-edge suction”—reduces the rise of the theoretical drag parabola below what it would be if only the pressures on the top and bottom of the wing were considered. Actually, of course, the details of the flow about the leading edge must, in any real case, be considerably different from the representations of the linear theory, since an infinite lift intensity is obviously impossible. It does not follow, however, that the theoretical forward force at the leading edge will not exist. The situation here is much the same as that encountered at the leading edge of an airfoil section in two-dimensional, incompressible flow. In this latter case, it is known, both from experiment and from the indications of more refined calculations, that the elementary theory gives an accurate prediction of the leading-edge suction within certain limits of angle-of-attack and leading-edge radius. The range of applicability of the linear theory as applied to swept wings at supersonic speeds must similarly be established by careful theoretical and experimental investigation.

The results of the present study are not, in general, conclusive with regard to the conditions necessary for the attainment of the theoretical force at the subsonic edge. The data for the triangular wings, however, do offer some possibly significant findings. These are illustrated in figure 11, which shows the effects of change in wing section upon the drag due to lift for the triangular wings previously

FIGURE 11.—Effect of wing section on drag rise of triangular wings.

FIGURE 12.—Effect of wing section on lift-drag ratio of triangular wings.

discussed. The two theoretical curves show the calculated drag rise with the leading-edge suction both included and omitted. For the wing with maximum thickness at midchord, the experimental curve is slightly above the theoretical curve with leading-edge suction omitted. This is as might be expected for a sharp-edged wing, the slight increase above the upper theoretical curve being due possibly to an increase in friction drag with increasing lift or to support-body interference. Moving the maximum thickness forward on the wing to the 20-percent-chord position resulted in a slight reduction in drag despite the retention of a sharp leading edge. This gain may be due either to the attainment of leading-edge suction as a result of the larger leading-edge wedge angle on this wing or to a change in the variation of friction drag with lift. In an attempt to bring the drag rise of the second wing down to the values indicated by the complete theory, the edge of this wing was rounded to a radius of 0.25 percent of the chord, which is of the same order of magnitude as the radius of an NACA low-drag section of comparable thickness ratio. This rounding of the leading edge afforded some benefit, the resulting experimental values being approximately midway between the two theoretical curves. Additional rounding—to a 0.50-percent radius over the entire span and then to a still greater value over the outer half—had no further effect.

The influence of the foregoing changes on the experimental curves of lift-drag ratio is shown in figure 12. The wing with maximum thickness at midchord has a value of $(L/D)_{max}$ of about 6.3. When the maximum thickness is moved forward to the 20-percent-chord station, the decrease in drag rise apparent in figure 11 more than outweighs the slight increase in minimum drag observed in figure 9. As a result, the maximum lift-drag ratio increases slightly.

Rounding the leading edge of the second wing, while reducing the drag rise as previously noted, does not alter the minimum drag. As a consequence, the maximum lift-drag ratio is increased to approximately 6.8. These results suggest that the aerodynamic gains predicted on the basis of the theoretical leading-edge suction can be at least partially realized in practice. The determination of the optimum profile shape for this purpose may, however, involve considerable detailed research.

It is interesting for contrast with the foregoing results to point out the detrimental effects at the test Mach number of rounding the leading edge on an unswept wing. In tests of an unswept, untapered wing of aspect ratio 4, rounding the leading edge to a radius of 0.25 percent of the chord resulted in a 27-percent increase in minimum drag and a consequent reduction in maximum lift-drag ratio from 6 to about 5.5. The rise in the drag curve was unaffected by the modification.

CONCLUDING REMARKS

The foregoing results represent only a small contribution to the body of experimental and theoretical knowledge now being accumulated concerning the characteristics of wings at supersonic speeds. As is the case with most measurements of over-all forces, the data of the present study raise more questions than they answer. Detailed and patient investigations of pressure distribution and boundary-layer flow are required to develop a rational explanation for many of the observed phenomena. Several major problems have not been discussed here at all, including the important question of the adequacy of the Kutta condition to describe the real flow at a highly swept, subsonic trailing edge. There is sufficient to be done, indeed, to keep many investigators occupied for years to come.

REPORT 1034

INVESTIGATION OF SPOILERAILERONS FOR USE AS SPEED BRAKES OR GLIDE-PATH CONTROLS ON TWO NACA 65-SERIES WINGS EQUIPPED WITH FULL-SPAN SLOTTED FLAPS¹

By JACK FISCHEL and JAMES M. WATSON

SUMMARY

A wind-tunnel investigation was made to determine the characteristics of spoiler ailerons used as speed brakes or glide-path controls on an NACA 65-210 wing and an NACA 65₂-215 wing equipped with full-span slotted flaps. Several plug-aileron and retractable-aileron configurations were investigated on the two wing models with the full-span flaps retracted and deflected. Tests were made at various Mach numbers between 0.13 and 0.71.

The results of this investigation have indicated that the use of plug or retractable ailerons, either alone or in conjunction with wing flaps, as speed brakes or glide-path controls is feasible and very effective. In an illustrative example, the estimated time required for descent of a high-performance airplane from 40,000 feet was reduced from 12.3 minutes to 3.3 minutes. The plug and retractable ailerons investigated, when used as speed brakes, had only a small effect on the wing pitching moments. The rolling effectiveness of the ailerons will not be impaired by such use and should be as good as the effectiveness when the ailerons are projected in normal manner from the retracted position.

INTRODUCTION

One of the less obvious but nevertheless important needs of the high-performance military and commercial aircraft currently in use or in the design stage is that of utilizing suitable devices as aerodynamic speed brakes or glide-path controls, or both. Speed brakes and glide-path controls are beneficial for aircraft under various normal or emergency operating conditions, such as: a rapid descent from high altitude while airplane speed is being limited, landing on short runways over obstacles, reducing speed rapidly to increase the firing efficiency of fighter aircraft, and so forth. For the high-performance aircraft, the use of full-span slotted flaps and spoiler lateral-control devices would be particularly beneficial for providing high lift for landing and take-off as well as adequate lateral control. In order to obviate the necessity of including additional devices on the airplane, the use as speed brakes of spoiler ailerons, either alone or in conjunction with slotted flaps, was reported in reference 1 and was shown to be satisfactory. By means of suitable linkage, the slotted flaps can be deflected, and the spoiler ailerons on

both wing semispans can be projected equally above the wing to act as speed brakes or glide-path controls; and in either the neutral or an extended position, the ailerons can at the same time be operated differentially by movement of the control stick to provide lateral control.

The lateral control characteristics of various spoiler ailerons on unswept wings have been presented previously (for example, see references 2 to 7); however, the aerodynamic characteristics of these ailerons pertaining to their use as speed brakes or glide-path controls have seldom been presented.

In order to provide some information on the characteristics of plug and retractable ailerons when used as speed brakes or glide-path controls, the incremental values of lift, drag, and pitching-moment coefficients obtained at various aileron projections and flap deflections during the investigations of references 3 to 5 are presented herein. These data were obtained through a large angle-of-attack range on semispan wings having NACA 65-210 and NACA 65₂-215 airfoil sections. The investigation was performed in the Langley 7- by 10-foot tunnels at various Mach numbers between 0.13 and 0.71. Complete lift, drag, and pitching-moment data of these aforementioned wings with ailerons neutral have been presented in references 5 and 8. Data illustrating the rolling effectiveness of the ailerons when used as speed brakes or glide-path controls and a discussion pertaining to the application of the incremental lift, drag, and pitching-moment data to aircraft are presented herein.

COEFFICIENTS AND SYMBOLS

C_L	lift coefficient $\left(\frac{\text{Twice lift of semispan model}}{qS}\right)$
C_D	drag coefficient (D/qS)
C_m	pitching-moment coefficient $(M_p/qS\bar{c})$
Δ	increment caused by aileron projection
C_l	rolling-moment coefficient (L/qSb)
c	local wing chord, feet
$\bar{c}$	wing mean aerodynamic chord, 2.86 feet $\left(\frac{2}{S} \int_0^{b/2} c^2 dy\right)$
b	twice span of each semispan model, 16 feet
y	lateral distance from plane of symmetry, feet

¹ Supersedes NACA TN 1933, "Investigation of Spoiler Ailerons for Use as Speed Brakes or Glide-Path Controls on Two NACA 65-Series Wings Equipped with Full-Span Slotted Flaps" by Jack Fischel and James M. Watson, 1949.

S	twice area of each semispan model, 44.42 square feet
D	twice drag of semispan model, pounds
L	rolling moment, resulting from aileron projection, about plane of symmetry, foot-pounds
M_p	twice pitching moment of semispan model about 35-percent root-chord station
q	free-stream dynamic pressure, pounds per square foot $\left(\frac{1}{2} \rho V^2\right)$
V	free-stream velocity, feet per second
V_i	indicated airspeed, miles per hour
ρ	mass density of air, slugs per cubic foot
α	angle of attack with respect to chord plane at root of model, degrees
δ_f	flap deflection, measured between wing chord plane and flap chord plane (positive when trailing edge of flap is down), degrees
M	Mach number (V/a)
R	Reynolds number
a	speed of sound, feet per second

CORRECTIONS

All data presented are based on the dimensions of each complete wing.

The test data have been corrected for jet-boundary effects according to the methods outlined in reference 9. The Glauert-Prandtl transformation (reference 10) has been utilized to account for effects of compressibility on these jet-boundary corrections. Blockage corrections were applied to the test data by the methods of reference 11.

MODEL AND APPARATUS

The right-semispan-wing models investigated with spoiler ailerons (figs. 1 to 6) were mounted in either the Langley 300 MPH 7- by 10-foot tunnel or the Langley high-speed 7- by 10-foot tunnel with their root sections adjacent to one of the vertical walls of the tunnel, the vertical wall thereby serving as a reflection plane. Two wings were used for this investigation: one wing embodied NACA 65-210 airfoil sections and the other wing embodied NACA 65₂-215 airfoil sections. The wings were constructed with the same plan-form dimensions (figs. 1, 3, and 5) and each wing had an aspect ratio of 5.76; a taper ratio of 0.57, and had neither twist nor dihedral. The NACA 65₂-215 wing was constructed with two trailing-edge sections which were used alternately for tests of the plain-wing configuration and for tests of the wing configuration with flaps (fig. 6). The NACA 65-210 wing was equipped with two trailing-edge sections—one to accommodate the basic plug-aileron and retractable-aileron configurations (fig. 2) and the other to accommodate the circular-plug-aileron configurations (fig. 4); each trailing-edge section had a cut-out to accommodate the flap in the retracted position ($\delta_f=0^\circ$). A more detailed

description of the construction and mounting of the models is presented in references 3, 4, 5, and 8.

A 0.25c slotted flap which extended from the wing root section to the 95-percent-semispan station was used on both semispan wings in this investigation. This flap was originally designed and constructed to conform to the contour of the NACA 65-210 wing and was used in all investigations on that wing (references 3, 4, and 8). Because of its availability and satisfactory aerodynamic characteristics, this flap was also used in the flap-deflected wing configurations tested on the NACA 65₂-215 wing (reference 5). The positions of the flap with respect to the wing at the various deflections investigated with each aileron configuration are shown in figures 1, 3, and 6. These positions were found to be optimum, aerodynamically, for each flap deflection (references 5 and 8).

Each of the various aileron configurations investigated had a span of 49.2 percent of the wing semispan and was fabricated from duralumin or steel sheet in five equal spanwise segments (figs. 1 to 6). The basic plug ailerons and retractable ailerons on the NACA 65-210 wing had $\frac{3}{16}$ -inch perforations which removed about 9 percent of the original aileron area (reference 3). On the NACA 65₂-215 wing, identical ailerons of varying projection were used in tests of both the plug-aileron and retractable-aileron configurations; these ailerons were fastened to the upper surface of the wing at the 0.70c station (fig. 6). Although these ailerons were not projected out of the wing profile (from the neutral position) as they would be in a practical airplane installation (for example, the configurations on the NACA 65-210 wing), the configurations investigated are believed to simulate practical airplane installations and to provide aerodynamic data representative of these installations. (See fig. 6.)

TESTS

All tests of the basic plug-aileron, the basic retractable-aileron, and the thin-plate circular-plug-aileron configurations on the NACA 65-210 wing model were performed in the Langley high-speed 7- by 10-foot tunnel. All tests of the double-wall circular-plug-aileron configuration on the NACA 65-210 wing model and of the two aileron configurations on the NACA 65₂-215 wing model were performed in the Langley 300 MPH 7- by 10-foot tunnel.

With the flap retracted or deflected, the aerodynamic characteristics of each wing-aileron configuration were determined at various aileron projections and for several angles of attack. Tests were made at Mach numbers between 0.13 and 0.71 (with corresponding Reynolds numbers of 2.6×10^6 to 11.6×10^6 , based on the wing mean aerodynamic chord of 2.86 ft). Negative aileron projections indicate that the ailerons were extended above the wing upper surface.

The average variation of Reynolds number with Mach number for all tests is shown in figure 7.

RESULTS AND DISCUSSION

EFFECT OF AILERON BRAKES ON WING AERODYNAMIC CHARACTERISTICS

Incremental data of lift, drag, and pitching-moment coefficients obtained at various aileron projections with the four aileron configurations investigated on the NACA 65-210 wing and with the flap retracted and deflected are presented in figures 8 to 15. Corresponding data obtained with the two aileron configurations on the NACA 65₂-215 wing are presented in figures 16 to 23.

Incremental lift coefficient ΔC_L .—The incremental values of lift coefficient generally became more negative with increase in aileron projection for all aileron configurations and flap conditions. The data obtained with the basic retractable aileron, however, showed inconsistent trends of reversed or positive values of ΔC_L for small aileron projections at various angles of attack and Mach numbers with the flap deflected. (See figs. 11, 22, and 23.) This phenomenon is usually exhibited by retractable ailerons with the flap deflected. A comparison of the present data with the rolling-moment data of references 3 to 5 shows, as anticipated, that the aforementioned effects paralleled the rolling effectiveness of the ailerons; that is, the rolling effectiveness increased when ΔC_L became more negative.

In general, the incremental values of lift coefficient increased negatively with increases in the Mach and Reynolds numbers and with increase in the flap deflection for all configurations. In most cases, increases in the angle of attack produced a small or inconsistent effect on the values of ΔC_L produced by almost all the ailerons; the thin-plate circular-plug aileron on the NACA 65-210 wing was the only configuration for which ΔC_L became more negative with increased angle of attack (figs. 12 and 13).

The plug ailerons on both wings usually produced slightly larger negative values of ΔC_L than the retractable ailerons. This effect is consistent with the fact that the rolling effectiveness usually observed for the plug aileron is greater than that for the retractable aileron (references 3 and 5). A comparison of the plug-aileron and retractable-aileron data obtained on the two wings also shows that more negative values of ΔC_L were generally obtained on the thicker wing. (See figs. 8 to 11, 16, 19, 20, and 23.)

Incremental drag coefficient ΔC_D .—The incremental drag data of figures 8 to 23—which are based on the values of drag coefficient measured on the wings at approximately a constant angle of attack (at the values of α and C_L shown in the figures for zero aileron projection)—exhibit certain trends that accompanied the lift changes discussed in the section entitled "Incremental lift coefficient ΔC_L ." In most cases, the incremental values of drag coefficient increased with increase in aileron projection; however, at large values of lift coefficient with the flap deflected, an opposite trend was exhibited over a part of the projection range. The values of ΔC_D exhibited a negligible or inconsistent variation with increase in Mach and Reynolds numbers, except possibly at low negative values of C_L with flap retracted (figs. 8 and 10).

In general, the values of ΔC_D became considerably larger (or more positive) as the flap was deflected at a constant value of lift coefficient; however, an increase in the angle of attack and lift coefficient in any flap configuration generally caused a decrease in the values of ΔC_D . This decrease in ΔC_D became more pronounced with increase in aileron projection and with deflection of the flap and, in some instances, particularly at the higher lift coefficients with the flap deflected, the values of ΔC_D became negative. An analysis of the data shows that these trends result from the smaller positive increment in profile drag and the larger reduction in induced wing drag produced by projection of the ailerons as the angle of attack and lift coefficient increased.

For all practical purposes, however, some of the aforementioned changes in ΔC_D —particularly the decreases in the values of ΔC_D with increase in C_L , and the negative values of ΔC_D —would probably never be realized by an airplane in flight. The loss in lift resulting from projection of the aileron brakes on the airplane would probably have to be restored by an increase in the wing angle of attack to retain constant lift and avoid excessive accelerations and sinking speeds. This increase would result in approximately a constant induced drag and an increase in the total wing drag because of the larger profile drag resulting from the higher wing angle of attack and the projected aileron brakes. In order to illustrate the changes in ΔC_D obtained at constant lift coefficient for various aileron projections over the lift-coefficient range, some of the data of figures 8 to 23 have been analyzed and plotted as shown in figure 24. The values of ΔC_D resulting from aileron projection, with angle of attack varied to maintain constant lift coefficient, increased with increase in aileron projection and flap deflection and, for a given aileron projection, ΔC_D was usually fairly constant over the lift-coefficient range. In addition, the incremental drag values were negligibly affected by changes in Mach and Reynolds numbers.

The plug and retractable ailerons produced approximately similar values of ΔC_D on each wing model, but the two circular-plug ailerons generally produced the highest values of ΔC_D on the NACA 65-210 wing model. The data also show that more positive values of ΔC_D were usually obtained on the NACA 65₂-215 wing than on the NACA 65-210 wing at corresponding aileron projections and lift coefficients; however, the large changes in ΔC_D observed for the plug ailerons on the NACA 65₂-215 wing at small projections (figs. 16 to 19, and 24) result principally from the sudden opening of the plug slot rather than from the projection of the aileron alone, as was discussed for the lateral-control investigation reported in reference 5.

Incremental pitching-moment coefficient ΔC_m .—In general, the values of ΔC_m obtained at various aileron projections became more negative (or less positive) with increase in angle of attack in all flap conditions and became more negative with increase in aileron projection in the flap-retracted condition. Changes in the Mach and Reynolds

numbers generally had a negligible or an inconsistent effect on the values of ΔC_m obtained in all flap conditions, and the values of ΔC_m usually became less negative (or more positive) with increase in flap deflection. Because all values of ΔC_m were fairly small, however, the incremental wing pitching moments would probably be easily trimmed on an airplane, regardless of flap condition or aileron configuration.

EFFECT OF AILERON BRAKES ON AIRCRAFT PERFORMANCE

In order to illustrate the utility and one of the advantages to be gained from the changes in lift and drag produced by spoiler ailerons when used as glide-path controls on an airplane, the descent characteristics from an altitude of 40,000 feet of a typical high-performance airplane with and without glide-path controls were computed and are presented in figure 25. Unpublished wind-tunnel data obtained on the model of a high-performance propeller-driven airplane having four engines were used to determine the characteristics of the basic airplane. This airplane had a wing loading of 63 pounds per square foot, a wing aspect ratio of 10.18, and a wing taper ratio of 0.43; in addition, an effective thrust of zero in the flap-retracted condition was assumed. The glide-path controls assumed for the airplane were plug ailerons projected 8 percent chord above both wing panels, and the incremental data used for the glide-path controls were taken from data obtained on the NACA 65₂-215 wing (fig. 16). Although the NACA 65₂-215 wing had a lower aspect ratio than that of the assumed airplane, the lift coefficients at which the assumed airplane flew, in the illustrative example, were low enough to minimize differences in the induced drag and, hence, the incremental drag resulting from aileron projection. For other cases, however, particularly at high lift coefficients, differences in aspect ratio may cause appreciable drag differences which should be considered in a performance analysis. The airplane descent was assumed to start at an altitude of 40,000 feet and a Mach number of 0.7, and the airplane maintained this Mach number until an indicated airspeed of 450 miles per hour was reached. This indicated airspeed was then maintained for the remainder of the descent to sea level.

As can be seen from figure 25, projection of the plug aileron on both wing panels of the airplane decreased the time required to descend from 40,000 feet to sea level from 12.3 to 3.3 minutes. Also a decrease in the horizontal distance required to reach sea level of approximately 73 miles was effected (a straight line of descent was assumed). This saving of time and distance in descending from high altitudes would be particularly important for an emergency condition, such as failure in the cabin pressurization, and also for normal operating conditions, such as at the termination of a long-distance flight at the most efficient altitude (reference 12).

The illustrative example presented in the foregoing discussion was computed with the assumption that the airplane angle of attack was varied to maintain the proper lift coefficient with the flap retracted. This method of operation, however, may not be the most effective one. Deflection of the flap and ailerons simultaneously to provide the necessary lift coefficient at a constant angle of attack—and, at the same time, to increase the drag—or deflection of the ailerons with

the flaps deflected may result in larger decreases in the time and distance required to reach sea level than are shown in the illustrative example. However, other problems, such as downwash fluctuations in the region of the tail plane and excessive flap loads possibly encountered at high Mach number, may complicate or prevent such means of operation. For the illustrative example (wherein a -8-percent-chord aileron projection was employed), in order to maintain a constant α approximately a 10° deflection of the full-span flap would probably be required for simultaneous operation of flap and ailerons as glide-path controls. In general, the simultaneous use of the flaps and the aileron brakes will probably depend on the variation of lift and pitching moment desired for particular maneuvers, such as fighter combat maneuvers, in which only a drag increment is desired.

In addition to their action as glide-path controls, spoiler-aileron brakes provide the added advantage of decreasing wing bending moments by moving the spanwise center of loading inboard on the wings, as shown in figure 26. This effect is particularly important and beneficial for airplanes during descent at high speeds and lessens the possibility of structural failure during this maneuver.

Projection of the ailerons with the flaps deflected in a landing approach would also substantially aid the airplane in landing over high obstacles and on short landing fields and would appreciably decrease the length of landing run. The use of spoiler ailerons as speed brakes to limit or reduce airplane speed in a dive or to reduce airplane speed rapidly in order to increase firing efficiency of fighter aircraft is also feasible, as is apparent from the data previously presented.

Another functional advantage obtainable with spoiler-aileron brakes is the possible use of the ailerons as a gust-alleviation device. Because of the relatively greater adverse effects on passenger riding comfort and wing structural loads of gusts at high speeds, an automatic spoiler-aileron gust-alleviation system should be given due consideration.

Although a comparison of the characteristics of the spoiler-aileron speed brakes discussed herein with the characteristics of other brake devices (such as those of references 13 to 15) is not presented, several advantages of the aileron brakes are readily apparent. These advantages include: The variable braking control permitted by the aileron brakes as compared with the inflexibility of control of some of the other devices; the use of spoiler-aileron brakes would obviate the necessity of including separate braking devices on an airplane; the aileron brakes may be used, retracted into the wing, and immediately used again, but a parachute brake can be used only once before disposal or repacking (on the ground) and is inflexible in control; and also, the spoiler-aileron device would not adversely affect the effectiveness of adjoining wing controls, whereas other devices may (reference 15). In addition, unlike reversible-pitch propeller brakes (reference 16), spoiler-aileron brakes may be used on aircraft having diverse propulsive systems and would obviate any complexity involved in the use of propeller brakes on conventionally powered aircraft. The projected ailerons, when used as glide-path controls or speed brakes, probably would not cause severe tail buffeting inasmuch as the ailerons are placed on the outboard part of the wing near the tip, and the

wake formed by them would be outboard of the tail surfaces. Few data are available, however, concerning any induced effects of the aileron brakes on the wing downwash or on fluctuations in the downwash, and further investigation of such effects may be desirable.

ROLLING CHARACTERISTICS OF THE SPOILER AILERONS USED AS SPEED BRAKES OR GLIDE-PATH CONTROLS

In references 3 to 5, the rolling effectiveness of the plug and retractable ailerons on the NACA 65-210 and NACA 65₂-215 wings was shown to be very satisfactory for normal operation from the retracted aileron position. In order to illustrate the rolling effectiveness of these ailerons from a projected position—that is, when they are used as glide-path controls or speed brakes—some of the data previously presented in references 3 to 5 have been replotted, with zero rolling moment corresponding to some finite aileron projection on both semispans of a complete wing, and are presented in figures 27 to 29. The values of lift coefficient and angle of attack listed on these figures are those obtained with the ailerons in the raised position on both wing panels.

These data indicate that the rolling effectiveness produced by the plug and retractable ailerons from a projected-aileron neutral position was very satisfactory, particularly for the flap-deflected condition. For normal operation from the retracted aileron position, an aileron control-stick differential providing approximately equal up and down projections will probably be required for the plug ailerons; whereas a differential providing large up projections and little or no down projections for lateral control may be required for the retractable ailerons. However, when the ailerons are also used as speed brakes and glide-path controls, any extreme aileron control-stick differential normally employed for lateral control (such as that for the retractable ailerons) would probably have to change as the brakes project on both semispan wings, so that an aileron control-stick linkage allowing approximately equal up and down projections would be obtained for moderate brake projections on both wing panels.

CONCLUSIONS

A wind-tunnel investigation was made to determine the characteristics of plug and retractable ailerons used as speed brakes or glide-path controls on an NACA 65-210 and an NACA 65₂-215 wing equipped with full-span slotted flaps. The investigation was performed at various Mach numbers from 0.13 to 0.71. The results of the investigation led to the following conclusions:

1. The time for descent and distance for descent from high altitudes and wing bending moments can be greatly reduced by use of spoiler ailerons as brakes.
2. When used as speed brakes or glide-path controls, the rolling effectiveness of plug and retractable ailerons need not be impaired as compared with the effectiveness of the ailerons from the fully retracted position.
3. The incremental values of drag coefficient ΔC_D produced by projection of the ailerons on both wing panels of a complete wing generally became more positive with increase in aileron projection and flap deflection and were inconsistently or negligibly affected by changes in Mach

number. In addition, the ailerons generally produced larger increments of drag on the thicker wing model.

4. The increment in lift coefficient ΔC_L produced by projection of the ailerons generally became more negative with increase in aileron projection, flap deflection, and Mach and Reynolds numbers.

5. In general, the incremental values of pitching-moment coefficient ΔC_m produced by projection of the ailerons were fairly small, varied only slightly with changes in angle of attack, Mach number, aileron projection, or flap deflection and were about the same on both wing models.

REPORT 1035

ANALYSIS OF MEANS OF IMPROVING THE UNCONTROLLED LATERAL MOTIONS OF PERSONAL AIRPLANES¹

By MARION O. MCKINNEY, Jr.

SUMMARY

A theoretical analysis has been made of means of improving the uncontrolled motions of personal airplanes. The purpose of this investigation was to determine whether such airplanes could be made to fly uncontrolled for an indefinite period of time without getting into dangerous attitudes and for a reasonable period of time (1 to 3 min) without deviating excessively from their original course.

The results of this analysis indicated that the uncontrolled motions of a personal airplane could be made safe as regards spiral tendencies and could be greatly improved as regards maintenance of course without resort to an autopilot. The only way to make the uncontrolled motions completely satisfactory as regards continuous maintenance of course, however, is to use a conventional type of autopilot.

Theoretical analysis indicated that, although most present-day personal airplanes possess a slight degree of positive spiral stability, they can easily get into dangerous attitudes and deviate excessively from their original course in uncontrolled flight because of out-of-trim moments and insufficient spiral stability. In order to insure even reasonably satisfactory uncontrolled motions, these out-of-trim moments must be almost entirely eliminated by trimming the airplane in flight and by keeping control-system friction low or using some mechanical system to provide positive centering of the controls. Spiral stability can be increased by increasing tail length or increasing the vertical-tail area and dihedral angle simultaneously, or by increasing all of these factors simultaneously, without adversely affecting the flying qualities of the airplane.

INTRODUCTION

The problem of making a personal airplane fly uncontrolled for an indefinite period of time without getting into dangerous attitudes and for a reasonable period of time (1 to 3 min) without excessive change in heading has attracted considerable interest. Personal airplanes, when flown by inexperienced pilots or without the proper instruments, may get into dangerous attitudes during periods of blind flying. They may also wander off course while the pilot is busy with maps and navigation problems or is otherwise occupied so that he does not concentrate on flying the airplane. An analysis has been made therefore to determine means of improving the uncontrolled motions of a personal airplane. Although an airplane may possess sufficient stability to

insure its return to the original flight attitude following a disturbance such as a gust, it cannot be expected to return to its original heading with respect to the compass without the application of corrective control. If an autopilot is not used to supply this control action, the problem then becomes one of making the airplane safe in uncontrolled flight and reducing the deviation from course to a minimum.

SYMBOLS

All forces and moments are referred to the stability system of axes which is defined as an orthogonal system having its origin at the center of gravity and the Z-axis in the plane of symmetry and perpendicular to the relative wind (positive direction downward), the X-axis in the plane of symmetry and perpendicular to the Z-axis (positive direction forward), and the Y-axis perpendicular to the plane of symmetry (positive direction to right).

S	wing area, square feet
S_t	vertical tail area, square feet
b	wing span, feet
l	distance from airplane center of gravity to vertical-tail center of pressure, feet
m	mass of airplane, slugs
ρ	air density, slugs per cubic foot
V	airspeed, feet per second
q	dynamic pressure, pounds per square foot $\left(\frac{1}{2} \rho V^2\right)$
β	angle of sideslip, degrees except where otherwise noted
r	yawing angular velocity, radians per second
p	rolling angular velocity, radians per second
C_L	lift coefficient (Lift/ qS)
C_Y	lateral-force coefficient (Lateral force/ qS)
C_l	rolling-moment coefficient (Rolling moment/ qSb)
C_n	yawing-moment coefficient (Yawing moment/ qSb)
$C_{Y\beta}$	variation of lateral-force coefficient with angle of sideslip in radians ($\partial C_Y / \partial \beta$)
$C_{l\beta}$	variation of rolling-moment coefficient with angle of sideslip, per degree except where otherwise noted ($\partial C_l / \partial \beta$)
$C_{n\beta}$	variation of yawing-moment coefficient with angle of sideslip, per degree except where otherwise noted ($\partial C_n / \partial \beta$)

μ	relative-density factor ($m/\rho S b$)

CALCULATIONS

Two types of calculations were performed in the present investigation: calculations of spiral-stability boundaries and calculations of the motions of several configurations of a hypothetical personal airplane for several disturbances. The characteristics of the basic airplane, which is fairly representative of present-day two-place personal airplanes, are given in references 1 and 2 and were determined by averaging the characteristics of several personal airplanes. The various modified configurations include changes in the dihedral angle, vertical-tail area, and tail length for improving the uncontrolled motions of the conventional personal-airplane configuration. The results of the calculations apply directly only to the hypothetical personal airplane which had a wing loading of 9.25 pounds per square foot and a span of 32 feet. The results can be applied fairly well to specific personal airplanes, however, by dividing the values of time by $\frac{10.5}{b} \sqrt{\frac{W}{S}}$ where $\frac{W}{S}$ and b are the wing loading and span, respectively, of the specific airplane.

The spiral-stability boundaries were calculated by the method presented in reference 3 which states that, for level flight, neutral spiral stability occurs when

$$C_{l_\beta} C_{n_r} = C_{n_\beta} C_{l_r}$$

The values of the stability derivatives C_{n_r} , C_{n_β} , and C_{l_r} used in the boundary calculations are given in table I. The derivative C_{l_β} was treated as the dependent variable. The

TABLE I.—VALUES OF STABILITY DERIVATIVES USED IN CALCULATIONS OF SPIRAL-STABILITY BOUNDARIES

C_{n_β}	C_{n_r}		C_L	C_{l_r}	
	Normal tail arm (0.466)	Long tail arm (0.926)		Ailerons fixed	Ailerons free
0	-0.039	-0.078	0.20	0.050	-----
.001	-.092	-.184	.35	.086	0.030
.002	-.145	-.290	.40	.100	-----

.004	-.252	-.505	.80	.200	-----
.005	-.305	-.610			

spiral-stability boundaries were calculated with the assumption that the value of C_{n_β} was increased by increasing the vertical-tail area so that the value of $-C_{n_r}$ increased as C_{n_β} increased.

The rolling and yawing motions of the airplane following various control and gust disturbances were calculated by using the equations of motion presented in reference 3. The applied disturbing moments used in the calculations are given in table II and the stability derivatives used in the motion calculations are presented in table III. The lift coefficient of 0.35 is fairly representative of the lift coefficient of personal airplanes at cruising speed, and the lift coefficient of 1.8 represents the maximum lift coefficient of the airplane with flaps down.

RESULTS AND DISCUSSION

A personal airplane may get into a dangerous attitude or deviate excessively from its original course in uncontrolled flight as far as its lateral characteristics are concerned for two reasons: it may be out of trim, or it may be spirally unstable.

$^1\beta$ in radians.

Several factors are involved in eliminating out-of-trim moments and spiral stability may be increased by several means. The present analysis therefore is divided into two parts for convenience in discussion. The first part treats the uncontrolled motions of a conventional personal airplane and means of improving these motions without changing the geometric configuration of the airplane. The second part treats the uncontrolled motions of various configurations modified geometrically to improve the spiral stability.

CONVENTIONAL AIRPLANE CONFIGURATION

Spiral stability.—An airplane must be spirally stable if it is to fly uncontrolled without diverging from its original attitude. The first step in an analysis of means of improving the uncontrolled lateral motions, therefore, is to determine whether present-day personal airplanes are spirally stable. An indication of whether such airplanes are spirally stable can be obtained from figure 1. This figure shows calculated spiral-stability boundaries for a hypothetical personal airplane at various lift coefficients with fixed controls as functions of the directional-stability parameter $C_{n\beta}$ and the effective-dihedral parameter $-C_{l\beta}$. An airplane for which the point on the chart would be on the right side of the boundary is spirally stable; whereas one for which the point would be on the left side of the boundary is spirally unstable. The crosshatched region indicates the position in which points for most present-day personal airplanes would be located on the chart. The lift coefficient corresponding to the cruising speed was determined for several personal airplanes from published performance specifications and was found to be between 0.25 and 0.35. The data presented in figure 1 indicate therefore that most present-day personal airplanes possess a slight degree of positive spiral stability for the cruising-flight condition for which good uncontrolled behavior is most desired.

The significance of a slight degree of positive spiral stability is illustrated by the calculated motion of the hypothetical personal airplane following a disturbance by a rolling gust. The location of the point representing this airplane relative to the spiral-stability boundary is shown in figure 2 (a) where the conventional personal airplane with controls fixed is designated configuration 1. The motion of this airplane following a disturbance by a mild rolling gust ($\frac{pb}{2V} = 0.01$ for 1 sec) is presented in figure 3 where the variations of the angles of bank and heading with time are shown. This figure shows that the gust caused the airplane to bank about 5° and that the airplane slowly returned toward 0° bank. As a result of this bank, the airplane turned considerably off its original course. This motion represents about as poor behavior as could be expected of present-day personal airplanes since the directional stability of the hypothetical airplane ($C_{n\beta} = 0.00115$) is higher than that of most personal airplanes and the cruising lift coefficient of the hypothetical airplane ($C_L = 0.35$) is as high as that of any present-day personal airplane. Most personal airplanes, particularly those with relatively high performance, would be expected

to return toward 0° bank more rapidly and turn less in response to the same disturbance than configuration 1 since they would probably be more spirally stable than this hypothetical airplane.

The effect on spiral stability of freeing the ailerons is illustrated by the calculations for the hypothetical personal airplane with ailerons free, designated configuration 1A. The following assumptions were made for these calculations: that the value of $-C_{l\beta}$ was not affected by the freeing of the ailerons, that the airplane had an NACA 4412 airfoil section with Frise ailerons, and that no friction was present in the aileron control system to prevent the ailerons from floating freely. These ailerons have a strong up-floating tendency so that, as the airplane turns with the stick free, the aileron on the faster-moving wing deflects up and the aileron on the slower-moving wing deflects down. This movement of the ailerons tends to roll the airplane out of the turn. In effect, this movement of the ailerons causes the value of C_{lr} to be lower with stick free than with stick fixed and thereby shifts the spiral-stability boundary as shown for configuration 1A in figure 2 (b). This effect of freeing the ailerons on the motion resulting from a rolling-gust disturbance is illustrated in figure 3 which shows that with the ailerons free (configuration 1A) the airplane returns toward 0° bank more rapidly and does not turn so far off the course as with the ailerons fixed. The airfoil section and the aileron balance assumed for configuration 1A give about as much up-floating tendency as can be expected without resort to some such device as downwardly deflected tabs on the ailerons to provide additional up-floating tendency; therefore, the difference between the motions for configurations 1 and 1A represents the maximum that can be expected from freeing the ailerons unless additional up-floating tendency is provided.

FIGURE 1.—Spiral-stability boundaries for a personal airplane with fixed controls.

FIGURE 2.—Spiral stability of the conventional personal airplane for configurations 1 and 1A.

The effect of freeing the rudder can be ascertained from an analysis of the equation for neutral spiral stability ($C_{l\dot{\beta}}C_{n\dot{\gamma}} = C_{n\dot{\beta}}C_{l\dot{\gamma}}$). Freeing the rudder changes the values of $C_{n\dot{\beta}}$ and $C_{n\dot{\gamma}}$ in approximately the same ratio so that freeing the rudder has almost no effect on spiral stability.

The analysis has shown that most present-day personal airplanes are spirally stable with the controls fixed and will return toward 0° bank following a disturbance although they will have changed heading somewhat and that these airplanes are just as spirally stable or even more spirally stable with controls free than with controls fixed. It is known, however, that in uncontrolled flight most personal airplanes tend to deviate from their original attitude and not return. Since this characteristic, therefore, cannot usually be attributed to spiral instability it must result from out-of-trim moments.

FIGURE 3.—Motions of the conventional personal airplane resulting from a mild gust disturbance (gust strength $\frac{pb}{2V} = 0.01$ for 1 sec) for the two configurations shown in figure 2.

Out-of-trim moments.—Almost all personal airplanes are out of trim in roll and yaw to a certain extent because of improper rigging, change of trim with power, absence of trim tabs, and control-system friction which prevents proper centering of the controls. As pointed out previously, an airplane has no stability of course. An airplane which is out of trim cannot, therefore, be reasonably expected to fly uncontrolled for an appreciable period of time without considerable change in heading. Trim tabs, or some other means of trimming the airplane in flight should be considered essential, therefore, if the airplane is to fly uncontrolled for a reasonable period of time without excessive change in heading. Control-system friction will tend to hold the controls in the proper position after the pilot has trimmed the airplane with the stick and the rudder pedals, but it will cause considerable trouble that tends to offset this one good characteristic. For example, friction keeps the controls from centering after they are deflected by a gust or other disturbance. Friction also obscures the feel of the controls, a condition which is always objectionable, particularly since the pilot cannot center the controls without the aid of instruments under blind-flying conditions.

The effect of out-of-trim moments on the uncontrolled motions of the hypothetical personal airplane is shown in figures 4 and 5. Figure 4 shows the variation of bank and heading with time when the ailerons are 1° out of trim and figure 5 shows similar motions for the case of 1° out-of-trim

FIGURE 4.—Motions of the conventional personal airplane resulting from 1° out-of-trim aileron deflection for the two configurations shown in figure 2.

rudder deflection. The calculated motions presented in these figures show that, if either the ailerons or rudder are out of trim, the airplane will bank and turn at a fairly rapid rate with no tendency to return to its original attitude as regards either bank or heading. This is true either with the ailerons fixed (configuration 1) where the airplane has slight positive spiral stability or with ailerons free (configuration 1A) where the airplane has considerably more spiral stability. It is apparent from these calculated motions that almost no out-of-trim moments can be tolerated so that, in addition to providing some means of trimming the airplane in flight, the effect of control-system friction in holding the controls deflected and obscuring the feel of the controls must be eliminated.

As pointed out in reference 4, the allowable limits for control-system friction cannot be set at the present time. Vibration of the airplane may relieve, to a certain extent, the effect of friction in holding the controls deflected so that the allowable limits for control friction cannot be determined

FIGURE 5.—Motions of the conventional personal airplane resulting from 1° out-of-trim rudder deflection for the two configurations shown in figure 2.

solely from static considerations of the aerodynamic and frictional hinge moments. Some special flight research work is required to establish an upper limit for the allowable friction as regards proper centering of the ailerons and rudder to prevent an airplane from getting into dangerous attitudes or deviating excessively from its original course in uncontrolled flight.

If keeping the friction forces in the control system low enough is found to be too difficult to be practical for a personal airplane, some mechanical device might be employed that would eliminate the effect of friction without necessitating the elimination of the friction. One such device, the effect of which is being studied experimentally in flight tests at the Langley Aeronautical Laboratory, is illustrated schematically in figure 6. This device consists essentially of preloaded springs that provide positive centering for the controls since at any deflection they provide a restoring force which is greater than the static-friction force in the control system. Since these springs would cause a

FIGURE 6.—Schematic diagram of a device for positively centering the controls.

nonlinear control-force gradient through zero deflection which might be annoying to the pilot at times, means for engaging and disengaging the centering device at will might be required. Because of the stretch in the control system, such a device might preferably be installed at the ailerons and rudder rather than on the control stick or rudder pedals as indicated by the sketch. This device could also be used to trim the airplane if the preload in the springs is greater than the control forces required for trim.

If out-of-trim moments are eliminated by trimming the airplane in flight and by eliminating the effect of control-system friction in preventing the controls from centering properly, a conventional personal airplane should be fairly safe as regards the ability to fly uncontrolled for indefinite periods of time without getting into a dangerous attitude and should be fairly satisfactory as regards the ability to fly uncontrolled for reasonable periods of time without excessive deviations from its original course. A considerable improvement in the uncontrolled motions of a personal airplane may, however, be obtained by modifying it to obtain greater spiral stability.

MODIFIED AIRPLANE CONFIGURATION

Several means are available for modifying a conventional personal airplane so as to increase its spiral stability. These methods are fairly obvious from examination of the relation from reference 3 which shows that an airplane is spirally stable when

$$C_{l\beta}C_{n_r} > C_{n\beta}C_{l_r}$$

This expression indicates that spiral stability can be increased by increasing the values of $-C_{l\beta}$ and $-C_{n_r}$ or by reducing the values of $C_{n\beta}$ and C_{l_r} . The value of $-C_{l\beta}$ can be increased by increasing the dihedral angle without appreciably affecting the other stability derivatives. The values of $C_{n\beta}$ and $-C_{n_r}$ are both functions of the vertical-tail size and tail length as shown by the following approximate equations:

$$C_{n\beta} \approx \frac{S_t}{S} \frac{l}{b} C_{L_{a_t}}$$

and

$$-C_{n_r} \approx 2 \frac{S_t}{S} \left(\frac{l}{b}\right)^2 C_{L_{a_t}}$$

where the principal assumption is that the airplane has about zero $C_{n\beta}$ without a vertical tail. These two equations indicate that $C_{n\beta}$ and $-C_{n_r}$ can be varied either simultaneously or independently by adjusting the vertical-tail area and tail length. The value of C_{l_r} cannot be changed greatly for the controls-fixed condition by changes to the geometry of the airplane. As previously mentioned, however, C_{l_r} can be varied considerably with the ailerons free by adjusting the aileron floating characteristics.

As pointed out in reference 4, the design conditions for increasing spiral stability often conflict with other factors known to be essential in the attainment of satisfactory flying qualities. When an airplane is modified so as to improve its uncontrolled motions by increasing its spiral stability, the effect of these changes on its flying qualities should be considered. The discussion of the effects of modifications to the conventional personal airplane is presented in two parts: the effect on flying qualities and the effect on the uncontrolled motions.

Effect of modifications on flying qualities.—Experience has shown that increasing the dihedral angle of an airplane so as to increase its spiral stability causes its flying qualities to become less satisfactory since the rolling velocity in an aileron roll tends to reverse. With most personal airplanes, however, some increase in dihedral angle can be effected without causing the flying qualities to become unsatisfactory. Experience has also shown that the spiral stability of most personal airplanes should not be increased by reducing the size of the vertical tail (reducing $C_{n\beta}$) since this change would result in unsatisfactory flying qualities in the form of excessive sideslip in aileron rolls. Analysis of figure 1 indicates that the spiral stability of a personal airplane can be increased by increasing the vertical-tail area and dihedral angle simultaneously so as to maintain the same ratio of $C_{n\beta}$ to $C_{l\beta}$ as that of the original airplane. This change can be made without sacrificing controllability. The effect of increasing the tail length and reducing the tail size of a personal airplane so as to increase the damping in yaw without increasing $C_{n\beta}$ has not been definitely determined. Flight experience with models has indicated, however, that increasing the tail length will not have an adverse effect on controllability.

On the basis of this analysis several modified configurations of the hypothetical conventional personal airplane were chosen for a more detailed analysis of flying qualities and uncontrolled motions. These configurations are indicated by the sketches of figure 7 and by the spiral stability charts of figure 8. Configuration 1 represents the conventional personal airplane which is used as a basis for comparison. Configuration 2 represents an airplane with an increase in dihedral angle of about 6° from configuration 1. Configuration 3 incorporates an increase in dihedral angle of 10° and an increase in vertical-tail area of about 2.5 times that of configuration 1. Configuration 4 represents an airplane having twice the tail length and half the tail area of the conventional personal airplane. Configuration 5 represents

a combination of the high dihedral of configuration 2 and the tail length and tail area of configuration 4. Configuration 6 incorporates a simultaneous increase in dihedral angle

FIGURE 7.—Sketches of the conventional personal airplane (configuration 1) and the modified airplanes (configurations 2 to 6).

(a) $l=0.466$.
(b) $l=0.926$.

FIGURE 8.—Spiral stability of the conventional personal airplane (configuration 1) and the modified airplanes (configurations 2 to 6).

of 10° and an increase in vertical-tail area of about 2.5 times that of configuration 4.

The effects of these various modifications on controllability are shown in figure 9 by the calculated rolling motions resulting from 50° total aileron deflection. Figure 9 (a) shows that the controllability in cruising flight is not greatly affected by any of the modifications to the conventional personal-airplane configuration. Figure 9 (b), however, shows that

(a) $C_L=0.35$.
(b) $C_L=1.80$.

FIGURE 9.—Rolling motions resulting from 50° total aileron deflection for the six configurations shown in figures 7 and 8.

increasing the dihedral angle (configurations 1 to 2 or 4 to 5) has a pronounced adverse effect on the controllability. The flying qualities for configuration 2 are unsatisfactory since the rolling velocity reverses. Increasing the damping in yaw (configurations 1 to 4 or 2 to 5) or increasing the dihedral angle and vertical-tail area simultaneously (configurations 1 to 3 or 4 to 6) improves the controllability of the airplane at high lift coefficients.

Effect of modifications on uncontrolled motions.—The effects of the various modifications on the uncontrolled motions of the personal airplane are shown in figures 10 to 12. These figures show that all the modifications for increasing the spiral stability of the airplane improved its uncontrolled motions. In response to a rolling gust (fig. 10) the modified configurations returned toward 0° bank more rapidly and did not turn as far off course as the original airplane configuration. In response to an out-of-trim aileron or rudder deflection (figs. 11 and 12) the modified configurations did not bank as far or turn off course as fast as the original airplane configuration. These data indicate that, if a personal airplane is modified so as to increase its spiral stability, larger out-of-trim moments can be tolerated than on the conventional configuration.

Increasing the dihedral angle alone (configurations 1 to 2 or 4 to 5) is the least effective method of improving the uncontrolled motions of a personal airplane since the motions resulting from an out-of-trim rudder deflection are about the

same with the high dihedral as with the original dihedral. (See figs. 10 to 12.) Since increasing the dihedral alone also causes the controllability to become less satisfactory, this method of increasing the spiral stability does not appear to be very satisfactory. Changing the tail length of personal airplanes very much is probably not very practical because of the greater landing-gear length required when the tail length is increased. The most practical method of increasing the spiral stability of a personal airplane so as to improve its uncontrolled motions appears to be to increase its dihedral angle and vertical-tail area simultaneously (configurations 1 to 3 and 4 to 6), so as to keep the ratio of C_{n_β} to C_{l_β} about the same, and to use as great a tail length as is practical. As pointed out previously, it is also possible to improve the uncontrolled motions still more for the control-free condition by increasing the upward-floating tendency of the ailerons provided there is no friction to prevent the ailerons from floating freely. This change probably would not affect the controllability of the airplane.

FIGURE 10.—Motions resulting from a mild gust disturbance (gust strength $\frac{pb}{2V} = 0.01$ for 1 sec) for the six configurations shown in figures 7 and 8.

FIGURE 11.—Motions resulting from 1° out-of-trim aileron deflection for the six configurations shown in figures 7 and 8.

GENERAL CONSIDERATIONS REGARDING MAINTENANCE OF COURSE

As pointed out previously, an airplane has no stability of course and consequently cannot be expected to return to its original course after a disturbance unless a conventional type of autopilot is used. This fact is illustrated in figures 3 and 10 where it is shown that there is a change of heading after a gust disturbance even for very spirally stable configurations. Continuous maintenance of course cannot, therefore, be obtained without an autopilot. Fairly good maintenance of course over a reasonably long period of time should be possible, however, without an autopilot if the airplane is spirally stable and stays in trim. From the theory of random motion, the deviation from course due to random gust disturbances would be expected to average out to no deviation over an infinite period of time. For any finite period of time, however, the deviations from course due to random gusts would tend to add up to no deviation but

would not be expected to add up to exactly zero deviation. Because of this tendency for the deviations caused by random gusts to cancel out, the deviation from course over a reasonably long period of time would be expected to be fairly small.

CONCLUSIONS

An analysis of the uncontrolled motions of personal airplanes has shown that a personal airplane can be made safe as regards spiral tendencies and its uncontrolled motions as regards maintenance of course can be greatly improved without resort to an autopilot. The only way to make the uncontrolled motions completely satisfactory as regards continuous maintenance of course, however, is to use a conventional type of autopilot.

Theoretical analysis has indicated that most present-day personal airplanes possess a slight degree of positive spiral stability but can easily get into dangerous attitudes and deviate excessively from their original heading in uncontrolled flight because of out-of-trim moments and insufficient spiral stability. In order to insure even reasonably satisfactory uncontrolled motions, these out-of-trim moments must be eliminated or at least reduced to very small magnitudes. Some means of trimming the airplane in flight is necessary, therefore, and the effect of control-system friction in preventing proper centering of the controls by the pilot or by the aerodynamic forces must be almost entirely eliminated by having very low friction or by having some mechanical device that will provide positive centering of the controls. Increasing the spiral stability will also improve the uncontrolled motions of personal airplanes. An increase in spiral stability for personal airplanes can be obtained by increasing tail length or increasing the vertical-tail area and dihedral angle simultaneously, or by increasing all of these factors simultaneously, without adversely affecting the flying qualities of the airplane.

REPORT 1036

EXPERIMENTAL INVESTIGATION OF THE EFFECTS OF VISCOSITY ON THE DRAG AND BASE PRESSURE OF BODIES OF REVOLUTION AT A MACH NUMBER OF 1.5¹

By DEAN R. CHAPMAN and EDWARD W. PERKINS

SUMMARY

Tests were conducted to determine the effects of viscosity on the drag and base pressure of various bodies of revolution at a Mach number of 1.5. The models were tested both with smooth surfaces and with roughness added to evaluate the effects of Reynolds number for both laminar and turbulent boundary layers. The principal geometric variables investigated were afterbody shape and length-diameter ratio. For most models, force tests and base pressure measurements were made over a range of Reynolds numbers, based on model length, from 0.6×10^6 to 5.0×10^6 . Schlieren photographs were used to analyze the effects of viscosity on flow separation and shock-wave configuration near the base and to verify the condition of the boundary layer as deduced from force tests. The results are discussed and compared with theoretical calculations.

The results show that viscosity effects are large and depend to a great degree on the body shape. The effects differ greatly for laminar and turbulent flow in the boundary layer, and within each regime depend upon the Reynolds number of the flow. Laminar flow was found up to a Reynolds number of 6.5×10^6 and may possibly exist to higher values.

The flow over the afterbody and the shock-wave configuration near the base are shown to be very much different for laminar than for turbulent flow in the boundary layer. The base pressure on bodies with boattailing is much higher with the turbulent layer than with the laminar layer, resulting in a negative base drag in some cases. The total drag characteristics at a given Reynolds number are affected considerably by the transition to turbulent flow. The foredrag of bodies without boattailing and of boattailed bodies for which the effects of flow separation are negligible can be calculated with reasonable accuracy by adding the skin-friction drag based upon the assumption of the low-speed friction characteristics to the theoretical wave drag.

For laminar flow in the boundary layer the effects of varying the Reynolds number were found to be large, approximately doubling the base drag in many cases. The total drag of the bodies without boattailing varied about 20 percent over the Reynolds number range investigated. For turbulent flow in the boundary layer, however, variations in Reynolds number had only a small effect on base drag and total drag.

INTRODUCTION

The effects of viscosity on the aerodynamic characteristics of bodies moving at low subsonic speeds have been known for many years and have been evaluated by numerous investigators. The effects of viscosity at transonic speeds have been investigated to a limited extent, and significant effects on the flow over airfoils have been reported by Ackeret (reference 1) and Liepmann (reference 2). The relative thoroughness of these two investigations has furnished a good start toward a satisfactory evaluation and understanding of the effects of viscosity in transonic flow fields. However, little is known about viscous effects at supersonic speeds.

The experiments reported in references 3, 4, and 5 have succeeded in evaluating the magnitude of the skin friction for supersonic flows in pipes and on rotating surfaces, but not for flow over a slender body or an airfoil.² Reference 6 contains a small amount of data on the effects of Reynolds number on the drag of a sphere and a circular cylinder; however, these data are not applicable to aerodynamic shapes which are practical for supersonic flight.

It has been sometimes assumed that the effects of viscosity are small and need be considered only when determining the magnitude of skin friction. In reviewing past data for the effects of viscosity it was found that in many reports, such as references 7 and 8, the model size was not stated, thereby rendering the calculation of Reynolds number and the evaluation of such tests quite difficult. Preliminary tests made during 1945 in the Ames 1- by 3-foot supersonic wind tunnel No. 1, which is a variable-pressure tunnel, showed a relatively large effect of Reynolds number on the drag of bodies of revolution. The results of this cursory investigation were not reported because the magnitude of support interference was not known and because certain inaccuracies in the balance measurements were known to exist in the data taken at low tunnel pressures. An investigation of wing-body interaction at supersonic speeds has been conducted subsequently and the results presented in reference 9. Because of the support interference and the balance inaccuracies noted at low pressures the data presented therein on the effect of

¹ Supersedes NACA RM A7A31a, "Experimental Investigation of the Effects of Viscosity on the Drag of Bodies of Revolution at a Mach Number of 1.5" by Chapman, Dean R., and Perkins, Edward W., 1947. The principal results of various investigations conducted subsequent to 1947 which either pertain to or supplement the experiments described herein are indicated in footnotes.

² Subsequent to 1947 several investigations of skin friction have been conducted which indicate that at the supersonic Mach number of the present investigation the laminar and turbulent skin-friction coefficients for a flat plate are about 3- and 12-percent lower, respectively, than for low-speed flow at the same Reynolds number.

Reynolds number on the drag of smooth bodies are not sufficiently accurate throughout the range of Reynolds numbers for direct application to the conditions of free flight.

Since the effects of viscosity were known to be relatively large at the outset of this investigation, the purpose of the present research was made twofold. The primary purpose was to develop an understanding of the mechanism by which viscosity alters the theoretical inviscid flow over bodies of revolution at supersonic speeds, and the secondary purpose was to determine the magnitude of these effects for the particular bodies investigated. The experiments were conducted during 1946.

APPARATUS AND TEST METHODS

WIND TUNNEL AND INSTRUMENTATION

A general description of the wind tunnel and the principal instrumentation used can be found in reference 9. Included therein is a description of the strain-gage balance system employed for measuring aerodynamic forces and the schlieren apparatus which forms an integral part of the wind-tunnel equipment. In order to obtain accurate data at low as well as high tunnel pressures, a more sensitive drag gage was used in the present investigation than in the investigation of reference 9; however, all other details of the balance system were the same.

The tunnel total pressure, the static reference pressure in the test section, and the pressure in the air chamber of the balance housing were observed on a mercury manometer. Because the difference between the base pressure and the static reference pressure in the test section was ordinarily too small (only 0.5 cm. of mercury at low tunnel pressures) to be accurately read from a mercury manometer, a supplementary manometer using a fluid of lower specific gravity was employed. Because of its lower vapor pressure and its property of releasing little or no dissolved air when exposed to very low pressures, dibutyl phthalate, having a specific gravity of approximately 1.05 at room temperatures, was used as an indicating fluid in this manometer instead of the conventional light manometer fluids such as water and alcohol.

FIGURE 1.—Principal body shapes investigated.

MODELS AND SUPPORTS

Photographs of the models, which were made of aluminum alloy, are shown in figures 1 and 2, and their dimensions are given in figure 3. Models 1, 2, and 3 were each formed of a 10-caliber ogive nose followed by a short cylindrical section; they differ from one another only in the amount of boat-tailing. The shape of the ogive was not varied in this investigation because the flow over it is not affected appreciably by viscosity. Models 4, 5, and 6, which differ from one another only in thickness ratio, were formed by parabolic arcs with the vertex at the position of maximum thickness. For convenience, some of the more important geometric properties of models 1 through 6 are listed in the following table:

Model	Frontal area A (sq in.)	Nose half angle (deg)	Length diameter ratio l/D	Base-area ratio A_B/A
1-----	1.227	18.2	7.0	1.00
2-----	1.227	18.2	7.0	.558
3-----	1.227	18.2	7.0	.348
4-----	.866	11.3	8.8	.191
5-----	1.758	15.9	6.2	.186
6-----	3.426	21.8	4.4	.187

(a) Models used for boundary-layer tests and for comparison tests with other investigations.
FIGURE 2.—Special-purpose models.

(b) Models used to evaluate effect of length-diameter ratio on base pressure.
FIGURE 2.—Concluded.

In addition to the above-mentioned models, several other bodies were tested for certain specific purposes. Thus, models 7 and 8 were made unusually long so that the skin friction would be a large portion of the measured drag, thereby enabling the condition of the boundary layer to be deduced from force tests. Various substitute ogives, shown in figure 2 (a), were made interchangeable with the smooth ogive that is shown attached to the cylindrical afterbody of model 8. These ogives were provided with different types and amounts of roughness and could be tested either alone or with the long cylindrical afterbody attached. When the ogives were tested alone, a shroud of the same diameter as the ogive was used to replace the cylindrical afterbody. Model 9, a body with a conical nose, and model 10, a sphere of 1-inch diameter, were tested in order to compare the results of the present investigation with existing theoretical calculations and with the results of other experimental investigations. Models 11, 12, 13, and 14 were constructed to determine the effects of the length-diameter ratio for a fixed shape of afterbody. In all cases when a smooth surface was desired, the models were polished before testing to

(b) Models with cylindrical afterbodies.

FIGURE 3.—Model dimensions.

obtain a surface as free from scratches and machining marks as possible.

The models were supported in two different ways: by a rear support and by a side support, as shown in figure 4. The rear support used in the majority of the cases consisted of a sting which supported the model and attached to the balance beam. A thin steel shroud enclosed the sting and thereby eliminated the aerodynamic tare forces. Use of the rear support allowed force data, base pressure data, and schlieren photographs to be taken simultaneously. The side support which attached to the lower side of the model consisted of a 6-percent-thick airfoil of straight-side segments and 7° semiwedge angle at the leading and trailing edges. The side support was used to determine the effects of the axial variation in test-section static pressure on base pressure, and, in conjunction with a dummy rear support, to evaluate the effects of support interference.

(a) Rear support.
(b) Side support.

FIGURE 4.—Typical model installations.

TEST METHODS

The tests were conducted at zero angle of attack in a fixed nozzle designed to provide a uniform Mach number of approximately 1.5 in the test section. For the positions occupied by the different models, the free-stream Mach number actually varied from 1.49 to 1.51. This is somewhat lower than the Mach number of the tests reported in reference 9, which were conducted farther downstream in the test section.

Before and after each run precautions were taken to test the pressure lines for leaks and the balance system for friction or zero shift. Each run was made by starting the tunnel at a low pressure, usually 3 pounds per square inch absolute, and taking data at different levels of tunnel stagnation pressure up to a maximum of 25 pounds per square inch absolute. Because of the lag in the manometer system, approximately 15 minutes at low pressures and 5 minutes at high pressures were allowed for conditions to come to equilibrium. The over-all variation in Reynolds number based on body length ranged from about 0.10×10^6 to 9.4×10^6 . The specific humidity of the air usually was maintained below 0.0001 pound of water per pound of dry air, and in all cases was below 0.0003.

In general, each body was tested with a polished surface and then later with roughness added to fix transition. As illustrated in figure 2 (a), several different methods of fixing transition on a body in a supersonic stream were tried. The

usual carborundum method employed in subsonic research was not used because of the danger of blowing carborundum particles into the tunnel-drive compressors. The method finally adopted was to cement a $\frac{1}{8}$ -inch-wide band of particles of table salt around the body. This method proved successful at all but the very low Reynolds numbers. On models 1, 2, 3, and 12, roughness was located $\frac{1}{8}$ inch downstream of the beginning of the cylindrical section. On models 4, 5, and 6 the roughness was placed 4.5 inches from the nose and on model 8, $\frac{1}{8}$ inch upstream of the beginning of the cylindrical afterbody. Models 7, 9, 10, 11, 13, and 14 were tested in the smooth condition only.

RESULTS

REDUCTION OF DATA

The force data included in this report have been reduced to the usual coefficient form through division by the product of the free-stream dynamic pressure and the frontal area of the body. In each case, conditions just ahead of the nose of a model are taken as the free-stream conditions.

The measurements of the pressure on the base of each model are referred to free-stream static pressure and made dimensionless through division by the free-stream dynamic pressure. Thus, the base pressure coefficient is calculated from the equation

$$P_b = \frac{p_b - p_\infty}{q_\infty} \quad (1)$$

where

- P_b base pressure coefficient
- p_b pressure acting on the base
- p_∞ free-stream static pressure
- q_∞ free-stream dynamic pressure

The dynamic pressure is calculated from the isentropic relationships. A small experimentally determined correction is applied for the loss in total pressure due to condensation of water vapor in the nozzle. The Reynolds number is based upon the body length and is calculated from the isentropic relationships using Sutherland's formula for the variation of viscosity with the temperature of the air.

It is convenient to consider the force due to the base pressure as a separate component of the total drag. Accordingly, the base drag is referred to the frontal area and in coefficient form is given by

$$C_{D_b} = -P_b \left(\frac{A_b}{A} \right) \quad (2)$$

where

- C_{D_b} base drag coefficient
- A_b area of base
- A frontal area of the body

The foredrag is defined as the sum of all drag forces that act on the body surface forward of the base. Hence, the foredrag coefficient is given by

$$C_{D_F} = C_D - C_{D_b} \quad (3)$$

where C_D is the total drag coefficient and C_{D_F} the foredrag coefficient. The concept of foredrag coefficient is useful for several reasons. It is the foredrag that is of direct importance to the practical designer when the pressure acting on the base of a body is altered by a jet of gases from a power plant. Considering the foredrag as an independent compo-

FIGURE 5.—Axial variation of the static pressure in the test section of the $M=1.5$ nozzle.

FIGURE 6.—Comparison of the foredrag coefficient of model 9 with and without corrections applied for the axial variation of the test-section static pressure.

nent of the total drag greatly simplifies the drag analysis of a given body. Finally, the foredrag, as will be explained later, is not affected appreciably by interference of the rear supports used in the investigation.

Since the nozzle calibration with no model present showed that the static pressure along the axis of the test section was not constant (fig. 5), the measured coefficients have been corrected for the increment of drag or pressure resulting from the axial pressure gradient. A detailed discussion of this correction is presented in appendix A, and the experimental justification is shown in figures 6 and 7.

FIGURE 7.—Comparison of base pressure coefficients of model 1 measured at various positions along the tunnel axis, with and without corrections applied for the variation of test-section static pressure.

PRECISION

The table which follows lists the total uncertainty that would be introduced into each coefficient in the majority of the results if all of the possible errors that are known to exist in the measurement of the forces and pressures and the determination of free-stream Mach number and gradient corrections were to accumulate. Actually the errors may be expected to be partially compensating, so the probable inaccuracy is about half that given in the table. The sources and estimated magnitudes of the probable errors involved are considered at greater length in appendix B. The values in the following table are for the lowest and highest tunnel pressures and vary linearly in between. The table does not apply to data that are presented in figures 9 (b), 13, and 14. It also does not apply to models 4, 5, and 6 in figures 23 (a) and 29 (a) where the possible variation in the balance cali-

bration constant may increase the limits of error as discussed in appendix B.

Coefficient	Maximum value of error at lowest pressure	Maximum value of error at highest pressure
Total drag	$\pm (2.4\% \text{ plus } 0.004)$	$\pm (1.1\% \text{ plus } 0.004)$
Foredrag	$\pm (1.6\% \text{ plus } 0.004)$	$\pm (0.6\% \text{ plus } 0.004)$
Base pressure	$\pm (1.6\% \text{ plus } 0.005)$	$\pm (0.5\% \text{ plus } 0.005)$
Base drag	$\pm [0.8\% \text{ plus } 0.005 (A_b/A)]$	$\pm [0.5\% \text{ plus } 0.005 (A_b/A)]$

EFFECTS OF SUPPORT INTERFERENCE

Previous to the present investigation an extensive series of tests was conducted to determine the body shape and support combinations necessary to eliminate or evaluate the support interference. Based upon the results obtained, a summary of which appears in appendix C, it is believed that all the drag data presented herein for the models tested in the smooth condition are free from support interference effects with the exception of the data shown in figure 27. Also, for the models tested with roughness, the foredrag data are free from interference effects. However, an uncertainty in the base pressure coefficient exists which may vary from a minimum of ± 0.005 to a maximum of ± 0.015 for the different bodies. As a result, the base drag coefficients and total drag coefficients for the same test conditions are subject to a corresponding small uncertainty.

THEORETICAL CALCULATIONS

Although at present no theoretical method is available for calculating the base pressure and hence the total drag of a body, several methods are available which provide an excellent theoretical standard to which the experimental measurements of foredrag can be compared. In this report the theoretical foredrag is considered to be the sum of the theoretical wave drag for an inviscid flow and the incompressible skin-friction drag corresponding to the type of boundary layer that exists on the body.

A typical pressure distribution for the theoretical inviscid flow over one of the boattailed bodies tested in this investigation is shown in figure 8. For purposes of comparison the pressure distribution as calculated by the linear theory of von Kármán and Moore is included in this figure.

The wave drag of the cone-cylinder bodies was obtained from the theoretical flow over cones (references 10 and 11).³ The wave drag for the ogive-cylinder bodies was calculated by the method of characteristics for rotationally symmetric supersonic flow as given in references 12 and 13. In accordance with the theoretical results of reference 14, the fluid rotation produced by the very small curvature of the head shock wave was neglected. For moderate supersonic Mach numbers this procedure is justified experimentally in reference 8, where the theoretical calculation using the method of characteristics as presented in reference 12 are shown to be in excellent agreement with the measured pressure distributions for ogives with cylindrical afterbodies.

FIGURE 8.—Typical pressure distribution for a boattailed body at 1.5 Mach number.

An estimation of the skin-friction drag in any given case requires a knowledge of the condition of the boundary layer. The method used herein for laminar flow is as follows:

$$C_{D_f} = C_{f_{lam}} (A_F/A) \quad (4)$$

where

- C_{D_f} skin-friction drag coefficient for the model at the Reynolds number, Re , based on the full length of the model
- $C_{f_{lam}}$ low-speed skin-friction coefficient for laminar boundary-layer flow over a flat plate at Re
- A_F wetted area of the model forward of the base
- A frontal area of the model

For the models with roughness added it is assumed that the disturbance of the boundary layer resulting from the salt band was sufficient to cause transition to a turbulent boundary layer to occur at the band. The skin-friction drag is estimated by means of the equation

$$C_{D_f} = C'_{f_{lam}} \left(\frac{A_{lam}}{A} \right) + C_{f_{turb}} \left(\frac{A_F}{A} \right) - C'_{f_{turb}} \left(\frac{A_{lam}}{A} \right) \quad (5)$$

where

- $C'_{f_{lam}}$ low-speed skin-friction coefficient for laminar boundary-layer flow at the effective Reynolds number, Re' , based on the length of the model from the nose to the point where the salt band was added
- A_{lam} wetted area of that portion of the model forward of the salt band

³ In the original publication of the present investigation (1947) numerical values for the wave drag of the cones were based on the graphs of references 10 and 11. For the present report, however, slightly different numerical values are used which are based on more recent tabulated values of the surface pressure on cones in supersonic flow.

$C_{f_{turb}}$ low-speed skin-friction coefficient for turbulent boundary-layer flow over flat plate at the Reynolds number Re , based on the full length of the model

$C_{f'_{turb}}$ low-speed skin-friction coefficient for turbulent boundary-layer flow at the effective Reynolds number Re'

This method of calculation presumes that the fixed roughness was of such a nature as to cause the turbulent boundary-layer flow downstream of the point where the roughness was added to be the same as would have existed had the boundary-layer flow been turbulent all the way from the nose of the body.

DISCUSSION

FLOW CHARACTERISTICS

Before analyzing the effects of viscosity on the drag of the bodies of revolution, it is convenient to consider qualitatively the effects on the general characteristics of the observed flow. In so doing it is advantageous to consider first the condition of the boundary layer characterized by whether it is laminar or turbulent and then the effect of variation in Reynolds number on flow separation for each type of boundary layer.

Once the effects of the Reynolds number and the condition of the boundary layer on flow separation are known, the observed effects on the shock-wave configuration at the base of the model are easily explained. Likewise, once the effects on flow separation and shock-wave configuration are known, the resulting effects of viscosity on the foredrag, base drag, and total drag are easily understood.

Condition of the boundary layer.—Since results observed at transonic speeds (references 1 and 2) have shown that the general flow pattern about a body depends to a marked degree on the type of boundary layer present, it might be expected that the boundary-layer flow at supersonic speeds also may be of primary importance in determining the over-all aerodynamic characteristics of a body. Consequently, the determination of the extent of the laminar boundary layer under normal test conditions is of fundamental importance.

In an attempt to determine the highest Reynolds number at which laminar flow exists on models tested in this investigation, a relatively long polished body (model 7) was tested from a low pressure up to the highest tunnel pressure obtainable. In this case, the diameter of the shroud which enclosed the rear support sting was made the same as the diameter of the body. The foredrag measurements on this model are shown in figure 9 (a). Since the skin friction is a relatively large portion of the measured foredrag, the condition of the boundary layer can be deduced from these force tests. The data indicate that the boundary layer on this body was still laminar up to the highest obtainable Reynolds number of 6.5×10^6 . The computed foredrag data used for comparison are obtained by adding a laminar or turbulent skin-friction coefficient based on low-speed characteristics to the experimental wave drag of the ogive nose. This latter is determined by subtracting from the ogive foredrag coefficients the low-speed laminar skin-friction coefficients for the smooth ogive at the higher Reynolds numbers where the error, resulting from the assumption of the low-speed co-

FIGURE 9.—Variation of foredrag coefficient with Reynolds number for models with long cylindrical afterbodies.

efficients, is a small percent of the deduced wave drag. (The theoretical wave drag, based on the theoretical pressure distribution from the method of characteristics, is approximately 5 percent higher than the experimental wave drag.) Schlieren photographs from which the condition of the boundary layer may be observed are shown in figure 10. They confirm the previous finding by showing that transition does not occur on the body, but begins a short distance downstream from the base of the model, as indicated by arrow 1 in the photograph.

(a) $Re = 3.7 \times 10^6$.(b) $Re = 6.5 \times 10^6$.

FIGURE 10.—Schlieren photographs showing laminar flow over the cylindrical afterbody of model 7 at two values of the Reynolds number. Knife edge horizontal.

A close examination of the photographs in figure 10 reveals that the beginning of transition (arrow 1) is located at the same point on the support shroud as the waves (arrows 2 and 3) which originate from a disturbance of the boundary layer. It was found by measurements on the schlieren photographs that the point of origin of these waves coincided with the intersection of the shroud and the reflected bow wave. This suggests that transition on the shroud is being brought about prematurely by the reflected bow waves. Additional evidence that this is not natural transition is obtained in noting from figure 10 that the point where transition begins does not move with a change in Reynolds number. If the model were longer than a critical length, which is about 11 inches for the conditions of the present tests, these reflected waves would strike the model somewhere on the afterbody and premature transition would be expected to affect the results. Figure 9 (b) shows the results of the measurements of fore-drag on a 16.7-inch body (model 8), which is considerably longer than the critical length. These force data confirm the above conjecture by clearly indicating a partially turbulent boundary layer on the body even at Reynolds numbers

as low as 2×10^6 . The schlieren photographs of the flow over this body are presented in figure 11. It is seen that, in this case also, the transition to turbulent flow (arrow 1) is located at the same point as the waves (arrows 2 and 3) originating from the disturbance of the boundary layer by the reflected bow wave. Similarly, an additional small wave (arrow 4) can be traced back to a disturbance of the boundary layer caused by a shock wave originating from an imperfect fit of the glass windows in the side walls.

FIGURE 11.—Schlieren photograph showing premature transition on the cylindrical afterbody of model 8. Reynolds number 9.35×10^6 .

Although the maximum possible extent of laminar flow that may be expected on bodies of revolution cannot be determined on the basis of the present tests because of this interference from the reflected shock waves, the foregoing results show that, under the conditions of these tests, a laminar boundary layer exists over the entire surface of a smooth model about 11 inches long up to at least 6.5×10^6 Reynolds number. In comparison to the values normally encountered at subsonic speeds, a Reynolds number of 6.5×10^6 at first appears to be somewhat high for maintenance of laminar flow over a body, unless the pressure decreases in the direction

of the flow over the entire length of the body. The pressure distribution over model 7, shown in figure 12, has been determined by superimposing the pressure distribution which exists along the axis of the nozzle with no model present upon the theoretical pressure distribution calculated for model 7 by the method of characteristics. The resulting pressure distribution shows that the pressure decreases considerably along the ogive, but actually increases slightly along the cylindrical afterbody.

FIGURE 12.—Theoretical pressure distribution over the surface of model 7 at zero angle of attack and 1.5 Mach number.

An increase in the stability of the laminar boundary layer with an increase in Mach number has been indicated by the analysis of reference 15. With a given body shape, for which the pressure distribution changes with Mach number, an increase in stability with increasing Mach number has also been indicated for subsonic flows by the results of references 6 and 16 as well as by the experimental data given for airfoils in reference 15. The theoretical work of Lees (reference 17), however, indicates that the Reynolds number for neutral stability of laminar flow over an insulated flat plate decreases with an increase in Mach number.

It appears from the results of the present tests that any shock waves which originate from imperfections in the nozzle walls and disturb the boundary layer on a body can bring about transition prematurely. This may have some bearing on the results of the supersonic wind-tunnel tests conducted in the German wind tunnels at Kochel, since shock waves, ordinarily numbering about 15, are readily visible in various schlieren photographs. (See reference 18, for example.)

In order to cause the laminar boundary layer to become turbulent in the present investigation, an artifice such as adding roughness was necessary. In a supersonic stream, however, the addition of roughness to a body also increases

the wave drag. The magnitude of the wave drag due to roughness was determined by testing with full diameter shrouding and no afterbody attached, first the smooth ogive, and then the ogives with various amounts and kinds of roughness added (fig. 2 (a)). The corresponding foredrag measurements are shown in figure 13. These data illustrate that little additional drag is attributable to roughness at the low Reynolds numbers where the boundary layer is relatively thick, but that an appreciable amount of wave drag is attributable to the roughness at the higher Reynolds numbers. For all subsequent results presented, the amount of drag caused by the artificial roughness has been subtracted from the measured data taken for the bodies tested with transition fixed. In order to calculate the amount of drag caused by the roughness for models of diameters different from the ogives tested, it was assumed that for any model the increment in drag coefficient attributable to the drag of the artificial roughness was inversely proportional to the diameter of the model at the station at which the roughness was applied.

FIGURE 13.—Variation of foredrag coefficient with Reynolds number of the ogives with varying degrees of roughness added.

The foredrag measurements of model 8, which consists of a cylindrical afterbody with any one of the interchangeable ogives directly attached, are presented in figure 14. These data, from which the drag increment due to the added roughness has been subtracted as noted previously, show that the degree of roughness produced by sand blasting the surface of the ogive is insufficient to cause transition at low Reynolds numbers; whereas, the roughness produced by the $\frac{3}{16}$ -inch- or the $\frac{3}{8}$ -inch-wide salt band caused transition at all Reynolds numbers.

A vivid illustration of the turbulent character of the boundary layer on those bodies with roughness added is given by the schlieren photographs in figure 15. The boundary layer is best seen in the photograph taken with the knife edge horizontal. A comparison of these photographs with

those of laminar boundary layers (fig. 10, for example) illustrates how the condition of the boundary layer is apparent from schlieren photographs.

FIGURE 14.—Variation of foredrag coefficient with Reynolds number for model 8 with various amounts of roughness.

Flow Separation.—Changes in flow separation brought about by changing the boundary-layer flow from laminar to turbulent alter the effective shape of the body, the shock-wave configuration, and also the drag. It is therefore essential to consider the effects on flow separation of both the condition of the boundary layer and the Reynolds number.

The location and degree of separation of the laminar boundary layer for the boattailed bodies tested in the smooth condition varied noticeably with the Reynolds number of the flow. The schlieren photographs of model 6 in figure 16 are typical of this effect. Additional photographs, presented in figure 17, illustrate the same phenomena in the flow over models 2, 3, and 10, each at two different Reynolds numbers. In each case, as the Reynolds number of the flow is increased, the separation decreases, the convergence of the wake increases, and the trailing shock wave moves forward.

Separation of an apparently laminar boundary layer at supersonic speeds has been pointed out previously by Ferri in reference 19 for the two-dimensional flow over the surface of curved airfoils. The schlieren photographs of Ferri indicated that a shock wave formed at the point of laminar separation. On the other hand, the schlieren pictures of the flow fields for the bodies of revolution tested in the

(a) Knife edge vertical.

(b) Knife edge horizontal.

FIGURE 15.—Schlieren photographs of model 8 with transition fixed. Reynolds number 7.2×10^6 .

present investigation, show no definite shock wave accompanying separation except for the sphere (fig. 17) in which case the shock wave is very weak. It may be concluded, therefore, that a separation of the laminar boundary layer is not necessarily accompanied by a shock wave at supersonic speeds. The same conclusion for transonic flows has been drawn in reference 2.

In order to analyze more closely the details of the flow separation, the pressure distribution along the streamline just outside of the separated boundary layer was calculated for several flow conditions over models 3 and 6. The calculations were made using the method of characteristics and by obtaining the contour of the streamline just outside the separated boundary layer from enlargements of the schlieren photographs. Typical results from these calculations for model 3 are presented in figure 18. It is seen that the pressure on the outside of the boundary layer is approximately constant downstream of the point of separation as is characteristic along the boundary of a dead-air region. The pressure along the line of separation can be expected to be approximately equal to that in the dead-air region, and hence, equal to the base pressure. A comparison of the calculated values of the average pressure in the dead-air region with the measured values of the base pressure for several

conditions of flow over models 3 and 6 is given in the following table:

Model	Reynolds number	Calculated pressure coefficient of dead-air region	Measured base pressure coefficient
3-----	0.6×10^6	-0.06	-0.06
3-----	2.0×10^6	-.11	-.12
6-----	$.6 \times 10^6$	-.10	-.11
6-----	1.5×10^6	-.13	-.13

The preceding results indicate that under certain conditions the base pressure for laminar flow over highly boattailed bodies is directly related to the separation phenomenon which occurs forward of the base. This suggests that, if a means can be found to control the separation, the base pressure also can be controlled.

The theoretical pressure distributions on models 4 and 5 are similar to the pressure distribution on model 6, which is shown in figure 19. In each case the pressure in inviscid flow would decrease continually along the direction of flow upstream of the observed position of laminar separation. For subsonic flow this condition ordinarily would be termed favorable and separation would not be expected. Further research on this subject appears necessary in order to gain a satisfactory understanding of the observed results.

The findings of previous investigations of low-speed flows indicate that if a boundary layer which is normally laminar over the afterbody is made turbulent by either natural or artificial means, the resistance to separation is increased greatly. The tests on models 2, 3, 4, 5, and 6 with roughness added show clearly that this is also the case in supersonic flows. The two schlieren photographs presented in figure 20 were taken of model 6 with and without roughness added and are typical of this effect. A comparison of the two

$Re = 0.58 \times 10^6$.

$Re = 0.87 \times 10^6$.

$Re = 1.1 \times 10^6$.

$Re = 1.4 \times 10^6$

FIGURE 16.—Schlieren photographs showing the effect of Reynolds number on laminar separation for model 6. Knife edge vertical.

FIGURE 17.—Schlieren photographs showing the effect of Reynolds number on laminar separation for models 2, 3 and 10. Knife edge vertical.

photographs shows that, without roughness added, separation occurs near the point of maximum thickness, but if transition is fixed ahead of this point the separation point moves downstream close to the base.

Shock-wave configuration.—It is to be expected that the changes in flow separation due to changes in the condition of the boundary layer and in the Reynolds number of the flow will bring about changes in the shock-wave configuration at the base of a body. The schlieren photographs of figures 16 and 17, which show how the laminar separation decreases and the convergence of the wake increases as the Reynolds number is increased, also show that these phenomena are accompanied by a forward motion of the trailing shock wave. In general, as long as the boundary layer is laminar, the trailing shock wave moves forward as the Reynolds number increases, but no major change in the shock-wave configuration takes place.

The shock-wave configuration on a boattailed body with a turbulent boundary layer, however, is very much different from the configuration with a laminar layer, as is illustrated by the schlieren photographs of model 6, shown in figure 20. Such configuration changes due to the transition to turbulent boundary-layer flow correlate quite well with the angle β that the tangent to the surface just ahead of the base makes with the axis of symmetry. Figure 21 shows the changes in shock-wave configuration for models 1 through 6 arranged in order of increasing angle β . It is seen that, on the boattailed bodies with a small angle β , the transition to a turbulent boundary layer is accompanied by the appearance of a weak shock wave originating at the base of the body (models 4 and 2). For bodies with larger boattail angles (model 5) the strength of this wave, hereafter termed the "base shock wave," increases until it is approximately as strong as the original trailing shock wave. For even larger boattail angles,

FIGURE 18.—Calculated pressure distribution for model 3 at a Reynolds number of 0.6×10^6 .

Apparent points of laminar separation occur in this region as determined from Schlieren photographs in figure 16 ($Re = 0.6 \times 10^6$ to $Re = 1.4 \times 10^6$)—

FIGURE 19.—Calculated pressure distribution on model 6.

⁴ Subsequent experiments with turbulent flow on model 3 at higher Mach numbers have shown that the base shock wave also exists at a Mach number of 2.0, but virtually disappears at a Mach number of 3.0 and higher.

(a) Laminar boundary layer, $Re = 0.87 \times 10^6$.

(b) Turbulent boundary layer, $Re = 0.87 \times 10^6$.

FIGURE 20.—Schlieren photographs of model 6 illustrating the effect on flow separation of the condition of the boundary layer.

the base shock wave becomes more distinct, and eventually is the only appreciable shock wave existing near the base of the body (models 3 and 6).⁴ In such a case, the compression through the base shock wave occurs forward of the base. This, as will be shown later, greatly increases the base pressure and decreases the base drag.

Compared to the phenomena observed with a laminar boundary layer (fig. 16), changes in the Reynolds number for a body with a turbulent boundary layer do not alter the shock-wave configuration to any significant extent, because the turbulent layer, even at low Reynolds numbers, ordinarily does not separate. This fact is evident in figure 22, which shows the schlieren photographs of model 3 at different Reynolds numbers with roughness added. No apparent change in the flow characteristics takes place as the Reynolds number is increased. With a turbulent boundary layer,

Model 1
 $Re = 3.8 \times 10^6$
 $\beta = 0^\circ$

Model 4
 $Re = 4.0 \times 10^6$
 $\beta = 8.55^\circ$

Model 2
 $Re = 3.8 \times 10^6$
 $\beta = 9.08^\circ$

Model 5
 $Re = 2.7 \times 10^6$
 $\beta = 12.13^\circ$

Model 3
 $Re = 3.8 \times 10^6$
 $\beta = 15.25^\circ$

Model 6
 $Re = 1.1 \times 10^6$
 $\beta = 16.75^\circ$

Laminar

Turbulent

FIGURE 21.—Schlieren photographs showing the effect of turbulent boundary layer on shock-wave configuration at base of models 1, 2, 3, 4, 5 and 6. Knife edge vertical.

therefore, the effect on base drag of varying the Reynolds number may be expected to be much less than with a laminar layer.

ANALYSIS OF THE DRAG DATA

The qualitative effects of viscosity on flow separation and on shock-wave configuration, which have been discussed in the preceding sections, provide the physical basis for understanding the effects of varying the Reynolds number and changing the condition of the boundary layer on the drag coefficients of the various bodies tested.

Foredrag.—The foredrag coefficients of models 1 through 6 with laminar flow in the boundary layer are shown in figure 23 (a) as a function of the Reynolds number. These data show that, over the Reynolds number range covered in the tests, the foredrag of model 1 decreases about 20 percent, while that of model 6 increases about 15 percent. The foredrag of the other bodies does not change appreciably.

The reason the effects of Reynolds number vary consid-

erably with different body shapes is clearly illustrated by a comparison of the measured foredrags with the theoretical foredrags. In figure 24 (a) the theoretical and measured values of foredrag are compared for model 1, which has no boattailing, and for model 3, which is typical of the boat-tailed models. From this comparison, it is seen that, as previously noted for other models without boattailing, the theoretical and experimental foredrags for model 1 are in good agreement. The decrease in foredrag with increasing Reynolds number for the bodies without boattailing is due entirely to the decrease in skin-friction coefficient. For model 3, which has considerable boattailing, the curves of figure 24 (a) show that the theoretical and experimental foredrags agree only at high Reynolds numbers. At the low Reynolds numbers the measured foredrags are lower than the theoretical values because of the separation of the laminar boundary layer as previously illustrated by the schlieren photographs in figures 16 and 17. With sep-

FIGURE 22.—Schlieren photographs showing the absence of any effect of Reynolds number on the flow over the afterbody of model 3 with roughness added. Knife edge vertical.

aration, the flow over the boattail does not follow the contour of the body, and the pressure in the accompanying dead-air region is higher than it would be if the separation did not occur (fig. 18). This makes the actual foredrag lower than the theoretical value for a flow without separation. At the higher Reynolds numbers, the separation is negligible and the flow closely follows the contour of the body; hence, the theoretical and experimental foredrags agree. The reason for the approximately constant foredrag of models 2, 3, 4, and 5, therefore, is that the changes due to skin friction and flow separation are compensating. For model 6 with a smooth surface, the foredrag shown in figure 23 (a) rises rather rapidly at low Reynolds numbers because the separation effects for this relatively thick body (fig. 16) more than compensate for the changes in skin friction due to the variation of the Reynolds number.

Figure 23 (b), which shows the foredrag coefficients of model 1 through 6 with roughness added, indicates that the foredrag for all the bodies decreases as the Reynolds number increases above a Reynolds number of 1.75×10^6 . This is to be expected, since with the change to turbulent boundary layer and consequent elimination of separation, the only factor remaining to influence the foredrag coefficients is the decrease of skin-friction coefficients with increase in Reynolds number. Below a Reynolds number of 1.75×10^6 , however, the foredrag of all the models except model 1 increases with increasing Reynolds number. The cause of this somewhat puzzling behavior is apparent upon closer examination of the data.

Figure 24 (b) shows a comparison of the theoretical fore-

drags with the experimental values for models 1 and 3 with roughness added. The theoretical value for skin-friction drag was calculated assuming laminar flow up to the location of the roughness, and turbulent flow behind it. This value of drag was added to the theoretical wave drag to obtain the theoretical foredrag. It is seen from figure 24 (b) that for model 1 the curves of theoretical and experimental foredrag have the previously indicated trend of decreasing drag with increasing Reynolds number over the entire range. However, for model 3, which is typical of the boattailed bodies, the measured foredrag at low Reynolds numbers falls considerably below the theoretical value in the manner previously noted. The reason for this is evident from an examination of the schlieren photographs shown in figure 25, which were taken of the flow over models 3 and 6 with roughness added. They show that at the low Reynolds numbers a flow separation similar to that observed for the smooth body (fig. 16) occurs, and the resulting shock-wave configuration is characteristic of the configuration for a laminar boundary layer rather than that for a turbulent boundary layer. It appears that, at the low Reynolds numbers, the amount of roughness added does not cause transition far enough upstream of the point for laminar separation so that the free stream can provide the boundary layer with the necessary additional momentum to prevent separation. The portions of the drag curves in which the desired transition was not realized are shown dotted over the region in which separation was apparent from the schlieren pictures. For model 1, the schlieren photographs showed that at the low Reynolds numbers the amount of roughness added was

FIGURE 23.—Variation of foredrag coefficient for models 1, 2, 3, 4, 5 and 6 in the smooth condition and with roughness added.

(a) Smooth condition.

(b) Roughness added.

FIGURE 24.—Comparison of theoretical and experimental foredrag coefficients for models 1 and 3.

(a) Model 3, $Re = 0.58 \times 10^6$.(b) Model 6, $Re = 0.62 \times 10^6$.

FIGURE 25.—Schlieren photographs at low Reynolds numbers of models 3 and 6 with roughness added. Knife edge vertical.

sufficient to effect transition some distance ahead of the base, although not immediately aft of the roughness.

The agreement between the experimental and the theoretical results obtained by the use of equations (4) and (5) indicates that, at a Mach number of 1.5 and in the range of Reynolds numbers covered by this investigation, the familiar low-speed skin-friction coefficients can be used with fair approximation to estimate drag due to skin friction at supersonic speeds.

A comparison of the curves of figures 23 (a) and 23 (b) shows that for a given body at a given value of the Reynolds number the foredrag with roughness added is consistently higher than the corresponding foredrag of the smooth-surfaced body. In the general case, this over-all increase in foredrag is attributable both to the increase in the skin-friction drag of the body and to the change in flow separation with

FIGURE 26.—Variation of base-pressure coefficient with Reynolds number for models 1, 2, 3, 4, 5 and 6 in the smooth condition and with roughness added.

consequent increase in the pressure drag of the boattail. For model 1, which has no boattailing, the increase in skin friction is the sole factor contributing to the increase in foredrag.

Base pressure and base drag.—Figure 26 (a) shows the base pressure coefficients plotted as a function of the Reynolds number for models 1 through 6, each with a smooth surface. It is evident from the data in this figure that the effects of Reynolds number on base pressure for a body with a laminar boundary layer are quite large. In the range of Reynolds numbers covered, the base pressure coefficient of model 1 increases about 60 percent, and the coefficients of models 2, 3, and 4 more than double. The thicker bodies with boattailing, models 5 and 6, do not exhibit such large changes in base pressure coefficient, for the coefficients apparently reach a maximum at a relatively low Reynolds number, and then decrease with further increase in the Reynolds number.

The base pressure coefficients for models 1 through 6 with roughness added are shown in figure 26 (b). Here again, the portions of the curves which correspond to the low Reynolds number region wherein transition was not completely effected are shown as dotted lines. Model 1 exhibits the lowest base pressure and model 6 the highest; in this latter case the base pressure is even higher than the free-stream static pressure. The physical reason for this is evident from the schlieren photograph at the bottom of figure 20, which shows that a compression through the shock wave occurs just ahead of the base of model 6. Except for the large changes in pressure

coefficient at low Reynolds numbers where the desired transition was not effected, the variation of base pressure coefficient with Reynolds number is relatively small for the bodies with roughness added.

From a comparison of the curves for the bodies with roughness added to the corresponding curves for the smooth-surfaced bodies, it is evident that a large change in the base pressure coefficient is attributable to the change in the condition of the boundary layer. In general, the base pressures for bodies with roughness added are considerably higher than the corresponding base pressures for the smooth-surfaced bodies. In the case of the boattailed bodies the physical reason for this increase in the base pressure is the appearance of the base shock wave, as shown in figure 21. For model 1, which has no boattailing, the mixing action and greater thickness of the turbulent boundary layer are probably responsible for the observed increase.

The foregoing data show that the effects of Reynolds number and condition of the boundary layer on the base pressure of a body moving at supersonic speeds depend considerably upon the shape of the afterbody. In order to ascertain whether the effects of viscosity also depend upon the length-diameter ratio for a fixed shape of afterbody, some models of different length-diameter ratios were tested and the data presented in figures 27 (a) and 27 (b) which show the variation of base pressure coefficient with Reynolds number. The data presented in this figure are not free of

FIGURE 27.—Variation of base-pressure coefficient with Reynolds number for bodies without boattailing but with different length-diameter ratios.

support interference. From these data it is apparent that the effects of viscosity on the base pressure increase with the length-diameter ratio of the body.⁵ It is to be noted that the base pressure increases as the length-diameter ratio increases. This is somewhat at variance with the results of reference 20, which showed an effect, but not a systematic one, of length-diameter ratio on the base pressure of bodies without boattailing.

The base drag coefficient can be obtained from the base pressure coefficient of the models by using equation (2). The base drag coefficients for the smooth-surfaced bodies are presented in figure 28 (a) and for the bodies with roughness added in figure 28 (b). These curves are, of course, similar to the corresponding curves of base pressure coefficient given in figures 26 (a) and 26 (b). In this form the ordinates can be added directly to the foredrag coefficients of figure 23 to obtain the total drag coefficient of a given body. It is seen that the contribution of the base pressure to the total drag is very small for models with large amounts of boattailing, such as models 3, 4, 5, and 6.

Total drag.—The total drag coefficients for models 1 through 6 with smooth surfaces are shown in figure 29 (a) as a function of Reynolds number. These data show that the drag coefficients of both models 1 and 2 with a laminar boundary layer increase a little over 20 percent from the lowest to the highest value of Reynolds number obtained in

the tests. The other models exhibit somewhat smaller changes. The data presented in figures 23 and 28 indicate that the principal effect controlling the variation of total drag with Reynolds number for laminar flow in the boundary layer is the effect of Reynolds number on the base drag of the bodies. For the special case of highly boattailed bodies, however, this effect is of little relative importance because the base drag is a small part of the total drag. In such cases, the over-all variation of drag coefficient is due almost entirely to the variation of foredrag with Reynolds number.

Figure 29 (b) shows the total drag coefficients plotted as a function of the Reynolds number for models 1 through 6 with roughness added. Again, the portions of the curves that are shown dotted represent the Reynolds number region in which the amount of roughness added is insufficient to cause complete transition. All the curves have approximately the same trend, the over-all effect on the drag coefficients being about 15 percent or less for the various bodies.

A comparison of the curves of total drag for bodies with roughness added to the corresponding curves for bodies with smooth surfaces shows an interesting phenomenon. At the higher Reynolds numbers the drag of models 1 and 6 is actually decreased slightly by the addition of roughness, in spite of the corresponding increase in skin-friction drag. The reason is, of course, that the base drags are very much

⁵ Similar experiments conducted at a Mach number of 2.0 have shown the same trend. Both sets of data show reasonable correlation with the ratio of boundary-layer thickness to base diameter.

FIGURE 28.—Variation of base-drag coefficient with Reynolds number for models 1, 2, 3, 4, 5 and 6 in the smooth condition and with roughness added.

FIGURE 29.—Variation of total drag coefficient with Reynolds number for models 1, 2, 3, 4, 5 and 6 in the smooth condition and with roughness added.

lower for the turbulent boundary layer than for the laminar. The drag coefficients of the other bodies (models 2, 3, 4, and 5) are somewhat higher with roughness added, because the increase in friction drag of the turbulent boundary layer is greater than the decrease in base drag.

The importance of always considering both the Reynolds number of the flow and condition of the boundary layer is illustrated by the total drag characteristics of model 2. For example, if model 2 were tested with a turbulent boundary layer at a Reynolds number of 2×10^6 , the drag would be about 35 percent higher than if tested with a laminar boundary layer at a Reynolds number of 0.5×10^6 . Although discrepancies as large as these have not been reported as yet in the drag data from different supersonic wind tunnels, certain consistent differences, varying from about 5 to 25 percent, have been reported (reference 18) in the drag data of similar projectiles tested in the Gottingen and the Kochel tunnels. Although in reference 18 the discrepancies between the two tunnels were attributed only to the variation in skin friction with Reynolds number, it appears from the results of the present investigation that such discrepancies are attributable primarily to differences in flow separation and base pressure.

A comparison of the effects of viscosity for pointed bodies with the effects for a blunt body shows clearly that body shape must be considered, and that conclusions about viscosity effects based upon tests of blunt bodies may be completely inapplicable to the aerodynamic shapes which are suitable for supersonic flight. For example, in the case of a sphere at 1.5 Mach number with an over-all Reynolds number variation of from 7.5×10^4 to 9.0×10^5 , the agreement between the drag data from Gottingen (reference 7), Peenemunde (reference 18), and the present wind tunnel is within 1 percent of the values measured for free-flight (references 7 and 21). It is evident that the effects of viscosity on the drag of a sphere are quite different from the effects on the pointed bodies tested in this investigation.

CONCLUSIONS

The conclusions which follow apply for a Mach number of 1.5 and at Reynolds numbers based upon model length up to about 5×10^6 for bodies of revolution similar to the ones tested.

1. The effects of viscosity differ greatly for laminar and turbulent flow in the boundary layer, and within each regime depend upon the Reynolds number of the flow and the shape of the body.

2. Laminar flow was found on the smooth bodies up to a Reynolds number of 6.5×10^6 and may possibly exist to considerably higher values.

3. A comparison between the test results for laminar and for turbulent flow in the boundary layer at a fixed value of the Reynolds number shows that:

- (a) The resistance to separation with turbulent flow in the boundary layer is much greater.

- (b) The shock-wave configuration near the base of boat-tailed bodies is markedly different for the two types of boundary layer flow.
- (c) The foredrag coefficients with turbulent boundary layer ordinarily are higher.
- (d) The base pressure on boattailed bodies is much higher with the turbulent boundary layer.
- (e) The total drag is usually higher with the turbulent boundary layer.

4. For laminar flow in the boundary layer the following effects were found:

- (a) The laminar boundary layer separates forward of the base on all boattailed bodies tested, and the position of separation varies noticeably with Reynolds number. Laminar separation is not necessarily accompanied by a shock wave originating from the point of separation. On many of the models the pressure in an inviscid flow would continually decrease in the direction of the flow upstream of the separation point.
- (b) The trailing shock wave moves forward slightly as the Reynolds number is increased, but no significant change takes place in the shock-wave configuration near the base.
- (c) With increasing Reynolds numbers, the foredrag coefficients increase for highly boattailed bodies and decrease for bodies without boattailing. For moderately boattailed bodies the variation of the foredrag coefficient with Reynolds number is relatively small.
- (d) The base pressure changes markedly with Reynolds number. For bodies with the same afterbody shape, the base pressure also depends upon the length-diameter ratio of the body.
- (e) Total drag varies considerably with the Reynolds number, changing more than 20 percent for several of the models.

5. For turbulent flow in the boundary the following effects were found:

- (a) Separation does not ordinarily occur upstream of the base except for highly boattailed bodies.
- (b) The shock-wave configuration near the base does not change noticeably as the Reynolds number changes.
- (c) The foredrag coefficients decrease slightly as the Reynolds number is increased.
- (d) The base pressure changes very little with changing Reynolds number.
- (e) The total drag decreases as the Reynolds number is increased.

APPENDIX A

VARIATION OF TEST-SECTION STATIC PRESSURE

Since the static pressure with no model present varied along the axis of the test section as shown in figure 5, it was necessary to apply a correction to the measured coefficients to account for the increment in drag or pressure resulting from this axial pressure gradient. Although the axial variation of test-section static pressure is not monotonic, the pressures at the downstream end of the test section are uniformly lower than the pressures of the upstream end where the nose of a model is ordinarily placed. This means that the actual pressure exerted at a given point on a body is lower than it would be if the ambient pressure gradient were zero as it is in free flight. The gradient corrections are calculated on the assumption that the magnitude of the pressure exerted at an arbitrary point on the body in the tunnel is lower than it would be if no gradient were present by an increment equal to the amount which the static pressure decreases (with no model present) from the position of the model nose to the position of the arbitrary point. At the Mach number of the present tests it is not necessary to include the corresponding axial variation of dynamic pressure in the corrections since it varies only ± 0.2 percent from the mean test-section value used in all calculations. The corrections to the measured coefficients of model 1 located 2.5 inches downstream from the reference pressure orifice, for example, amount to ± 0.012 in foredrag coefficient and -0.026 in base-drag coefficient; the corresponding percentages of the uncorrected coefficients of foredrag and base pressure are 12 and 15, respectively.

Because the gradient correction is relatively large in the present tests an experimental justification of such theoretical

corrections is in order. The validity of the corrections as applied to foredrag is confirmed by tests on model 9, which consists of a conical nose with a 20° included angle and a short cylindrical afterbody. The theoretical foredrag of this body, which is equal to the sum of the wave and friction drags can be easily determined as a function of Reynolds number. The wave drag of the conical nose is given by the calculations of Taylor and Maccoll (references 10 and 11). The frictional drag can be estimated using the low-speed laminar skin-friction coefficients, since the boundary layer was completely laminar over this model. A comparison of the corrected and uncorrected foredrag with the theoretical foredrag is shown in figure 6. The corrected foredrag coefficients are seen to be in good agreement with the theoretical values; whereas the uncorrected data fall below the wave drag at high tunnel pressures. This latter condition, of course, represents an impossible situation for a body without boattailing.

In order to check experimentally the validity of the corrections as applied to the measured base pressure, model 1 was tested on the side support at five different positions along the axis of the test section. Because the support system remained fixed relative to the body, the interference of the support is the same in each case, hence, any discrepancies in the measured base pressures at the various positions are attributable only to the pressure gradient along the tunnel axis. Figure 7 shows that the uncorrected base pressure data taken at the five different positions differ by about 25 percent, but the corresponding five sets of corrected data fall within about ± 1.5 percent of their mean, thus confirming the validity of the correction.

APPENDIX B

PRECISION OF DATA

The accuracy of the results presented can be estimated by considering the possible errors that are known to be involved in the measurement of the forces and pressures, and in the determination of the free-stream Mach number and gradient corrections.

The force measurements are subject to errors from shifts in the balance zero due to temperature effects and also from a shift in the calibration constant. The zero shift, which is less than ± 1 percent of the force data at low pressures and less than ± 0.2 percent at high pressures, was checked periodically by running the tunnel through the complete temperature range with no force applied to the balance. In the majority of cases the variation of the balance calibration constant, which was checked before and after each series of tests, permitted a possible deviation of ± 0.3 percent in the force data. All data presented in figures 9 (b), 13, 14, and the data for models 4, 5, and 6 in figures 23 (a) and 29 (a) were obtained during a period between two consecutive balance calibrations for which the constant differed by 6.4 percent. A comparison of the data obtained during this period with theoretical results and with the results of subsequent reruns of some of the same models indicates that the change in balance calibration occurred before the data in question were obtained. The results in the afore-mentioned figures were therefore computed on the basis of the later calibration. It is estimated that the maximum error in the balance calibration constant for these results is at worst no greater than $+0.3$ to -3.0 percent.

The pressure data, including the dynamic pressure, are subject to small errors resulting from possible inexact readings of the mercury manometers. The base pressure data are also subject to an additional error resulting from the small variation in the specific gravity of the dibutyl phthalate indicating fluid. At the most, these sources can cause an

error in the total and foredrag coefficients of about ± 0.3 percent, and in the base-drag coefficient of about ± 0.8 percent. The error in dynamic pressure due to the uncertainty in the free-stream Mach number is negligible, since the isentropic relation for the dynamic pressure as a function of Mach number is near a maximum at a Mach number of 1.5. For slender bodies of revolution the variation of the force coefficients with Mach number is quite small; hence, errors resulting from the variation of free-stream Mach number from 1.49 to 1.51 are negligible.

On the basis of the data presented in figures 6 and 7, it is estimated that for all tunnel pressures the uncertainty in the gradient corrections to total drag, foredrag, and base pressure coefficients can cause at the most an error in these coefficients of ± 0.004 , ± 0.004 , and ± 0.005 , respectively. It should be noted that in the table on precision, presented in the section on results, this source of error, which is independent of tunnel pressure, is expressed as an increment and not as a percentage of the measured coefficient.

Previous investigations have shown that an uncertainty may be introduced in supersonic wind-tunnel data if the humidity of the tunnel air is very high. To determine the effects of this variable in the present investigation, the specific humidity was varied from the lowest values (approximately 0.0001) to values approximately 20 times those normally encountered in the tests. Drag and base pressure measurements were taken on a body with a conical head and also on a sphere. The results showed no appreciable effect of humidity over a range much greater than that encountered in the present tests, provided the variation in test-section dynamic pressure with the change in humidity was taken into account in the reduction of the data. It is believed, therefore, that the precision of the results presented in this report is unaffected by humidity.

APPENDIX C

EFFECT OF SUPPORT INTERFERENCE

A knowledge of the effects of support interference upon the data in question is essential to an understanding of its applicability to free-flight conditions. Previous to the present investigation an extensive series of tests were conducted to determine the body shape and support combinations necessary to evaluate the support interference.

In general, it was found that for the models tested in the smooth condition (laminar boundary layer) the effect of the rear supports used in the present investigation was negligible for the boattailed models 2 and 3 and was appreciable only in the base pressure measurements for model 1. For model 1, combinations of rear support and side support were used to evaluate the effect of the rear support on the base pressure. The evaluation was made on the assumption of no mutual interference between the rear support and side support and was checked by the use of two different combinations of side support and rear support. The data indicate that the assumption is justified within the limits of the experimental accuracy and that the corrected, interference-free base pressures deduced by this method differ only slightly from those measured with the side support alone.

For the bodies with roughness added (producing a turbulent boundary layer) a complete investigation of the support interference was not made; consequently, a definite quantitative evaluation of the interference effects for each body in this condition cannot be given. From the data that were obtained it has been found that the foredrag is not affected appreciably by the presence of the supports used in the present investigation, but that a small amount of interference is evident in the base pressure coefficient which may vary from a minimum of ± 0.005 to a maximum of ± 0.015 for the different bodies. This uncertainty in the base pressure coefficient results in a correspondingly small uncertainty in the base drag coefficient and in the total drag coefficient.

REPORT 1037

GENERAL METHOD AND THERMODYNAMIC TABLES FOR COMPUTATION OF EQUILIBRIUM COMPOSITION AND TEMPERATURE OF CHEMICAL REACTIONS¹

By VEARL N. HUFF, SANFORD GORDON, and VIRGINIA E. MORRELL

SUMMARY

A rapidly convergent successive approximation process is described that simultaneously determines both composition and temperature resulting from a chemical reaction. This method is suitable for use with any set of reactants over the complete range of mixture ratios as long as the products of reaction are ideal gases. An approximate treatment of limited amounts of liquids and solids is also included. This method is particularly suited to problems having a large number of products of reaction and to problems that require determination of such properties as specific heat or velocity of sound of a dissociating mixture.

The method presented is applicable to a wide variety of problems that include (1) combustion at constant pressure or volume; and (2) isentropic expansion to an assigned pressure, temperature, or Mach number. Tables of thermodynamic functions needed with this method are included for 42 substances for convenience in numerical computations.

INTRODUCTION

The theoretical performance of propulsion systems having high combustion temperatures can be calculated on the assumption that chemical equilibrium exists among the products of reaction. The equilibrium composition and the temperature for a system of N products of reaction are determined by the simultaneous solution of at least $N+1$ equations involving dissociation, mass balance, and energy or entropy balance. This calculation becomes increasingly difficult as N increases.

Numerous methods for solving these equations may be found in the literature that provide a successive approximation or trial-and-error process for determining the composition at an assumed temperature and pressure. Examples of these methods are found in references 1 to 4. When it is desired to find the temperature of a system in equilibrium, with a parameter such as entropy or enthalpy assigned, the composition is usually computed at a sequence of temperatures that either converge to the correct temperature or are spaced to permit interpolation to obtain the correct temperature.

A rapidly convergent successive approximation process that determines composition at an assigned temperature or that simultaneously determines both composition and temperature for assigned values of another parameter, such as enthalpy or entropy, was developed at the NACA Lewis laboratory during 1948 and is presented herein. This proc-

ess also permits computation of the partial derivatives required to compute such thermodynamic properties as specific heat and velocity of sound corresponding to chemical equilibrium. The equations are derived that are required for solution of the following cases: (1) combustion at constant pressure or volume; and (2) isentropic expansion to an assigned pressure, temperature, or Mach number. Examples are given for (1) constant-pressure adiabatic combustion; (2) isentropic expansion to an assigned pressure; and (3) isentropic expansion to an assigned Mach number.

This method is particularly suitable for problems having a large number of products of reaction and for problems that require determination of partial derivatives. Although it is possible, at least in special cases, to devise a procedure that involves less numerical computation, the method presented is applicable in a wide variety of cases and its numerical application to a given process is always simple and essentially the same for all reactions.

Tables of thermodynamic functions are needed for computing equilibrium compositions and temperature of chemical reactions. Tables containing the functions specific heat at constant pressure C_p° , sensible enthalpy $H_T^\circ - H_0^\circ$, and molar entropy S_T° exist for at least part of the desired temperature range for most of the substances of interest in the analysis of aircraft-propulsion systems. Several special functions are required for convenient use with the method described herein; tables were therefore prepared, from January to June 1949, that contain, in addition to C_p° , $H_T^\circ - H_0^\circ$, and S_T° , assigned values of enthalpy H_T° and values of $\log K$ and $\frac{-\Delta H^\circ}{RT}$ (logarithm of equilibrium constant and enthalpy change divided by gas constant times temperature, respectively, for reaction of formation of a substance from its elements in atomic gas state).

The data selected from various sources or computed by the NACA have been smoothed, interpolated to every 100°, and extended to 6000° K. A high degree of self-consistency has been maintained in the temperature range from 1000° to 6000° K by computing from specific-heat data the values of the other functions and retaining, in general, more decimal places than are significant. Interpolation formulas are given that permit computation of self-consistent values for all the functions at any temperature between 1000° and 6000° K.

¹ Supersedes NACA TN 2113, "General Method for Computation of Equilibrium Composition and Temperature of Chemical Reactions" by Vearl N. Huff and Virginia E. Morrell, 1950, and NACA TN 2161, "Tables of Thermodynamic Functions for Analysis of Aircraft-Propulsion Systems" by Vearl N. Huff and Sanford Gordon, 1950.

GENERAL METHOD

The thermodynamic state following a specific process, such as combustion at constant pressure, can be determined from an appropriate combination of the following equations: (a) dissociative equilibrium; (b) conservation of mass; (c) conservation of energy; (d) pressure; and (e) entropy. Equations (a) and (b) are used to specify chemical equilibrium and, when used with any two of the remaining equations, define a process.

The successive approximation procedure presented herein for finding the simultaneous solution of a specific combination of equations (a) to (e) consists of the following steps:

(1) Estimates of composition and temperature are made and used in simple equations to compute the values of error parameters, which indicate inconsistency among the estimates of composition and temperature. (These estimates need not be based on previous experience, but for rapid convergence it is desirable that they be close to the final values.)

(2) A set of linear simultaneous correction equations is given that determine a new composition and a new temperature.

(3) The new composition is used to compute new values of the error parameters and step (2) is repeated until the desired accuracy is obtained.

EQUATIONS FOR DISSOCIATION, MASS, PRESSURE, AND VOLUME

The substances entering a reaction process will be designated the reactants and can be represented by the equivalent formula

where the subscripts $a_o, b_o, \dots$ are proportional to the total number of atoms of the elements $Z, Y, \dots$, respectively, contained in a quantity of the entering substance at the initial conditions. (A complete list of symbols is included in appendix A.) For example, the reactants for a rocket combustion process using 3 moles of ammonia (NH_3) for fuel and 2 moles of nitric acid (HNO_3) for an oxidant are

An equivalent formula would be

where the atoms hydrogen, nitrogen, and oxygen, may be represented by Z, Y , and X , respectively, and 11, 5, and 6 by a_o, b_o , and c_o , respectively. The weight of the equivalent formula M_r can be computed in the usual way and would be 177.128. (If desirable, the quantity of substance in the equivalent formula may be chosen to correspond to a specified value of M_r . For example, if M_r is to be one gram, the preceding values would be divided by 177.128.)

The reaction under consideration can be written

where n_i is the number of moles of the i th molecule or atom. The subscripts $a_i, b_i, \dots$, which can take on only positive

integral values or zero, denote the number of $Z, Y, \dots$ atoms in the i th molecule. For example, if Z, Y , and X again represent hydrogen, nitrogen, and oxygen, respectively, the values of a_i, b_i , and c_i for a water molecule H_2O would be 2, 0, and 1, respectively. It is assumed that the products of reaction are contained by a volume V numerically equal to the gas constant R times the absolute temperature T so that for ideal gases

$$p_i = n_i$$

During the solution of the problem, it is necessary to determine the number of formula weights of the reactants A that are required to balance the reaction given by equation (1). Products of reaction in the gas phase are assumed to be ideal gases that form ideal mixtures and each condensed phase is assumed to have a partial pressure of zero, even when finely divided and suspended in the gas. For solids and liquids therefore

$$p_i = 0$$

As an approximation, the following assumptions are also made: Each condensed product is insoluble in all others; the fugacity of each condensed phase is equal to 1 atmosphere; the total volume occupied by the liquids and solids is negligible with respect to the volume occupied by the gases; and the liquid and solid particles have the same temperature and flow velocity as the gases.

Dissociation equations.—For simplicity of nomenclature and presentation, the equations for dissociation can be written in terms of the atomic gas as

The corresponding equation for the equilibrium constant K_i of gaseous molecules is

$$K_i = \frac{p_i}{p_z^{a_i} p_y^{b_i} \dots} \quad (3)$$

For liquid or solid molecules, assuming the fugacity of each condensed phase is equal to 1 atmosphere,

$$K_i = \frac{1}{p_z^{a_i} p_y^{b_i} \dots} \quad (4)$$

where $p_z, p_y, \dots$ are the partial pressures of the $Z, Y, \dots$ atoms in equation (1), respectively. The equilibrium constants can also be expressed in terms of the free-energy changes $(\Delta F_T^\circ)_i$ across the dissociation reactions represented by equation (2) or

$$\ln K_i = \left(\frac{-\Delta F_T^\circ}{RT} \right)_i \quad (5)$$

Because the trial composition may not correspond to that at chemical equilibrium, variables δ_i are conveniently defined so that for gaseous molecules (logarithms to the base 10 are used)

$$\delta_i = \log p_i - a_i \log p_z - b_i \log p_y - \dots - \log K_i \quad (6)$$

and for liquid or solid molecules

$$\delta_i = -a_i \log p_z - b_i \log p_r - \dots - \log K_i \quad (7)$$

where K_i is defined by equation (5). The value of each δ_i must approach zero when the solution to the problem is found. Application of equation (6) or (7) to each product of reaction will result in one equation for each molecule considered since for atoms, δ_i is identically zero.

Mass-balance equations.—A mass-balance equation stating the conservation of atomic type can be written for each chemical element present.

$$\begin{aligned} a &= \frac{1}{A} \sum_i a_i n_i \\ b &= \frac{1}{A} \sum_i b_i n_i \\ &\dots = \dots \end{aligned} \quad (8)$$

where $a, b, \dots$ are the number of gram atoms of substance $Z, Y, \dots$ per equivalent formula required to form the products of reaction. A trial composition generally leads to values of $a, b, \dots$ that differ from the desired values of $a_o, b_o, \dots$ but the difference will vanish when the correct composition is found.

Total-pressure equation.—The total pressure P is the sum of the partial pressures

$$P = \sum_i p_i \quad (9)$$

For a process with an assigned pressure, the value of P must approach the assigned value P_o as the solution of the problem is found.

Constant volume.—For processes that occur at constant volume, the density of the mixture is constant. The density ρ is defined as

$$\rho = \frac{AM_r}{V} = \frac{AM_r}{RT} \quad (10)$$

For a reaction process with an assigned density, the value of ρ must approach the assigned value ρ_o as the solution of the problem is found.

COMBUSTION AT CONSTANT PRESSURE

For given initial conditions, the temperature and the composition following a combustion process are to be found. When chemical energy is included in the enthalpy of each substance, the enthalpy of the products of reaction following an adiabatic combustion must be equal to the enthalpy of the reactants at the initial conditions. An arbitrary base may be adopted for assigning absolute values to the enthalpy of various substances because only differences are measurable. The base used to compute values of enthalpy H_T° was selected to produce positive values for all molecular types entering a combustion process in order to avoid a possible source of difficulty that might occur in the recommended

method of adjustment when a logarithm of a negative number (or zero) might be required.

Enthalpy of fuel and oxidant.—The enthalpy at initial conditions of the amount of fuel and oxidant corresponding to the equivalent formula $Z_{a_o} Y_{b_o} \dots$ is denoted by h_o and is given by the expression

$$h_o = n_f (H_T^\circ)_f + n_g (H_T^\circ)_g \quad (11)$$

where n_f and n_g are the number of moles of fuel and oxidant, respectively, corresponding to the equivalent formula $Z_{a_o} Y_{b_o} \dots$ and $(H_T^\circ)_f$ and $(H_T^\circ)_g$ are the molar enthalpies of the fuel and the oxidant, respectively, at the initial conditions. The molar enthalpy H_T° is defined by the equation

$$H_T^\circ = \int_0^T C_p^\circ dT + H_0^\circ$$

where C_p° is the molar specific heat at constant pressure, and H_0° is the chemical energy of the substance at a temperature of $0^\circ K$. Values of H_T° for several fuels and oxidants are presented with the tables of thermodynamic functions.

Enthalpy of products of reaction.—The enthalpy of the products of reaction per equivalent formula can be conveniently represented by a variable h that is given by the equation

$$h = \frac{1}{A} \sum_i (H_T^\circ)_i n_i \quad (12)$$

When enthalpy is assigned, (for example, with adiabatic combustion) the difference between h and the assigned value h_o must vanish when the correct values of n_i, A , and T are found. If heat were lost (nonadiabatic combustion), the value of h_o would be accordingly reduced.

Equations for constant-pressure combustion.—The equations defining the constant-pressure combustion are:

Type	Number of equations
Dissociative equilibrium...	1 for each molecular type.
Conservation of mass....	1 for each chemical element.
Constant pressure.....	1.
Conservation of energy...	1.

These equations are to be solved simultaneously for the variables n_i, A , and T ($p_i = n_i$ for gases).

Correction equations.—Since the preceding equations are not all linear, it is usually not feasible to find a direct solution. The Newton-Raphson method for solving nonlinear simultaneous equations (reference 5) is well suited to this type of computation. This method can be illustrated by a simple example. If Q_1 and Q_2 are functions of q and r ,

$$Q_1 = f_1(q, r)$$

$$Q_2 = f_2(q, r)$$

By taking estimated values, for example q_o and r_o , each function may be expanded in a Taylor's series about the point (q_o, r_o) and when derivatives of higher order than the first are neglected

$$\Delta Q_1 = \frac{\partial Q_1}{\partial q} \Delta q + \frac{\partial Q_1}{\partial r} \Delta r$$

$$\Delta Q_2 = \frac{\partial Q_2}{\partial q} \Delta q + \frac{\partial Q_2}{\partial r} \Delta r$$

The desired changes ΔQ_1 and ΔQ_2 can be computed; if the partial derivatives can be numerically evaluated, solving for the approximate changes in q and r to effect simultaneously the desired changes in both Q_1 and Q_2 is comparatively simple because the equations are linear.

If each of the functions δ_i , a , b , . . . , P , and h given by equations (6) to (9) and (12) is expanded in a Taylor's series about an estimated set of values of the variables and terms involving derivatives of order higher than the first are neglected, the following set of simultaneous linear correction equations results:

For gaseous products

$$x_i - a_i x_Z - b_i x_Y - \dots - q_i x_T = -\delta_i \quad (13)$$

For solid or liquid products

$$-a_i x_Z - b_i x_Y - \dots - q_i x_T = -\delta_i \quad (14)$$

For all products

$$\begin{aligned} \sum_i a_i n_i x_i - A \Delta x_A &= \delta_a \\ \sum_i b_i n_i x_i - A b x_A &= \delta_b \end{aligned} \quad (15)$$

$$\dots = \dots$$

$$\sum_i p_i x_i = \delta_P \quad (16)$$

$$\sum_i h_i' x_i - A h x_A + T C' x_T = \delta_h \quad (17)$$

where the correction variables and the error parameters may be defined in the logarithmic form

$$x_i = \Delta \log n_i = \Delta \log p_i$$

$$x_Z, x_Y, \dots = x_i \text{ for atoms}$$

$$x_A = \Delta \log A$$

$$x_T = \Delta \log T$$

$$-\delta_i = \Delta \delta_i$$

$$\delta_a = A a \log \frac{a_o}{a}$$

$$\delta_b = A b \log \frac{b_o}{b}$$

$$\dots = \dots$$

$$\delta_P = P \log \frac{P_o}{P}$$

$$\delta_h = A h \log \frac{h_o}{h}$$

and where $q_i = \left(\frac{\Delta H}{RT} \right)_i = \frac{\partial \log K_i}{\partial \log T}$, $h_i' = (H_T^o)_i n_i$, $C' = \sum_i (C_p^o)_i n_i$

The solution to the set of simultaneous equations relates the value of the r^{th} estimate to the $(r+1)^{\text{th}}$ estimate as follows:

$$\begin{aligned} \log (n_i)_{r+1} &= \log (n_i)_r + x_i \\ \log (A)_{r+1} &= \log (A)_r + x_A \\ \log (T)_{r+1} &= \log (T)_r + x_T \end{aligned} \quad (18)$$

The expansion in the Taylor's series has been carried out in the logarithmic form because this form has been found to result in rapid convergence over a wide range of conditions and avoids the possibility of computing negative partial pressures. If the expansion is carried out in powers of $x_i = \frac{\Delta n_i}{n_i}$ or $x_i = n_i \Delta \left(\frac{1}{n_i} \right)$ the same correction equations result as for the logarithmic variables except for the definitions of the correction variables and error parameters. Quite satisfactory results have been obtained by taking $x_i = \frac{\Delta n_i}{n_i}$ when x_i is positive and $x_i = n_i \Delta \left(\frac{1}{n_i} \right)$ when x_i is negative.

MATRIX CONSTRUCTION AND REDUCTION

A coefficient matrix is a scheme of detached coefficients of a set of linear equations that are to be solved simultaneously. An augmented matrix is identical to a coefficient matrix except that the constants are included. Equations (13) to (17) constitute such a set of equations for the simultaneous determination of the variables x_i , x_A , and x_T .

Construction.—Because of the large number of zeros occurring in the matrix, a considerable saving in effort can be made by proper arrangement of the order of the rows and the columns. The following arrangement provides a partly symmetrical matrix that has been found to be among the easiest to evaluate as long as the products of reaction are principally gaseous and the dissociation constants are expressed in terms of the atomic species:

The order of the columns should be—

- (a) x_i of gaseous molecules
- (b) x_i of atoms
- (c) x_i of liquid and solid products
- (d) x_A
- (e) x_T
- (f) Constant terms of equations

The order of the rows is—

- (a) Dissociation equations in same order as gaseous molecules in columns
- (b) Mass-balance equations in order of atoms in columns
- (c) Dissociation equations for solid and liquid products in same order as solid and liquid in columns
- (d) Total-pressure equation
- (e) Heat-balance equation in combustion calculation

The augmented matrix of equations (13) to (17) arranged in this recommended order is shown in figure 1.

Equation	Gaseous molecules			Atoms			Solids or liquids					
	x_1	x_2	...	x_Z	x_Y	...	x_N	x_A	x_T	Const		
(13)	1	0	0	$-a_1$	$-b_1$	...	0	0	0	$-q_1$	$-\delta_1$

Solution.—One of the best methods of solving simultaneous linear equations is given by Crout (reference 6). With this method, an auxiliary matrix is constructed from an original augmented matrix by a simple routine. This auxiliary matrix is of the order equal to the original matrix. The solution for the set of equations can be obtained by a process of back substitution in the auxiliary matrix.

For convenience, the order of the matrix is reduced before the Crout method is applied. A matrix arranged as recommended can be partitioned so that a unit matrix $[U_m]$ of the order (m, m) appears in the upper left corner, where m is equal to the number of types of gaseous molecule. The original augmented matrix can then be written

$$\begin{bmatrix} U_m & \alpha_1 \\ \alpha_2 & \alpha_3 \end{bmatrix} \quad (19)$$

When the Crout method is applied to the original augmented matrix, the Crout auxiliary matrix can be expressed as

$$\begin{bmatrix} U_m & \alpha_1 \\ \alpha_2 & \alpha_4 \end{bmatrix} \quad (20)$$

where $[U_m]$, $[\alpha_1]$, and $[\alpha_2]$ are identical to the corresponding submatrices of the original matrix. By observing the operations involved in the construction of the Crout auxiliary matrix, $[\alpha_4]$ is shown to be identical to the auxiliary matrix of the augmented matrix $[\alpha_5]$ defined by

$$[\alpha_5] = [\alpha_3] - [\alpha_2][\alpha_1] \quad (21)$$

For computation, equation (21) is written

$$[\alpha_5] = [\alpha_2][\alpha_3] \begin{bmatrix} -\alpha_1 \\ U_k \end{bmatrix} \quad (22)$$

where $[U_k]$ is a unit matrix of order equal to the number of columns of $[\alpha_1]$. The numerical solution is then obtained by carrying out the matrix multiplication indicated in equation (22) to find $[\alpha_5]$. The Crout auxiliary matrix $[\alpha_4]$

FIGURE 2.—General form of submatrices of correction equations for adiabatic combustion at assigned pressure.

is constructed from $[\alpha_5]$. The values of the variables $x_{m+1}, \dots, x_{N+2}$ are found from $[\alpha_4]$ by the process of back substitution given by Crout. The values of the remaining variables are found by the matrix equation

$$\begin{bmatrix} x_1 \\ \vdots \\ x_m \end{bmatrix} = -[\alpha_1] \begin{bmatrix} x_{m+1} \\ \vdots \\ x_{N+2} \\ -1 \end{bmatrix} \quad (23)$$

For illustration, the submatrices $[\alpha_1]$, $[\alpha_2]$, and $[\alpha_3]$ were taken from figure 1 and used to construct figure 2. The submatrix $[\alpha_2; \alpha_3]$ corresponds to equations (15), (14), (16), and (17) and is shown in figure 2 (a). The transposed matrix of $\begin{bmatrix} -\alpha_1 \\ U_k \end{bmatrix}$ is shown in figure 2 (b); that is, the columns have been tabulated as rows with the first column at the top.

COMBUSTION AT CONSTANT VOLUME

The procedure given for finding the composition and the temperature of a combustion process at constant pressure can be applied to combustion at constant volume with the following changes:

(a) The correction equation for pressure is replaced by a correction equation for density obtained from equation (10)

$$x_A - x_T = \log \frac{\rho_o}{\rho} \quad (24)$$

(b) The correction equation for conservation of energy must be written in terms of internal energy E_T° and thus becomes

$$\sum_i (E_T^\circ)_i n_i x_i - A e x_A + T \sum_i (C_v^\circ)_i n_i x_T = A e \log \frac{e_o}{e} \quad (25)$$

where

$$e = \frac{1}{A} \sum_i (E_T^\circ)_i n_i$$

e_o is the assigned internal energy per equivalent formula at initial given conditions, and C_v° is the molar specific heat at constant volume. Substitution of these two equations in the matrix of figures 1 and 2 (a) will permit the composition and the temperature to be found for assigned values of density and internal energy. The application of this method to constant-volume combustion, which, for example, is involved in reciprocating engines and pulse-jet engines, has not been made at the Lewis laboratory.

ISENTROPIC EXPANSION TO ASSIGNED PRESSURE OR TEMPERATURE

Assigned pressure.—The calculation of temperature and equilibrium composition of the products of reaction following isentropic expansion to a fixed pressure involves the simultaneous solution of dissociation, conservation-of-mass, pressure, and entropy-balance equations.

For the reaction of equation (1), the dissociation, conservation of mass, and pressure equations (6) to (9) can again be applied. For the conditions following an isentropic expansion, the entropy s of the products of combustion per equivalent formula after expansion must be equal to the entropy s_o of the products of combustion per equivalent formula before expansion.

$$s_o = \left\{ \frac{1}{A} \sum_i [n_i (S_T^\circ)_i - R p_i \ln p_i] \right\}_{\text{combustion conditions}} \quad (26)$$

where $(S_T^\circ)_i$ is the absolute entropy of the product i at standard conditions. This formula is applicable to ideal solids and liquids, assuming $p_i = 0$, as long as their volume is negligible. After the expansion takes place, the entropy per equivalent formula is given by the expression

$$s = \left\{ \frac{1}{A} \sum_i [n_i (S_T^\circ)_i - R p_i \ln p_i] \right\}_{\text{exit conditions}} \quad (27)$$

Whereas equation (26) is, of course, evaluated at combustion-chamber temperature and pressure, equation (27) is evaluated for exit temperature and pressure. As the solution of the problem is found by successive adjustment of estimated quantities, the value of s approaches s_o .

In the adjustment of the values of n_i , A , and T , the correction equations (13) to (16), which have been derived from equations (6) to (9), can be applied. In addition, the fol-

lowing correction equation for entropy can be written from equation (27):

$$\sum s'_i x_i - A s x_A + C' x_T = \delta_s \quad (28)$$

where

$$\delta_s = A s \log \frac{s_o}{s}$$

$$s'_i = (S_T^\circ)_i n_i - R p_i (1 + \ln p_i)$$

The row matrix of equation (28) shown in figure 3 may be substituted in place of the **h** rows of figures 1 and 2 (a) and the computation carried out as in the combustion calculation.

Equation											
s	(28)	s'_1	s'_2	...	s'_r	s'_r	...	...	s'_N	$-A s$	C'
										δ_s	

FIGURE 3.—Row matrix to be substituted in place of **h** row in figure 1 and in figure 2 (a) for isentropic expansion to assigned pressure. Equation (28), entropy balance.

Assigned temperature.—For the computation of data for enthalpy-entropy diagrams and for other practical computations, it is often necessary to find the exit pressure and composition as a function of exit temperature. The procedure required is the same as that described for isentropic expansion to an assigned pressure except that, in addition to substituting the **s** row in place of the **h** row, the pressure equation (**p** row) and the temperature column (x_T) are dropped from the matrix of figure 1; accordingly, the **p** row and x_T column are dropped from figure 2 (a) and the **q** row from figure 2 (b).

ISENTROPIC EXPANSION TO LOCAL VELOCITY OF SOUND

The theoretical velocity of sound that includes the effect of dissociation can be computed at any point in a nozzle with a modification of the matrix previously derived to obtain the correction quantities.

Velocity of sound.—The velocity of sound u can be defined as

$$u^2 = \left(\frac{\partial P}{\partial \rho} \right)_s \quad (29)$$

where the subscript s denotes the condition of constant entropy. The total differential of pressure dP can be found from equation (9).

$$dP = \sum_i d p_i \quad (30)$$

and the total differential of density $d\rho$ can be found from equation (10).

$$d\rho = \frac{M_r}{RT} dA - \frac{A M_r}{RT^2} dT \quad (31)$$

Then

$$\frac{dP}{d\rho} = \frac{\sum_i d p_i}{\frac{M_r}{RT} dA - \frac{A M_r}{RT^2} dT} = \frac{\sum_i p_i \frac{d \log p_i}{d \log T}}{\frac{A M_r}{RT} \left(\frac{d \log A}{d \log T} - 1 \right)}$$

Therefore

$$u^2 = \left(\frac{\partial P}{\partial \rho} \right)_s = \frac{RT \sum_i p_i D_i}{A M_r (D_A - 1)} \quad (32)$$

where

$$D_i = \left(\frac{\partial \log n_i}{\partial \log T} \right)_s$$

$$D_A = \left(\frac{\partial \log A}{\partial \log T} \right)_s$$

This expression will permit evaluation of u^2 , provided the values of the partial derivatives D_i and D_A are found for conditions of chemical equilibrium and for an isentropic process. If the value of T is in degrees Kelvin and p_i in atmospheres the value of 8.3144×10^7 for R will give u in centimeters per second. The conditions of chemical equilibrium and constant entropy are introduced by writing the total differentials of equations (6) to (8) and (27). The total differential of these equations expressed in logarithmic variables and divided by $d \log T$ can be written, for gaseous products,

$$\frac{d \log p_i}{d \log T} - a_i \frac{d \log p_z}{d \log T} - b_i \frac{d \log p_r}{d \log T} - \dots - q_i = \frac{d \delta_i}{d \log T} \quad (33)$$

for liquid and solid products,

$$-a_i \frac{d \log p_z}{d \log T} - b_i \frac{d \log p_r}{d \log T} - \dots - q_i = \frac{d \delta_i}{d \log T} \quad (34)$$

and for all products of reaction,

$$\sum_i a_i n_i \frac{d \log n_i}{d \log T} - Aa \frac{d \log A}{d \log T} = Aa \frac{d \log a}{d \log T}$$

$$\sum_i b_i n_i \frac{d \log n_i}{d \log T} - Ab \frac{d \log A}{d \log T} = Ab \frac{d \log b}{d \log T}$$

$$\dots - \dots = \dots \quad (35)$$

$$\sum_i s_i' \frac{d \log n_i}{d \log T} - As \frac{d \log A}{d \log T} + C' = As \frac{d \log s}{d \log T} \quad (36)$$

If $d \log s$ is taken as 0, s is a constant; if $d \log a$, $d \log b$, . . . , and $d \delta_i$ are taken as 0, mass is constant, atomic types are conserved, and rate of change in composition corresponds to constant values of δ_i . With these assumptions the partial derivatives D_i and D_A may be substituted for the total derivatives in equations (33) to (36). The augmented matrix formed from these equations may be partitioned in a manner similar to the combustion matrix. The resulting submatrices are shown in figure 4 with the sign reversed. When D_i and D_A are determined by means of the matrices shown in figure 4, the velocity of sound can be calculated from equation (32). This equation can be applied to mixtures of liquid and solid products in equilibrium as long as their volume is negligible compared with the volume of the gas mixture and provided the liquid and solid particles move in velocity and temperature equilibrium with the gas.

Specific heat.—The molar specific heat at constant pressure of a mixture in equilibrium may be found from equation (12) as follows:

$$C_p = \frac{A}{n} \left(\frac{\partial h}{\partial T} \right)_p = \frac{1}{nT} \left[\sum_i (H_i^\circ) n_i \left(\frac{\partial \log n_i}{\partial \log T} \right)_p - Ah \left(\frac{\partial \log A}{\partial \log T} \right)_p + TC' \right] \quad (37)$$

	$-D_1$	$-D_2$		$-D_z$	$-D_r$			$-D_N$	$-D_A$
a	$a_1 n_1$	$a_2 n_2$		0	0	0	0	$a_N n_N$	$-Aa$
b	$b_1 n_1$	$b_2 n_2$		0	0	0	0	$b_N n_N$	$-Ab$
.....				0	0	0	0		0
N	0	0	0	a_N	b_N		0	0	q_N

(b) Submatrix $\begin{bmatrix} -a_i \\ -u_k \end{bmatrix}$ transposed.

FIGURE 4.—General form of submatrices of equations for partial derivatives at constant entropy.

where $n = \sum n_i$. Equation (30) can be written as

$$\sum_i p_i \frac{d \log n_i}{d \log T} = \frac{P d \log P}{d \log T} \quad (38)$$

If $d \log P$ is taken as 0, the pressure is constant; therefore, when equation (38) is substituted in the matrix of figure 4 in place of equation (36), the values of $\left(\frac{\partial \log n_i}{\partial \log T} \right)_p$ and $\left(\frac{\partial \log A}{\partial \log T} \right)_p$ can be found. These values can then be substituted in equation (37) to evaluate C_p° .

Isentropic expansion to assigned Mach number.—According to the law of conservation of energy the sum of the enthalpy and the kinetic energy of a certain quantity of gas at any point in a nozzle is constant. If this sum per equivalent formula at any point l is denoted by a parameter h^* , then

$$h^* = \left[h + \frac{1}{2} M_l^2 v^2 / J \right]_l \quad (39)$$

where v is the velocity of flow of the gas, J is a dimensional constant, and the subscript l indicates that the variables are evaluated at point l in the nozzle. The Mach number M of the flow is

$$M = \frac{v}{u} \quad (40)$$

Equations (32), (39), and (40) may be combined to give

$$h^* = \frac{\sum_i (H_i^\circ) n_i}{A} + \frac{M^2 \dot{R} T \sum_i p_i D_i}{2A(D_A - 1)} \quad (41)$$

where the value of R becomes 1.98718 (cal/(mole) (°K)). As the solution of the problem is found by successive adjustments of the estimated quantities, h^* approaches h_o .

If equation (41) is expanded in a manner similar to that used to obtain equation (17) and if the differentials of derivatives are assumed to be negligible, the correction equation becomes

$$\sum_i h_i'' x_i - Ah^* x_A + T C'' x_T = \delta_h^* \quad (42)$$

where

$$h_i'' = h_i' + \frac{M^2 R T p_i D_i}{2(D_A - 1)}$$

$$\delta_h^* = Ah^* \log \frac{h_o}{h^*}$$

$$C'' = \sum_i \left[n_i (C_s)_i + \frac{M^2 R p_i D_i}{2(D_A - 1)} \right]$$

Equation (42), together with equations (13) to (15) and (28), constitute the correction equations for the isentropic expansion to an assigned Mach number. The coefficients of these equations form the submatrices shown in figure 5.

In order to carry out the numerical computations, values of n_i , A , and T are estimated for the assigned conditions; the values of D_i and D_A are obtained by means of the submatrices of figure 4, and used to compute the numerical values of the elements of the bottom row of figure 5(a). The submatrices of figure 5 are then used to compute the values of the corrections to n_i , A , and T . This process can be repeated until the assigned conditions are satisfied.

FIGURE 5.—General form of submatrices of correction equations for isentropic expansion to assigned Mach number.

Throat area of supersonic nozzle.—The process of isentropic expansion to a local Mach number of 1 is particularly interesting in the determination of the throat area of a nozzle having greater than critical pressure ratio. By assuming that the flow is isentropic and that chemical equilibrium is maintained throughout the expansion process, the flow velocity v at the throat must be equal to the velocity of sound u at the throat. The values n_i , A , T , and u can be found for a Mach number of 1 by use of the procedure given.

The throat area t can be calculated from the equation

$$\frac{t}{m} = \frac{RT}{AM_u} \quad (43)$$

where m is the mass flow per second. If T is in degrees Kelvin and u is in centimeters per second, R equal to 82.0567 (cm³) (atm) / (°K) (mole) will give t/m in (cm²) (sec)/(gm). This equation can be applied to mixtures of liquid or solid phases in equilibrium provided that the volume occupied by the liquid and the solid phases is negligible compared with that of the gas phase and that the particles of liquid and solid are in thermal and velocity equilibrium with the gas phase.

EXAMPLE OF COMBUSTION OF DIBORANE WITH OXYGEN BIFLUORIDE

The calculation of equilibrium temperature and composition of the reaction of 1 mole of diborane (B₂H₆) with 5 moles of oxygen bifluoride (OF₂) is illustrated in this example for processes of

- constant-pressure adiabatic combustion
- isentropic expansion to 1 atmosphere
- isentropic expansion to the local velocity of sound

An equivalent formula of these reactants is

and $a_0=6$, $b_0=2$, $c_0=10$, and $d_0=5$.

The following gaseous products will be considered as the products of reaction: boron trifluoride BF₃, boron trioxide B₂O₃, boron fluoride BF, boron hydride BH, boron oxide BO, diatomic boron B₂, hydrogen H₂, water vapor H₂O, hydroxyl radical OH, hydrogen fluoride HF, oxygen O₂, fluorine F₂, atomic hydrogen H, atomic boron B, atomic fluorine F, and atomic oxygen O. No liquids or solids are included. If the products are numbered in the order given, they can be identified in the terminology of equation (1) as follows:

and therefore

$$a_1=0, b_1=1, c_1=3, \text{ and } d_1=0$$

Similarly,

and

$$a_2=0, b_2=2, c_2=0, \text{ and } d_2=3$$

All values of a_i , b_i , c_i , and d_i for this problem, together with the thermodynamic properties used, are listed in table I. Although these thermodynamic values and the enthalpies of B_2H_6 and of OF_2 have since been revised, and therefore do not correspond to the values listed in the thermodynamic tables presented in a later section, they are adequate for the purpose of this example. The enthalpy values used are

$$(H_{298.16}^\circ)_{\text{liquid } B_2H_6} = 570.149 \text{ kilocalories per mole}$$

$$(H_{128.3}^\circ)_{\text{liquid } OF_2} = 67.077 \text{ kilocalories per mole}$$

The enthalpy of the amount of fuel and oxidant at initial conditions corresponding to the equivalent formula is, from equation (11),

$$h_o = 570.149 + 5(67.077) = 905.534 \frac{\text{kilocalories}}{\text{equivalent formula}} \quad (44)$$

The values of a_i , b_i , c_i , d_i , and h_o are constant for all parts of this example.

COMBUSTION PROCESS

The adiabatic combustion process was assumed to occur at a constant pressure of 20.4 atmospheres.

First estimate.—From previous computations or from simple calculations with equilibrium constants, estimating reasonable values for the composition and the temperature is usually possible. This procedure is recommended inasmuch as close estimates reduce the number of trials that must be made. In order to show that an arbitrary composition which is not based on probable final values of the composition

can be used, however, the first estimates for this example for n_i and A have been taken equal to 1 mole and a temperature of 4000° K. The possibility of divergence is discussed in a later section. All estimated quantities will be used with three decimal places to distinguish them from numbers that are always integers.

Evaluation of submatrices.—The numerical values of the elements of the submatrices shown in figures 2(a) and 2(b) can now be computed and are shown in figure 6. The steps are as follows:

1. The values of a_i , b_i , c_i and d_i are entered in rows **a**, **b**, **c**, and **d** of figure 6(b) and a 1 is entered on each square of the diagonal of $[U_k]$ according to figure 2(b).

2. Values of $q_i = \left(\frac{\Delta H}{RT}\right)_i$ from tables of thermodynamic functions are entered in row **q** of figure 6(b). In this case they are obtained from table I.

3. The values of the elements of the δ row of figure 6 (b) may be computed from equation (6) for gaseous products

$$\delta_i = \log p_i - a_i \log p_H - b_i \log p_B - c_i \log p_F - d_i \log p_O - \log K_i$$

The values of $\log K_i$ are obtained from tables of thermodynamic properties, in this case table I. Because all molecules and atoms are estimated to be 1, their logarithms are 0 so that in this case

$$\delta_i = -\log K_i$$

4. The estimated values of n_i are entered in row **p** of figure 6 (a). In case liquids or solids are present their value will be zero.

FIGURE 6.—Numerical example of submatrices of correction equations for adiabatic combustion of diborane and oxygen bifluoride after first estimate of n_i , A , and T .

5. The values of the elements in rows **a**, **b**, **c**, and **d** of figure 6 (a), except columns x_A , x_T , and constant, are obtained by multiplying the value of n_i by the value of the corresponding element of the respective row in figure 6 (b). For example, the entries in the first column are $0 \times 1.000 = 0$, $1 \times 1.000 = 1.000$, $3 \times 1.000 = 3.000$ and $0 \times 1.000 = 0$.

6. Values of the elements of row **h** of figure 6 (a), except columns x_A , x_T , and constant, are obtained by multiplying the value of n_i by the value of $(H_T^\circ)_i$ from tables of thermodynamic functions, in this case table I. For example, the entry in the first column is $72,172 \times 1.000 = 72,172$. All values in row **h** have been divided by 10^5 .

7. The values of the elements of column x_A figure 6 (a) are obtained by summing elements to the left in each row and writing the negative of the total in column x_A except for row **p** where the value is zero.

8. The value of the x_T column (fig. 6 (a)) is zero except for the **h** row where the value is $T \sum_i (C_p^\circ)_i n_i$. The values of $(C_p^\circ)_i$ are obtained from tables of thermodynamic functions, in this case table I.

9. Values of the constant column for figure 6 (a) for all rows except row **p** are found as follows: The value already entered in the x_A column for row **a** is $-Aa$. With the estimated value of $A = 1.000$

$$a = \frac{Aa}{A} = \frac{8.000}{1.000} = 8.000$$

$$\delta_a = Aa \log \frac{a_o}{a}$$

$$= 8.000 \log \frac{6}{8.000} = -0.999$$

the values of δ_b , δ_c , δ_d , and δ_h are found in a similar manner.

FIGURE 7. Numerical example of the solution of correction equations by matrix methods.

10. The constant column of row **p** is found as follows: The sum of the elements of row **p** is the pressure $P = 16.000$; δ_P is computed from the formula

$$\delta_P = P \log \frac{P_o}{P}$$

$$\delta_P = 16.000 \log \frac{20.4}{16.000} = 1.688$$

The matrix multiplication $[\alpha_2] \alpha_3 \begin{bmatrix} -\alpha_1 \\ U_k \end{bmatrix}$ will result in the matrix $[\alpha_5]$ shown in figure 7 (a). The steps of this multiplication are shown in standard textbooks such as reference 7. Crout's auxiliary matrix corresponding to $[\alpha_5]$ may then be constructed and is shown in figure 7 (b) and the values of x_H , x_B , x_F , x_O , x_A , and x_T are shown in figure 7 (c). The values of the remaining functions are computed with the aid of equation (23). The solution is found to be

$$\begin{array}{ll} x_{BF_3} = 0.7056 & x_{OH} = 0.4907 \\ x_{B_2O_3} = -1.100 & x_{HF} = 1.377 \\ x_{BF} = 1.116 & x_{O_2} = 0.1737 \\ x_{BH} = 1.665 & x_{F_2} = -2.037 \\ x_{BO} = 0.6135 & x_H = 1.299 \\ x_{B_2} = -2.139 & x_B = 0.9290 \\ x_{H_2} = 0.03982 & x_F = 1.222 \\ x_{H_2O} = -0.7999 & x_O = 1.459 \\ x_A = 0.1232 & x_T = 0.1544 \end{array}$$

These values are to be applied to the initial estimates for n_i , A , and T according to the equation

$$(\log n_i)_{\text{second estimate}} = (\log n_i)_{\text{first estimate}} + x_i \quad (45)$$

For example, the second estimate of n_{BF_3} would be

$$(\log n_{BF_3})_{\text{second estimate}} = \log 1.000 + 0.7056$$

$$(n_{BF_3})_{\text{second estimate}} = 5.077$$

The second estimates of n_i , A , and T are then used to set up new submatrices according to the procedure described. The process is repeated until the desired accuracy has been obtained. For this example, six approximations were required to give the following final values of n_i , A , and T :

$$\begin{array}{ll} n_{BF_3} = 2.6593 & n_{OH} = 0.6785 \\ n_{B_2O_3} = 0.1235 & n_{HF} = 7.1456 \\ n_{BF} = 0.1936 & n_{O_2} = 0.9210 \\ n_{BH} = 0.0001 & n_{F_2} = 0.0003 \\ n_{BO} = 0.1669 & n_H = 1.7694 \\ n_{B_2} = 0 & n_B = 0.0577 \\ n_{H_2} = 0.1271 & n_F = 1.3043 \\ n_{H_2O} = 0.0627 & n_O = 5.1903 \\ A = 1.6622 & T = 4775.5^\circ \text{K} \end{array}$$

Discussion of convergence.—In order to demonstrate the convergence of the process with large errors in the first estimate, the example of the combustion of diborane and fluorine oxide was solved by using 1 mole of each product, a value of 1 for A , and a temperature of 4000° K for the first estimate. Because these first estimates were made without regard for the probable final values, large errors were present in the second approximation and six approximations were required to eliminate the error. The convergence is shown in terms of the parameters a , b , c , d , P , h , and ϵ in the following table where ϵ is defined as

$$\epsilon = \sum_i \left| \log k_i \right| + \left| \log \frac{a_o}{a} \right| + \left| \log \frac{b_o}{b} \right| + \left| \log \frac{c_o}{c} \right| + \left| \log \frac{d_o}{d} \right| + \left| \log \frac{P_o}{P} \right| + \left| \log \frac{h_o}{h} \right|$$

RESULTS OF APPROXIMATIONS								
Parameter	First estimate	Trial number						Desired value
		1	2	3	4	5	6	
a	8	36.840	7.005	6.286	6.079	6.002	6.000	6.000

ϵ	26.892	5.861	4.092	2.505	.537	.011	.002	0

This method has been used in routine computation for several years without encountering a divergent case in a practical problem. At least for special cases when temperature is assigned, the process will converge for all values of the first estimates. Divergence is known to occur for certain cases where temperature is used as a variable when the first estimate of temperature and composition is sufficiently in error. Although no mathematical analysis has been made to determine the theoretical limits of convergence, the process appears to be satisfactory for practical computation.

Special treatment would be required if divergence is encountered. Obtaining convergence should be possible by a sufficiently close new estimate of composition and temperature. This procedure is recommended when it is feasible but other procedures can be devised, depending on the individual case.

ISENTROPIC EXPANSION TO FIXED PRESSURE

The temperature and the composition of the products of reaction following an isentropic-expansion ratio of 20.4 at chemical equilibrium were also computed for the products of reaction of this example. The value of s_o is found from equation (26) by using the final values of each constituent of the adiabatic combustion and the absolute entropy values corresponding to the final combustion temperature. The calculated value of s_o was 763.476 calories per °K per mole.

First estimates.—The number of approximations necessary

for a complete calculation can be considerably reduced if the initial estimate is based on previous experience. The final values of n_i and A determined for the combustion process of this example can therefore be the basis for this first estimate.

Because the expansion ratio is 20.4, the four largest components can be estimated to be 1/20.4 of their combustion value.

$$\begin{aligned} n_{\text{BF}_3} &= 0.1304 \\ n_{\text{HF}} &= 0.3503 \\ n_{\text{H}} &= 0.0867 \\ n_{\text{O}} &= 0.2544 \\ A &= 0.0815 \end{aligned}$$

For convenience of presentation, the temperature was estimated to be 4000° K so that the values of table I could be used again. The remaining products can be estimated from the dissociation equations by setting $\log k_i = 0$. For example, p_{F} would be determined with the assumed values of p_{HF} and p_{H} from equation (6) and table I ($p_i = n_i$)

$$\begin{aligned} 0 &= \log 0.3503 - \log 0.0867 - \log p_{\text{F}} - 1.8944 \\ \log p_{\text{F}} &= -0.45556 + 1.06198 - 1.8944 \\ &= -1.28798 \end{aligned}$$

$$p_{\text{F}} = 0.0515$$

Similarly, p_{B} can be estimated with the assumed values of p_{BF_3} and p_{F}

$$\begin{aligned} 0 &= \log 0.1304 - \log p_{\text{B}} - 3 \log 0.0515 - 5.6953 \\ \log p_{\text{B}} &= -0.88472 + 3.86394 - 5.6953 \\ p_{\text{B}} &= 0.0019 \end{aligned}$$

If this procedure is followed for all the remaining constituents, the following list of first estimates can be made:

$$\begin{aligned} n_{\text{BF}_3} &= 0.1304 & n_{\text{OH}} &= 0.0150 \\ n_{\text{B}_2\text{O}_3} &= 0.0078 & n_{\text{HF}} &= 0.3503 \\ n_{\text{BF}} &= 0.0043 & n_{\text{O}_2} &= 0.0269 \\ n_{\text{BH}} &= 0 & n_{\text{F}_2} &= 0 \\ n_{\text{BO}} &= 0.0053 & n_{\text{H}} &= 0.0867 \\ n_{\text{B}_2} &= 0 & n_{\text{B}} &= 0.0019 \\ n_{\text{H}_2} &= 0.0029 & n_{\text{F}} &= 0.0515 \\ n_{\text{H}_2\text{O}} &= 0.0009 & n_{\text{O}} &= 0.2544 \\ A &= 0.0815 & T &= 4000^\circ \text{K} \end{aligned}$$

Construction of submatrices.—The construction of the submatrices may now be carried out and is shown in figure 8. The steps are the same as for the combustion example except for steps 6 to 9, which are different because the enthalpy equation has been replaced with the entropy equation.

The values of the elements of row s of figure 8(a) are obtained from the expression

$$s'_i = n_i [(S_T^\circ)_i - 1.98718 - 4.57565 \log p_i]$$

The values of $(S_T^\circ)_i$ are obtained from tables of thermodynamic data, in this case table I. For example, the entry in the first column is computed to be

$$\begin{aligned} (s_{\text{BF}_3})' &= 0.1304 (105.951 - 1.98718 - 4.57565 \log 0.1304) \\ &= 14.0848 \end{aligned}$$

7. The values of the entries in the x_A column of figure 8(a) are obtained in the same manner as for figure 6(a) except for the **s** row where the sum of the elements of the **p** row times 1.98718 is added to the sum of the elements of the **s** row and entered in column x_A .

8. The value of the entries in the x_T column is zero except for the **s** row where it is $\sum_i n_i (C_p^\circ)_i$. The values of $(C_p^\circ)_i$ are obtained from tables of thermodynamic data, in this case table I.

9. The value of δ_s is found in a manner similar to δ_a .

ISENTROPIC EXPANSION TO MACH NUMBER OF 1

The temperature and the composition of the products of reaction following an isentropic expansion to the local velocity of sound was computed for the products of reaction considered in this example, assuming chemical equilibrium. The value of s_0 is the same as that found for the isentropic expansion to 1 atmosphere.

First estimate.—For simplicity, the same first estimates of 1 mole, 1, and 4000° K, for n_i , A , and T , respectively, were again made.

Construction of submatrices.—The submatrices corresponding to figure 5 may be constructed and are shown in figure 9.

The submatrices corresponding to figure 4 are first constructed. The steps are the same as for figure 8 except that row **p** and the constant column are omitted. The matrix

multiplication may then be carried out and the values of the partial derivatives D_i and D_A computed in a manner similar to the computation in the combustion example. These values of D_i and D_A together with $(H_T^\circ)_i$ are used to calculate the elements of row **h*** of figure 9(a) except columns x_A , x_T , and constant. For example, when the values of $D_{BF_3}=12.990$ and $D_A=19.039$ are used, the value of

$$(h_{BF_3})'' = (h_{BF_3})' + \frac{M^2 R T p_{BF_3} D_{BF_3}}{2(D_A - 1)} \text{ becomes } 75,034 = 72,172 + \frac{1 \times 1.98718 \times 4000 \times 1.000 \times 12.990}{2(19.039 - 1)} \text{ (cal)}$$

All values in row **h*** have been divided by 10^5 .

The value of the element in row **h***, column x_A is the sum of the elements to the left. The element in row **h***, column x_T is given by

$$TC'' = T \sum_i \left[n_i (C_p^\circ)_i + \frac{M^2 R p_i D_i}{2(D_A - 1)} \right]$$

and the value of the constant column is obtained as in the previous examples. Matrix multiplication that was carried out for the determination of D_i and D_A values may now be extended by an additional row and column and the value of x_i , x_A , and x_T found as in the previous examples. These values may then be used to obtain the second estimates for n_i , A , and T and the computation repeated until the desired accuracy has been obtained.

TABLES OF THERMODYNAMIC PROPERTIES

Tables of thermodynamic data, completed June 1949, are presented for the following substances:

A	Al(g)	B	C	Cl	F	H	e ⁻	Li	N	O
	Al(s)	B ₂	CO	Cl ₂	F ₂	H ₂	F ⁻	LiF	N ₂	O ₂
	Al(liq)	BF	CO ₂	ClF		HCl	Li ⁺	LiH	NO	OH
	AlO	BF ₃				HF				
	Al ₂ O ₃ (g)	BH				H ₂ O				
	Al ₂ O ₃ (s)	BO								
	Al ₂ O ₃ (liq)	B ₂ O ₃ (g)								
		B ₂ O ₃ (s)								
		B ₂ O ₃ (liq)								

These tables are taken from NACA TN 2161 except that the values for BF have been revised. Many of the data in the tables are based upon estimated vibrational frequencies or insufficient spectroscopic or thermochemical data to provide accurate data at high temperatures. Nevertheless, the data are considered sufficiently accurate for engineering evaluations of performance of aircraft propulsion systems until better data become available.

PREPARATION OF TABLES

The values of enthalpy and entropy below 1000° K and the values of specific heat at all temperatures were based upon data taken from the literature or calculated by NACA from spectroscopic data or estimated fundamental frequencies. The calculations were made by use of the accurate summation method described in reference 8 or by the use of the tables prepared by F. J. Krieger of Douglas Aircraft Company, Inc. based upon a harmonic oscillator. The

values of enthalpy and entropy above 1000° K were computed from the specific-heat data and these values were then used to compute the values of the remaining functions.

The thermodynamic functions computed by NACA are based upon the fundamental constants from reference 9 and are given in terms of the thermochemical calorie defined as 4.18400 absolute joules (reference 10).

Specific heat.—The specific-heat data were interpolated and extrapolated when necessary to obtain values of C_p° at 298.16° K and every 100° from 300° to 6000° K. In many cases these C_p° data were smoothed by the following method: Values of the first differences of C_p° for 100° K intervals δC_p° were plotted against temperature and a smooth curve drawn. New values of C_p° were then computed from the values of δC_p° read from the curve. In some cases the new C_p° values were tabulated to more decimal places than the original data. Care was taken to see that the new C_p° values were within about 1 or 2 units in the last tabulated place of the reference data in all but a few cases in which the reference data were irregular.

In order to minimize the labor required to integrate C_p° to obtain the other functions, a linear variation of C_p° was assumed by use of the equation

$$C_p^\circ = c_1 + c_2 T \quad (46)$$

where c_1 and c_2 are constants evaluated for each 100° temperature interval above 1000° K.

The maximum difference between a smooth function representing C_p° and the series of 50 straight-line segments represented by equation (46) is usually less than 0.005 percent at any temperature. In a few cases near 1000° K the error approaches 0.05 percent.

Enthalpy and entropy.—The data for enthalpy and entropy below 1000° K were taken from the literature or computed at the Lewis laboratory and when necessary interpolated to give the values at 298.16° K and every 100° from 300° to 1000° K.

The values above 1000° K were obtained by integration of equation (46) for C_p° using the constants for each 100° K temperature interval.

The value of the change of enthalpy δH_T° for a temperature change $\delta T = T - T_1$ is given by

$$\delta H_T^\circ = \int_{T_1}^T C_p^\circ dT = \bar{C}_p^\circ \delta T \quad (47)$$

where $\bar{C}_p^\circ$ is given by

$$\bar{C}_p^\circ = (C_p^\circ)_1 + \frac{c_2}{2} \delta T \quad (48)$$

and $(C_p^\circ)_1$ is the value of C_p° corresponding to the temperature T_1 . The corresponding change in entropy δS_T° is given by

$$\delta S_T^\circ = \int_{T_1}^T \frac{C_p^\circ}{T} dT = c_1 \delta \ln T + c_2 \delta T \quad (49)$$

where $\delta \ln T$ is given by

$$\delta \ln T = \ln T - \ln T_1 \quad (50)$$

Values of enthalpy and entropy for each 100° above 1000° K were obtained by accumulatively adding to the values at 1000° K the changes of enthalpy and entropy computed for each 100° interval by means of equations (47) and (49).

The values of enthalpy and entropy were computed to more decimal places than are tabulated and then rounded. Equations (47) and (49) may therefore occasionally yield values that differ by one unit in the last tabulated place of enthalpy and entropy because of rounding. Inconsistencies from this source are unavoidable and are not considered in the following discussion.

The representation of C_p° from 1000° to 6000° K by means of 50 straight-line segments permitted computation of self-consistent values of enthalpy and entropy but lead to values slightly different from those that would have resulted from a more laborious integration of a smooth C_p° function. For example, the values of enthalpy at 6000° K differ from those obtained by applying Simpson's one-third rule by 0.0045, 0.0012, 0.0038, and 0.0031 percent for H_2O , H_2 , CO_2 , and BF_3 , respectively.

In a few cases, discrepancies exist between the reference values of enthalpy and the values of enthalpy given herein that cannot be accounted for by the error resulting from the method of integration used. From an analysis of the values in the reference tables, these discrepancies appear to be caused by a combination of small inconsistencies and round-

ing errors in the references. The maximum discrepancy noted in enthalpy occurred in H_2O and was less than 0.25 percent of the value of $H_T^\circ - H_0^\circ$.

Enthalpy H_T° .—For convenience of computation, tables of enthalpy H_T° , the sum of the sensible enthalpy $H_T^\circ - H_0^\circ$ and chemical energy at 0° K H_0° , were prepared. An arbitrary base may be adopted for assigning absolute values to the enthalpy of various substances inasmuch as only differences in enthalpy are measurable. The base used in these tables was selected to obtain positive values for H_T° of the substances commonly used as rocket and ram-jet propellants and occurring in the products of combustion; it is shown in the following table:

Base substance	Phase	Temperature (°K)	Enthalpy assigned, H_T° (kcal/mole)
A	Gas	0	0
AlF ₃	Crystal	298.16	0
BF ₃	Gas	0	0
CO ₂	Gas	0	0
Cl ₂	Gas	298.16	10
HF	Gas	0	0
H ₂ O	Crystal	0	0
LiF	Gas	298.16	80
N ₂	Crystal	0	0
O ₂	Crystal	0	0
e ⁻	Gas	0	60

In determining the value of H_T° to be assigned to a substance having a known heat of formation, it is convenient to use the values of H_T° assigned to the elements as shown in the following table:

Element	Phase	Enthalpy assigned, H_T° (kcal/mole)	
		0° K	298.16° K
A	Gas	0	1.4812
Al	Crystal	233.6251	234.6951
B	Crystal	-----	173.3793
C	Graphite	91.9274	92.1790
Cl ₂	Gas	7.8061	10.0000
F ₂	Gas	60.9562	63.0699
H ₂	Gas	67.4169	69.4407
Li	Crystal	-----	132.2250
N ₂	Gas	1.6992	3.7715
O ₂	Gas	2.0362	4.1109
e ⁻	Gas	60.0000	61.4812

For example, if the value of enthalpy H_T° to be assigned to H_2O (liq) is to be determined at 298.16° K, the reaction of formation would be

and ΔH_f° is defined as

$$\Delta H_f^\circ = (H_T^\circ)_{H_2O} - (H_T^\circ)_{H_2} - \frac{1}{2} (H_T^\circ)_{O_2} \quad (52)$$

therefore,

$$(H_T^\circ)_{H_2O} = \Delta H_f^\circ + (H_T^\circ)_{H_2} + \frac{1}{2} (H_T^\circ)_{O_2} \quad (53)$$

With the use of the value $\Delta H_f^\circ = -68.3174$ (kcal/mole),

$$\begin{aligned} (H_{298.16}^\circ)_{H_2O(l)} &= -68,317.4 + 69,440.7 + \frac{1}{2}(4110.9) \\ &= 3178.75 \text{ (cal/mole)} \end{aligned}$$

For convenience, the values of H_T° thus assigned to a number of compounds have been computed with the aid of data from references 8 and 10 to 23 and are listed in table II. The energy of gas imperfections has been included in computing the values of H_T° assigned to the liquid phase of ammonia, *n*-butane, chlorine, hydrogen, and water.

$-\Delta H^\circ/RT$ and $\ln K$.—From the values of H_T° and S_T° obtained as previously described, the values of $-\Delta H^\circ/RT$ and $\ln K$ were computed for the reaction of formation of each substance from its elements in the atomic gas state. For example, the reaction of formation of H_2O is

From the definitions of ΔH° and $\ln K$

$$\frac{\Delta H^\circ}{RT} = \frac{(H_T^\circ)_{H_2O} - 2(H_T^\circ)_H - (H_T^\circ)_O}{RT} \quad (55)$$

and

$$\ln K = \frac{(S_T^\circ)_{H_2O} - 2(S_T^\circ)_H - (S_T^\circ)_O}{R} - \frac{(H_T^\circ)_{H_2O} - 2(H_T^\circ)_H - (H_T^\circ)_O}{RT} \quad (56)$$

As shown by equations (3) and (4), K may be expressed in terms of partial pressures. For example, for gaseous H_2O ,

$$K = \frac{p_{H_2O}}{p_H^2 p_O}$$

The values of $\ln K$ have been converted to $\log K$ in the tables for convenience.

INTERPOLATION OF TABLES

Interpolation formulas are given that permit computation of self-consistent values of the thermodynamic functions at temperatures intermediate to those tabulated. Linear interpolation is recommended for simplicity, however, when a high degree of self-consistency is not required. Interpolation formulas such as those of Newton or Lagrange will give values near the self-consistent value. Inasmuch as the tables are based on linear variations in C_p° , linear interpolation yields self-consistent results for the C_p° function. An example of the values obtained by the interpolation formulas given and by linear interpolation is shown for each function.

Interpolation of specific heat.—The value of C_p° for any temperature T is given by

$$C_p^\circ = (C_p^\circ)_1 + \frac{\delta T}{T_2 - T_1} [(C_p^\circ)_2 - (C_p^\circ)_1] \quad (57)$$

where $(C_p^\circ)_1$ and $(C_p^\circ)_2$ are the tabular values corresponding to the tabular temperatures T_1 and T_2 between which T lies and $\delta T = T - T_1$. For example, the value of C_p° for H_2O at $1573.4^\circ K$ is computed to be

$$\begin{aligned} C_p^\circ &= 11.134 + \frac{73.4}{100} (11.343 - 11.134) \\ &= 11.287 \text{ (cal/(mole) } (^\circ K)) \end{aligned}$$

Interpolation of enthalpy.—The value of H_T° for any temperature T is given by

$$H_T^\circ = (H_T^\circ)_1 + \bar{C}_p^\circ \delta T \quad (58)$$

where $(H_T^\circ)_1$ is the value listed at T_1 and where

$$\bar{C}_p^\circ = \frac{(C_p^\circ)_1 + C_p^\circ}{2}$$

For example, for H_2O at $1573.4^\circ K$

$$\bar{C}_p^\circ = \frac{11.134 + 11.287}{2} = 11.211 \text{ (cal/(mole) } (^\circ K))$$

$$H_T^\circ = 25,202.3 + 11.211 \times 73.4 = 26,025.2 \text{ (cal/mole)}$$

By linear interpolation,

$$H_T^\circ = 26,027.2 \text{ (cal/mole)}$$

Interpolation of entropy.—Self-consistent values of entropy may be obtained with the aid of equation (49), which may be approximated by

$$\delta S_T^\circ = \bar{C}_p^\circ \delta \ln T \quad (60)$$

from which S_T° may be written

$$S_T^\circ = (S_T^\circ)_1 + \bar{C}_p^\circ \delta \ln T \quad (61)$$

where $(S_T^\circ)_1$ is the value listed at T_1 .

Equation (61) yields self-consistent values to within 0.0001 (cal/(mole) $(^\circ K)$) for all substances tabulated at temperatures above $1600^\circ K$ and for all substances except Al_2O_3 (s and g), BF_3 , B_2O_3 (liq and g), CO_2 , and H_2O for temperatures from 1000° to $1600^\circ K$. For these substances, the error due to use of equation (61) does not exceed 0.0003 cal/(mole) $(^\circ K)$, but equation (49) may be used if greater self-consistency is desired.

For example, for H_2O at $1573.4^\circ K$,

$$\begin{aligned} S_T^\circ &= 59.8687 + 11.211 (\ln 1573.4 - \ln 1500) \\ &= 60.4043 \text{ (cal/(mole) } (^\circ K)) \end{aligned}$$

By linear interpolation,

$$S_T^\circ = 60.4010 \text{ (cal/(mole) } (^\circ K))$$

Interpolation of $-\Delta H^\circ/RT$ and $\log K$.—The values of $-\Delta H^\circ/RT$ and $\log K$ for any temperature T are given by

$$\frac{-\Delta H^\circ}{RT} = \left(\frac{-\Delta H^\circ}{RT} \right)_1 - \frac{\delta T}{100} \left(\frac{a}{T} + b \right) \quad (62)$$

and

$$\log K = (\log K)_1 - \frac{\delta T}{100} \left(\frac{c}{T} + d \right) \quad (63)$$

where $(-\Delta H^\circ/RT)_1$ and $(\log K)_1$ are the values corresponding to T_1 and where a , b , c , and d are interpolation coefficients corresponding to T_1 .

For example, for H_2O at $1573.4^\circ K$,

$$\frac{-\Delta H^\circ}{RT} = 76.3615 - \frac{73.4}{100} \left(\frac{7366}{1573.4} + 0.05315 \right) = 72.8862$$

By linear interpolation,

$$\frac{-\Delta H^\circ}{RT} = 72.9433$$

and for $\log K$,

$$\log K = 20.5727 - \frac{73.4}{100} \left(\frac{3276}{1573.4} + 0.02690 \right) = 19.0247$$

By linear interpolation,

$$\log K = 19.0501$$

SOURCES OF DATA

A summary of the heat of formation and spectroscopic constants used in computing the tables and the references from which these data were taken are given in table III together with a summary of the source and the treatment of specific-heat, enthalpy, and entropy data. Additional discussion for a few substances follows.

Al₂O₃(s, liq, g).—The properties of Al₂O₃ in the solid, liquid, and gaseous phases were approximated by starting with data at 298.16° K for the solid phase and computing the properties of each phase from specific-heat data and enthalpy changes associated with phase changes. The specific heat for the solid was computed from a formula for C_p° given in reference 27. The value of $S_{298.16}^\circ$ for the solid was taken from selected values of National Bureau of Standards (issued undated but prior to June 30, 1948). The values of enthalpy and entropy up to 1000° K were then found by integration of the C_p° formula given in reference 27. The heat of fusion ($\Delta H_{\text{fusion}}^\circ = 6000$ cal/mole at 2320° K) was taken from reference 25. The C_p° values for Al₂O₃ (liq) above 2320° K were calculated from a formula based upon data given in reference 25.

Inasmuch as data on gaseous Al₂O₃ are unavailable in the literature, it was assumed that C_p° values for Al₂O₃(g) are the same as those for B₂O₃(g) given in reference 29. The heat of vaporization ($\Delta H_{\text{vaporization}}^\circ = 115.7$ kcal/mole at boiling point of $2980 \pm 60^\circ$ C) was taken from reference 40. The uncertainty in the values given for entropy and enthalpy is estimated to be ± 10 percent.

BF.—Since publication of Technical Note 2161, new thermodynamic data have been computed for BF based upon a $\sum$ ground state and a dissociation energy of 4.3 electron volts as quoted by reference 30.

BF₃.—The thermodynamic functions of BF₃ were computed by the rigid-rotator-harmonic-oscillator approximation with the following spectroscopic data given in references 31 and 41:

Vibrational frequencies			Moment of inertia (g)(cm ²)
	B ¹¹ F ₃ (cm ⁻¹)	B ¹⁰ F ₃ (cm ⁻¹)	
ν_1	888	888	$I_1 = 157.7 \times 10^{-40}$
ν_2	691.3	719.5	$I_2 = 78.84 \times 10^{-40}$
$\nu_2(2)$	1445.9	1497	$I_3 = 78.84 \times 10^{-40}$
$\nu_4(2)$	480.4	482.0	
Relative abundance (percent)	81.17	18.83	

B₂O₃(g).—The value for the heat required to convert solid B₂O₃ at 0° K to gaseous B₂O₃ at 1500° K listed in reference 29 as 106.065 (kcal/mole) was used to compute the value of (H_{1500}°)_{B₂O₃(g)}. The values of (S_{1500}°)_{B₂O₃(g)} and ($H_{1500}^\circ - H_0^\circ$)_{B₂O₃(g)} were taken from reference 29. The remaining values of enthalpy and entropy were computed by integration of the specific-heat data.

Cl₂ and HCl.—The C_p° data for Cl₂ and HCl from 1000° to 6000° K were taken from unpublished data obtained at the Jet Propulsion Laboratory of the California Institute of Technology.

ClF, F, and F⁻.—Recent spectroscopic and thermochemical measurements on compounds of fluorine (reference 42)

have indicated that the values of the heat of formation of ClF, F, and F⁻ are considerably less than the values given in reference 18. In a communication in May 1949, Dr. F. D. Rossini of the National Bureau of Standards listed their best current estimate for the heat of formation of ClF and F as -13.2 and 17.8 (kcal/mole), respectively. In accordance with these new values, the value of the heat of formation of F⁻ has been recalculated from data in reference 18.

HF.—The values of C_p° , $H_T^\circ - H_0^\circ$, and S_T° for HF at 298.16° K, 600° K, and every 1000° from 1000° to 6000° K were computed from spectroscopic data given in reference 36 using the accurate summation process. Intermediate values of C_p° were interpolated. Subsequent to the completion of computations for this substance, new spectroscopic data were made available by Dr. A. H. Nielsen of the University of Tennessee. Values of C_p° , $H_T^\circ - H_0^\circ$, and S_T° at 5000° K computed with these data differ from values herein by 1 percent for C_p° , 0.2 percent for $H_T^\circ - H_0^\circ$, and 0.03 percent for S_T° .

e⁻, F⁻, and Li⁺.—The use of metals with low ionization potentials introduces the possibility of the formation of appreciable quantities of ionized products. Because the partial pressure of ions is expected to be small, the zero-pressure properties of electron gas e⁻ have been tabulated from reference 38. The properties of F⁻ have been computed on the assumption that only the ground electronic state is stable. (See reference 43, p. 218.) The contributions of all energy levels above the ground level to the thermodynamic functions of Li⁺ are negligible. The value of C_p° tabulated for all these substances is $\frac{5}{2} R$.

Li.—In computing the thermodynamic functions of Li, the summation was carried over the first five energy levels.

LiF.—Spectroscopic data for LiF gas were not found in the literature. A vibrational frequency for the ground state of 1343 (cm⁻¹) and a moment of inertia $I_0 = 15.415 \times 10^{-40}$ (gm)(cm²) were graphically estimated from a plot of force constants against difference in atomic number of the two elements composing the substances NaH, C₂, and BeO, each substance of which is isoelectronic with LiF. It is expected that the anharmonicity constant for LiF is sufficiently large to increase materially the computed value of the specific heat. The uncertainty in the value of the enthalpy and the entropy is estimated to be ± 10 percent at 5000° K.

LiH.—Spectroscopic data for Li⁷H¹ given in reference 26 were modified for the normal isotopic mixture LiH using relative abundance percentages of isotopes and atomic weights given in reference 44 (pp. 163 and 188, respectively). The value obtained for the vibrational frequency of the ground state of LiH is 1360.37 (cm⁻¹) and for the moment of inertia is 3.77246×10^{-40} (gm)(cm²).

H₂O(s), N₂(s), and O₂(s).—The heat required to heat solid H₂O, N₂, and O₂ from 0° to 298.16° K in the natural state was taken from reference 37.

New data.—Subsequent to the completion of the computation for H₂, new values for C_p° , internal energy $E^\circ - E_0^\circ$, and S_T° were published in reference 45 and differ from the values in this report at 5000° K by 0.5 percent for C_p° , 0.1 percent for $H_T^\circ - H_0^\circ$, and 0.02 percent for S_T° .

TABLES OF THERMODYNAMIC PROPERTIES

The values of the functions of the 42 substances are given in tables IV to XLV at 298.16° K and every 100° from 300° to 6000° K together with interpolation coefficients for $-\Delta H^\circ/RT$ and $\log K$ at every 100° from 1000° to 6000° K.

LEWIS FLIGHT PROPULSION LABORATORY,
NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS,
CLEVELAND, OHIO, January 26, 1950.

APPENDIX—SYMBOLS

The following symbols are used in this report:

A	number of formula weights of reactants
$a, b, \dots$	summation of each atomic type over products of reaction per equivalent formula; with subscript, number of atoms of each element within chemical formula; in thermodynamic tables, interpolation coefficients
C_p°	molar specific heat at constant pressure and standard conditions (cal/(mole) (°K))
C', C''	specific heat coefficient for matrix
C_v°	molar specific heat at constant volume and standard conditions
D	operator $\left(\frac{\partial \log}{\partial \log T}\right)_i$
E_T°	molar internal energy at standard conditions
e	internal energy per equivalent formula
F_T°	molar free energy at standard conditions
g	gas phase of substance
H_0°	chemical energy at 0° K and standard conditions (kcal/mole)
H_T°	sum of sensible enthalpy and chemical energy at temperature T and standard conditions (kcal/mole)
$H_T^\circ - H_0^\circ$	sensible enthalpy at temperature T and standard conditions (kcal/mole)
$\frac{\Delta H^\circ}{RT}$	enthalpy change due to formation of substance from its elements in atomic gas state divided by RT
ΔH_f°	enthalpy change due to formation of substance from its elements in standard state (kcal/mole)
h	enthalpy per equivalent formula
h', h''	enthalpy coefficient for matrix
h^*	sum of heat and kinetic energies per equivalent formula
hc/k	ratio of Planck's constant times velocity of light to Boltzmann's constant, 1.43847 (cm) (°K)
I	moment of inertia (gm) (cm ²)
J	dimensional constant
K	equilibrium constant
liq	liquid phase of substance
M	Mach number
M_r	molecular weight of equivalent formula
m	mass flow per second
N	number of products of reaction

n	number of moles
P	total pressure
p	partial pressure
Q	any function
q, r	any variables; with subscript, matrix symbol for $\frac{\Delta H}{RT}$
R	universal gas constant, 1.98718 (cal/(mole) (°K))
S_T°	molar entropy at standard conditions (cal/(mole) (°K))
s	entropy per equivalent formula; in thermodynamic tables, solid phase of substance
s'	entropy coefficient for matrix
T	temperature (°K)
t	throat area
U_m, U_k	unit matrix
u	velocity of sound
V	volume
v	velocity of flow
$Z, Y, \dots$	elements within representative chemical formula
x	correction variables
$\alpha_1, \alpha_2, \dots$	submatrices
Δ	increment
δ	increment due to a temperature change; with subscript, error parameter
ϵ	total-error parameter
$\nu_1, \nu_2, \nu_3(2)$	spectroscopic constants
$\nu_4(2)$	
$\omega_e, \omega_e x_e$	spectroscopic constants
ρ	density
Subscripts:	
$a, b, \dots$	number of atoms within chemical formula
f	fuel
g	oxidant
l	any point in nozzle
m	number of types of gaseous molecule
o	initial given condition
P	constant pressure
s	constant entropy
T	temperature (°K)
$\dots Y, Z$	product index numbers (i) that designate atomic gases
$1, 2, \dots, i, \dots N$	product index number

* Specific heat, enthalpy, and entropy at 298.16° and every 100° from 300° to 1000° and specific heat for each 100° from 1000° to 6000° K were computed from spectroscopic data given in reference listed by accurate summation method.

^b Data from selected values of National Bureau of Standards issued undated but prior to June 30, 1948.

^c Graphically smoothed.

^d Extrapolated.

^e Specific heat, enthalpy, and entropy at 298.16° and every 100° from 300° to 1000° and specific heat for each 100° from 1000° to 6000° K were computed from spectroscopic data by rigid rotator-harmonic oscillator approximation.

^f See discussion in text.

^g Interpolated.

^h Computed with aid of data in reference listed.

ⁱ Unpublished data from Battelle Memorial Institute also used.

TABLE XVI—THERMODYNAMIC PROPERTIES OF BH (GAS)

[Molecular weight, 11.828]

T (°K)	C_p ($\frac{\text{cal}}{\text{mole} \cdot ^\circ\text{K}}$)	$H_T^\circ - H_0^\circ$ ($\frac{\text{kcal}}{\text{mole}}$)	H_T° ($\frac{\text{kcal}}{\text{mole}}$)	S_T° ($\frac{\text{cal}}{\text{mole} \cdot ^\circ\text{K}}$)	$\frac{\Delta H^\circ}{RT}$	$\delta \left(-\frac{\Delta H^\circ}{RT} \right) = \frac{-\delta T}{100} \left(\frac{a}{T} + b \right)$		$\log K$	$\delta \log K = \frac{-\delta T}{100} \left(\frac{c}{T} + d \right)$

TABLE XXIII—THERMODYNAMIC PROPERTIES OF CO₂ (GAS)

[Molecular weight, 44.010]

T (°K)	C_p ($\frac{\text{cal}}{\text{mole} \cdot ^\circ\text{K}}$)	$H_f^\circ - H^\circ$ ($\frac{\text{kcal}}{\text{mole}}$)	H_f° ($\frac{\text{kcal}}{\text{mole}}$)	S_f° ($\frac{\text{cal}}{\text{mole} \cdot ^\circ\text{K}}$)	$\frac{\Delta H^\circ}{RT}$	$\delta \left(\frac{-\Delta^\circ H}{RT} \right) = \frac{-\delta T}{100} \left(\frac{a}{T} + b \right)$		$\log K$	$\delta \log K = \frac{-\delta T}{100} \left(\frac{c}{T} + d \right)$

REPORT 1038

WIND-TUNNEL INVESTIGATION OF AIR INLET AND OUTLET OPENINGS ON A STREAMLINE BODY¹

By JOHN V. BECKER

SUMMARY

In connection with the general problem of providing air flow to an aircraft power plant located within a fuselage, an investigation was conducted in the Langley 8-foot high-speed tunnel to determine the effect on external drag and pressure distribution of air inlet openings located at the nose of a streamline body. Air outlet openings located at the tail and at the 21-percent and 63-percent stations of the body were also investigated. Boundary-layer transition measurements were made and correlated with the force and the pressure data. Individual openings were investigated with the aid of a blower and then practicable combinations of inlet and outlet openings were tested. Various modifications to the internal duct shape near the inlet opening and the aerodynamic effects of a simulated gun in the duct were also studied.

The results showed that the external drag (measured drag less computed drag due to internal duct losses) of the body with suitably designed nose-inlet and tail-outlet openings was no higher than the drag of the streamline body over a wide range of rates of internal air flow. The static-pressure distribution with the best inlet profiles developed during the investigation was almost identical with that of the corresponding portion of the streamline body. As a consequence, the same favorable laminar-boundary-layer flow as on the streamline body was obtained. The local velocity increments over the nose profiles were so low that the critical speed of a fuselage employing these shapes would depend on the peak-velocity increments occurring elsewhere than on the nose.

The results of the tests suggested that outlet openings should be designed so that the static pressure of the internal flow at the outlet would be the same as the static pressure of the external flow in the vicinity of the opening. Radical changes in the internal-duct arrangement near the inlet openings had little effect on the external drag or pressure distribution.

INTRODUCTION

Various wind-tunnel tests of full-scale airplanes and of airplane models have shown large external losses associated with the power-plant installations. The external drag of clean NACA cowlings with no protruding scoops or surface irregularities was shown in reference 1 to be considerable. At high speeds, prohibitive increases in the

external drag may occur as a result of the formation of compression shocks on cowlings (reference 2) or protruding scoops. The excessive cowlings drag costs at high speeds can be reduced to some extent by reducing the bluntness of the nose profile (reference 2); however, the improvement which can be made in this direction is limited for conventional installations in which the engine is located at the nose of the fuselage. If it is assumed that the engine is located near the center of the fuselage or nacelle, then radical changes in the shape of the nose are possible. The present investigation was designed to explore the possibilities of high-speed drag reduction by use of nose inlets proportioned solely from aerodynamic requirements without any restrictions arising from engine dimensions, location, or air-flow requirements.

At the outset of the present investigation little information was available in regard to the characteristics of inlet openings at the nose of a streamline body. Previous tests had been made without air flow into the openings, a condition seldom occurring in practice, and the results were therefore inconclusive. Little pressure-distribution or critical-speed data were available, and it was not known whether any appreciable laminar boundary layer could exist behind an inlet opening.

The principal purpose of this investigation was to develop nose-inlet openings of various relative sizes which would have the lowest possible external drag and the highest possible critical compressibility speed. The air-inlet flow rates used were not restricted to the relatively small requirements of radial engines but were varied from zero flow to inlet-velocity ratios in excess of unity. Pressure-distribution and boundary-layer data were obtained to aid in interpreting the drag results and to permit the estimation of the critical speeds. Typical annular and tail-outlet openings were similarly investigated. In order to avoid possible confusing interference effects, the inlet and the outlet openings were tested separately with the internal air flow being supplied through wing ducts from a blower located outside of the wind tunnel. Representative combinations of the inlet and outlet openings were then tested without the use of the blower. The effects on external drag of a protruding simulated gun in the inlet opening and of various internal-duct arrangements near the nose were also included in the investigation of the individual inlet openings.

¹ Supersedes NACA ACR, "Wind-Tunnel Tests of Air Inlet and Outlet Openings on a Streamline Body" by John V. Becker, November 1940.

The external drag cost of an inlet opening at the nose of a smooth streamline body is generally greater at low Reynolds numbers, when the opening may disturb extensive low-drag laminar boundary layers, than at high-speed flight Reynolds numbers, where the boundary-layer flow may be almost wholly turbulent. Although it was impossible to attain full-scale conditions in this investigation, the boundary-layer-flow condition corresponding to high Reynolds numbers was simulated by artificially forcing transition to take place near the nose of the models. The tests were made both with the natural-transition and the fixed-transition boundary-layer conditions. The results thus show the effect of the openings at conditions corresponding to extremes of the Reynolds number range.

SYMBOLS

V	free-stream velocity
p_0	free-stream static pressure
ρ_0	free-stream density
q_0	free-stream dynamic pressure $\left(\frac{1}{2} \rho_0 V^2\right)$
v	mean velocity in duct
p	local static pressure
ρ	density in duct
V_i	initial velocity of air passing through duct
V_w	hypothetical final velocity of air passing through duct based on total pressure at discharge
A	cross-sectional area of inlet or outlet opening
d	diameter of inlet or outlet opening
D	maximum diameter of streamline body
F	maximum cross-sectional area of streamline body
L	length of streamline body
l	distance between end of streamline body and end of nose
R	maximum radius of streamline body
R	fuselage Reynolds number (VL/ν)
ν	kinematic viscosity
P	pressure coefficient $((p - p_0)/q_0)$
a	velocity of sound in air
M	Mach number (V/a)
Q	volume of flow through duct, cubic feet per second
α	angle of attack referred to center line of streamline body, degrees
C_{D_F}	external-drag coefficient

y'	nose-profile ordinate measured from inlet-opening radius
Y	value of y' at $L/4$ station

APPARATUS AND METHODS

The tests were made in the Langley 8-foot high-speed tunnel in its original form incorporating an 8,000-horsepower drive motor. The tunnel was of the closed-throat, circular-section, single-return type and was capable of air speeds of about 500 miles per hour at the time of these tests. This tunnel was chosen for the investigation principally because of the low turbulence of the air stream, which permitted the boundary-layer-flow conditions more nearly to approach those obtained in free air than in streams of high turbulence. Most of the tests were run at low speed (140 miles per hour).

Streamline body.—The streamline body (fig. 1 and table I) is a slightly modified version of fuselage form No. 111 of reference 3. The thickness distribution was modified slightly to eliminate the unfavorable pressure gradient occurring ahead of the 50-percent station of the original 111 form. This modification was made to encourage a more extensive laminar boundary layer. The fineness ratio of 5 is representative of several current pursuit-type fuselages.

The streamline body was mounted in the wind tunnel on a 24-inch-chord airfoil of NACA 27-212 section, which completely spanned the jet (fig. 2). The wing contained two large ducts to permit air to be supplied to or drawn from the openings on the body. The ratio of wing chord at the body to the length of the body is within the range of current practice.

Inlet openings.—Nose-inlet openings of three sizes were tested (figs. 1 and 3; ordinates in table I). The largest opening, nose A, was approximately the size, relative to the maximum cross section of the body, of average NACA cowling

FIGURE 1.—Streamline body with general arrangement of inlet and outlet openings

FIGURE 2.—Model installed in Langley 8-foot high-speed tunnel. Nose B.

FIGURE 3.—Nose inlet openings compared with streamline nose.

inlet openings. Nose B had one-half the area of nose A, and nose C, one-quarter the area of nose A. The profile shapes of the noses were developed in a series of tests (not discussed in detail in this report) in which the nose lengths and profiles were progressively modified until the most satisfactory pressure-distribution characteristics were obtained. The profiles all fall within the profile of the streamline body. It will be noticed that the nose ordinates (table I) are given only to the quarter-length station. Beyond this point, streamline-body ordinates apply. Several modifications of the straight duct (fig. 1) that was used in most of the nose-inlet tests will be described later in the discussion of the results.

Outlet openings.—Outlet openings at the tail and annular outlets located ahead of and behind the wing were investigated (figs. 1, 4, and 5). The tail-outlet profiles coincide with the streamline-body lines. Various tail-outlet areas were obtained by successively decreasing the length of the body. The internal duct was of converging section to represent typical practice in the design of outlet openings. The annular outlet openings were designed primarily to exhaust the air as nearly as possible in the stream direction. The

FIGURE 4.—Typical tail outlet opening. Tail C.

FIGURE 5.—Annular outlet opening at $x=0.63L$.

areas were selected from consideration of the quantity of air required by a radial engine large enough to occupy the maximum section of a fuselage. The outlet openings are not in any sense optimum shapes arrived at on the basis of experiment as in the case of the inlet openings; they merely represent typical design practice.

Blower setup.—Air flow in the tests of the individual openings was supplied by a 50-horsepower centrifugal blower mounted outside the wind tunnel on the floor of the test chamber (figs. 6 and 7). Freedom of the floating balance structure was maintained by a mercury seal that connected the blower duct to the wing duct leading to the model. The air flow through the mercury seal was at right angles to the longitudinal (drag) axis of the wind tunnel so that the flow had no momentum in the drag direction. Preliminary tests were made throughout the range of blower speeds at zero air speed in the tunnel, with and without air inlet, to insure that the pressures and flow at the mercury seal had no effect on the drag scale readings.

The flow was metered by a venturi installed on the balance ring between the mercury seal and the model. Several calibrations were made with the venturi in its operating position by surveying the flow in the duct with a rake of 25 total-pressure and 7 static tubes.

FIGURE 6.—Schematic diagram of setup for tests with blower.

FIGURE 7.—General view of blower setup in the test chamber of the Langley 8-foot high-speed tunnel.

The flow in the system was controlled either by regulating the blower speed or by adjusting a butterfly valve. The zero flow condition was obtained by closing a special airtight valve located near the end of the wing duct. Utmost care was taken to prevent leakage in the system.

Inlet-outlet combinations.—The combinations tested and the internal-duct arrangement are shown in figure 1. The wing-duct openings within the body were faired over and sealed to prevent leakage. Flow regulation was accomplished by means of perforated plates of various conductance installed as shown in figure 2. Static-pressure orifices were installed at two stations in the converging section of the duct ahead of the outlet openings. The flow quantity was determined from the magnitude of the pressure drop between these stations according to a calibration obtained during the tests of the individual outlet openings with the blower-venturi setup. The total pressure and the static pressure at the outlet were determined from this same calibration. In several cases, as a check on the calibration, the quantities were measured directly by means of a small pitot-static tube mounted in the outlet opening.

No particular attempt was made to design an efficient internal-duct system because interest was centered on the external drag and because the blower was more than adequate to overcome large internal losses. However, in the combination tests with the duct open—that is, with no resistance plates inserted to restrict the flow—the internal losses were practically negligible owing to the low duct velocities.

Method of fixing boundary-layer transition.—Transition in the tests designated “with fixed transition” was fixed artificially by means of a $\frac{1}{4}$ -inch wide ring of No. 180 carborundum grains glued to the surface at the desired station. It was found necessary to fix transition on the wing at the 10-percent station by the same method in order to make the drag of the wing constant so that the effective drag of the body could be obtained accurately.

Except for the strips of carborundum, the surfaces of the model were made aerodynamically smooth—that is, further conditioning would result in no decrease in drag.

Static-pressure measurement.—Flush orifices, closely spaced near the nose and in the vicinity of the openings, were installed along the top of the body. Additional static pressures on the bottom and on the side of the streamline body were obtained by means of a small movable static tube. The pressure tubing was led through a channel in the wing to a multiple-tube alcohol manometer in the test chamber.

Boundary-layer measurements.—The measurement of the boundary-layer profiles used in determining the transition point and in showing the effect on skin friction of air inlet was made with small survey units comprised of a single static and four total-pressure tubes. A discussion of the details of the method of determining the location of transition and a description of the small survey unit are given in reference 4.

Wake surveys.—In order to ascertain whether the drag-force measurements were affected by possible variations in the wind-tunnel pressure gradient due to air inlet at the nose, momentum-loss measurements were made in the wake behind the model with nose B. Vertical total-pressure-loss

profiles were obtained at 23 spanwise stations behind the wing and body at several rates of air inlet. The effective drag of the body was obtained by subtracting from the total drag of the section surveyed the drag of a corresponding section of the wing. The wake surveys were made only with nose B.

TESTS

The drag and the pressure-distribution measurements were made simultaneously. The transition determinations required a separate series of runs for each configuration.

Tests of the wing alone and of the wing with the streamline body were carried to 450 miles per hour. The tests of the openings were made at one speed only: 140 miles per hour. This speed was selected from considerations of the available blower performance and of the magnitude of the drag forces required for adequate precision.

The tests were made at an angle of attack of 0° (referred to the axis of the streamline body) with the exception of the runs with the gun in the inlet opening of nose B, which were carried to 3.5° .

RESULTS

The method of computing the velocity, the Mach number, and the Reynolds number in the Langley 8-foot high-speed tunnel is described in reference 5.

The drag data are presented in terms of the external-drag coefficient C_{D_F} plotted as a function of the internal-flow quantity coefficient $\rho Q/\rho_0 FV$. The external-drag coefficient represents the effective external drag of the body in the presence of the wing; the drag due to the internal flow was deducted from the measured effective body drag in all the tests.

The drag due to the internal flow arises from the change in the momentum of the flow in the drag direction. From the momentum equation,

$$\text{Drag force} = \text{Mass flow} \times (V_i - V_w)$$

where V_i and V_w are taken at the same static pressure and in the same direction as the air stream.

For the inlet-opening tests,

$$V_i = V$$

and

$$V_w = 0$$

because the air was brought to rest in the drag direction. The drag-coefficient increment due to the internal flow therefore is

$$C_{D_{F_{i_{inlet}}}} = \frac{\rho Q V}{q_0 F} = 2 \left(\frac{\rho Q}{\rho_0 F V} \right)$$

For the outlet-opening tests, the air exhausted through the outlets had no initial velocity in the drag direction—that is, $V_i = 0$. The velocity at the exit opening v_e was necessarily measured where the static pressure p_e was generally different from the stream static pressure. Therefore the final outlet velocity attained at some distance behind the model where the pressure had returned to the free-stream static pressure

p_0 was computed by Bernoulli's theorem

$$V_w = \left[v_e^2 + \frac{2(p_e - p_0)}{\rho_0} \right]^{1/2}$$

and

$$C_{D_{F_{i_{outlet}}}} = -\frac{\rho Q}{q_0 F} \left[v_e^2 + \frac{2(p_e - p_0)}{\rho_0} \right]^{1/2}$$

or

$$C_{D_{F_{i_{outlet}}}} = -2 \left(\frac{\rho Q}{\rho_0 F V} \right) \left[\left(\frac{v_e}{V} \right)^2 + \frac{(p_e - p_0)}{q_0} \right]^{1/2}$$

For the tests in which inlet-outlet combinations were investigated,

$$C_{D_{F_{i_{combination}}}} = C_{D_{F_{i_{inlet}}}} + C_{D_{F_{i_{outlet}}}}$$

whence

$$C_{D_{F_{i_{combination}}}} = 2 \left(\frac{\rho Q}{\rho_0 F V} \right) \left\{ 1 - \left[\left(\frac{v_e}{V} \right)^2 + \frac{(p_e - p_0)}{q_0} \right]^{1/2} \right\}$$

or, in terms of the mean total-pressure loss in the duct ΔH ,

$$C_{D_{F_{i_{combination}}}} = 2 \left(\frac{\rho Q}{\rho_0 F V} \right) \left[1 - \left(1 - \frac{\Delta H}{q_0} \right)^{1/2} \right]$$

It will be observed from these equations that the large internal drag in the inlet tests and the thrust in the outlet tests are balanced in the combination tests, so that only a relatively small internal drag due to total-pressure losses in the duct occurs.

The internal flow quantity coefficient $\rho Q/\rho_0 FV$ appearing in the equations is the ratio of the mass flow through the internal ducts to the mass flow at stream velocity through the area F , the maximum cross-sectional area of the body.

The pressure-distribution results obtained in the tests of the individual inlet and outlet openings are presented for a number of values of the ratio of mean velocity in the opening to stream velocity v/V . This parameter determines the local angle of attack at the inlet nose lip and hence governs the pressure distribution over a given nose shape.

The characteristics of the streamline body are shown in figures 8 to 11. Low-speed pressure-distribution data are given in figure 8, and the variation with Mach number of the peak pressure coefficients P_{max} on top of the body for the wing-body combination is presented in figure 9 with extrapolations to show the critical Mach number of the combination and of the body alone. The variation with Mach number of the critical pressure coefficient P_{cr} , the pressure coefficient corresponding to the local attainment of sonic velocity, is also shown in figure 9. Figure 10 shows the results of the transition measurements, and in figure 11 the force-test results, for Reynolds numbers ranging from 4,000,000 to 20,000,000 and the corresponding M values of 0.10 to 0.60 are given.

The results of the tests of the inlet openings with the inlet air exhausting through the external-blower system are presented in figures 12 to 21. Figure 12 shows the pressure distributions about the three inlet openings for various values of v/V (ratio of mean inlet velocity to stream velocity) compared with the streamline-body distribution. Only the

FIGURE 8.—Measured static-pressure distribution about streamline body mounted on NACA 27-212 airfoil compared with theoretical distribution on wing alone and body alone. $M=0.18$; $R=7.6 \times 10^6$.

FIGURE 9.—Variation with Mach number of peak pressure coefficient on top of streamline body. Comparison with theory.

forward quarter of the body is represented because the pressures over the remainder of the body were essentially unaffected by the inlet openings. In figure 13 the pressure distributions on the bodies with noses A, B, and C and on the streamline body are compared at the condition of zero inlet flow and at a flow coefficient of 0.057, a practicable high-speed value. The inlet-velocity ratios corresponding to this flow coefficient are approximately 0.20, 0.40, and 0.80, respectively, for noses A, B, and C.

The drag and the transition results obtained are correlated in figure 14. Figure 15 shows the drag-force data obtained with transition artificially fixed near the leading edge of the noses as compared with that of the streamline body with transition fixed at corresponding locations. The drag obtained from the wake surveys is also plotted in figure 15.

FIGURE 14.—Correlation of external-drag coefficient and transition-point location for the three nose inlet openings.

FIGURE 16.—Typical static-pressure distribution diagram for nose-inlet openings B and C at low rates of air inlet.

FIGURE 17.—Boundary-layer velocity profiles at two stations for various air-inlet velocity ratios, and the corresponding diagrams of local velocity distribution over the top of the body. Nose B; fixed transition.

In the correlation of the pressure distribution and the transition data, it was found that for values of ΔP (fig. 16) greater than approximately 0.2, transition (fig. 14) occurred at the location of the pressure peak. For lower values of ΔP (higher rates of air inlet), extensive laminar boundary layers existed in spite of the large adverse pressure gradient that followed the peak.

The effect of air inflow (nose B) on the boundary-layer velocity profiles at two stations on the body is shown in figure 17.

In figure 18 the changes in pressure distribution resulting from modifications of the lip shape of nose inlet B-4 (one of the intermediate shapes tested in developing nose B) are given. The force-test results obtained with these modifications showed that shapes B-4a and B-4b caused very slight

FIGURE 18.—The effect on static-pressure distribution of variations in nose shape at the duct entry. $\frac{v}{V} = 0.30$.

FIGURE 19.—Nose C with conical expanding duct and with inner cowl.

increases in external drag; the cut-out, B-4c, had no effect on the drag. Major changes in the internal duct employed with nose C (fig. 19) had no measurable effects on either the external pressure distribution or the external drag.

Optimum nose shapes for arbitrary inlet-duct sizes.—In order to make possible the derivation of optimum nose profiles for inlet-opening sizes other than those investigated, the three nose profiles tested were reduced to the same length

FIGURE 20.—Comparison of the three inlet-opening nose profiles reduced to the same length and depth.

FIGURE 21.—Variation with duct diameter of the distance between the end of the nose and the tip of the streamline body.

(measured from the $L/4$ station of the streamline body) and the same depth. The ordinates thus obtained are given in table II and plotted in figure 20. The marked similarity of the profiles plotted in this way suggested that optimum nose shapes for intermediate inlet-opening sizes on the streamline body could be obtained either by interpolation or by the use of the mean of the three profiles of figure 20. The optimum nose length as a function of the inlet-opening diameter is given in figure 21. The actual nose-profile ordinates for a given inlet diameter are related to the nondimensional ordinates of figure 20 and table II as follows:

$$x' = \left(\frac{x'}{X} \right) X$$

or

$$x' = \left(\frac{x'}{X} \right) \left(\frac{L}{4} - l \right)$$

where l is obtained from figure 21. Similarly,

$$y' = \left(\frac{y'}{Y} \right) \left(y_{L/4} - \frac{d}{2} \right)$$

where y_{LA} is the ordinate of the streamline body at the quarter-length station. If desired, the nose ordinates referred to the end and center line of the streamline body (as in table I) may be obtained from the relations

$$\frac{x}{L} = \frac{x'}{L} + \frac{l}{L}$$

and

$$\frac{y}{R} = \frac{y'}{R} + \frac{d}{D}$$

or

$$\frac{x}{L} = \left(\frac{x'}{X}\right) \left(0.25 - \frac{l}{L}\right) + \frac{l}{L}$$

and

$$\frac{y}{R} = \left(\frac{y'}{Y}\right) \left(0.90 - \frac{d}{D}\right) + \frac{d}{D}$$

The results obtained in the tests of the outlet openings with air supplied by the blower are shown in figures 22 to 26. Figures 22 and 23 show the pressure and force-test results for outlets at the tail. Transition measurements with the largest tail outlet showed that transition occurred at the same station as on the streamline body (fig. 10). The pressure distribution obtained with the two annular outlets is shown in figure 24. Force-test results for the 63-percent annular outlet are given in figure 25. Transition measurements with the 21-percent annular outlet showed that transition occurred at the outlet for all rates of flow. The 63-percent

FIGURE 22.—The static-pressure distribution on the afterbody with a typical tail outlet. Tail D.

annular outlet was about $0.14L$ behind the most rearward position of the transition point but appeared to have a slight influence on the transition location, such that the location was displaced somewhat toward the tail as the flow rate was increased.

Figure 26 shows a sketch of the probable outlet flow conditions with tail outlet D and with a suggested improved form of tail outlet.

Before the results of the inlet-outlet combination tests are presented, figure 27 is given in order to show the relatively small internal drag occurring in the combination tests. At high flow rates, where no internal resistance plate was required, this internal drag approached zero; whereas in the individual opening tests the internal drag was several times the external drag of the body. The external-drag determinations in the combination tests were consequently more reliable than in the tests of the single openings.

Figures 28 to 32 show the drag results obtained for the combinations of inlets with three tail outlets. Figure 33 compares the drag of the 63-percent annular outlet with that of tail outlet C when tested in combination with nose B.

The pressure-distribution results obtained with the combinations are not shown because no consistent measurable interference effects occurred—that is, the outlets had no appreciable effects on the pressures at the inlets and vice versa. Similarly, the transition locations on the combinations were the same as in the tests of the inlet openings alone.

In figure 34 the drag of the nose B and tail C combination is compared with an estimate of the drag based on the tests of the single openings. The drag increments (above the streamline-body drag) due to nose B and tail C were added to the streamline-body drag in making the estimate.

FIGURE 23.—Variation with flow coefficient of the external-drag coefficient obtained with the tail outlet openings. Fixed transition on nose.

FIGURE 24.—The static-pressure distribution with annular outlet openings.

The main increase in drag due to the guns (table III) occurred at angles of attack other than zero as a result of partial separation of the external flow at the top of the nose as evidenced by the pressure-distribution plots (fig. 35). Increasing the rate of air inlet had a beneficial effect in reducing or preventing this separation. The smooth-barrel cannon had considerably less drag than the machine gun (sketched in fig. 35). Decreases in the length of the barrel extending beyond the nose resulted in appreciable drag reductions. It has been found that the drag of a smooth-barrel gun was considerably reduced by replacing the sharp edge at the muzzle

FIGURE 25.—Variation with flow coefficient of the external-drag coefficient obtained with the annular outlet opening at the 63-percent station.

FIGURE 26.—Sketch of flow conditions (no internal losses) for a tail outlet opening, similar to those tested, and for a suggested improved type.

of the gun with a rounded edge of small radius. It is considered likely that the unfavorable effects of the guns would be somewhat less in the high Reynolds number (fixed transition) condition than shown in table III, because no drag would result from disturbance of the laminar flow.

PRECISION

The accuracy of the body-drag determinations was somewhat impaired by the high drag of the wing with fixed transition relative to the body drag, the effective body drag varying from about 0.5 to 0.3 of the wing drag. In the tests of the individual openings, additional sources of error were the leakage of air in the external ducts and possible changes in the tunnel-pressure gradient due to the removal or the

FIGURE 27.—Comparison of magnitude of total body drag with internal drag in typical tests of individual openings and of a combination of an inlet and an outlet opening.

addition of air to the tunnel stream. The results obtained with the inlet-outlet combinations, however, are believed free of these two sources of inaccuracy because no air was added or removed from the tunnel and no leakage was likely due to the absence of all external ducts. A buoyancy correction of about 10 percent of the effective body drag was applied to all of the force-test results.

The wake measurements are more nearly free of these sources of error that affect the force tests. Evaluation of the possible magnitude of the drag-test errors will be made in the discussion of the results.

The precision of measurement of the rate of internal air flow is considered to be of a high enough order so that the external-drag determinations are practically unaffected by the small error in obtaining the internal drag, except possibly in the case of the individual opening tests at the highest rates of air flow. Repeated calibrations of the venturi during the tests showed excellent agreement.

The only significant sources of error in the pressure data are due to the inaccuracy of flow measurement and the

FIGURE 28.—Variation with flow coefficient of the external-drag coefficients for nose inlet opening A combined with various tail outlet openings.

tunnel-wall effects. The maximum possible change in the pressure coefficients due to the tunnel-wall effects was computed to be only about 3 percent. Possible errors in flow measurement could cause measurable changes in pressure coefficients only at the lowest inlet-velocity ratios.

DISCUSSION

STREAMLINE BODY

Pressure distribution and transition.—The presence of the wing had a pronounced effect on the pressure distribution over the body (fig. 8). The local velocities over the central portion were increased and the peak-pressure point was moved forward. At low Reynolds numbers the disturbances due to the wing controlled the location of transition on the body. (See sketch in fig. 10.) There was a rapid forward movement of the transition point with Reynolds number so

FIGURE 29.—Variation with flow coefficient of the external-drag coefficients for nose inlet opening B combined with various tail outlet openings.

that at the highest test Reynolds number transition occurred considerably ahead of the leading edge of the wing (fig. 10). If a similar forward movement of transition with Reynolds number should occur under flight conditions, the extent of laminar flow obtainable at full-scale Reynolds number would be slight.

Critical speed.—The variation with the Mach number of the peak pressure coefficient on top of the body (fig. 9) was found to agree well with the theoretical variation (obtained from reference 6). Extrapolations of the low-speed, peak negative pressure coefficients to the critical pressure coefficient (at which the speed of sound is attained locally) were made according to the theory. The critical Mach number

FIGURE 30.—Variation with outlet velocity ratio of the external-drag coefficients for nose B combined with various tail outlet openings. Fixed transition.

of the streamline body alone was thus found to be 0.84 (fig. 9), which corresponds to 600 miles per hour at 20,000 feet (-12° F) in standard air. The critical speed of a wing-body combination is considerably less than that of either component, owing to the increase in peak negative pressures on the wing due to the presence of the body. (See reference 6.)

Effective body drag.—Figure 11 shows the large differences in drag at low Reynolds numbers between the fixed and the natural transition conditions. Calculations based on flat-plate skin-friction coefficients showed that these differences are wholly accounted for by the changes in skin friction on the body. The difference decreases with increasing Reynolds number due to the forward movement of the transition point (fig. 10). The rise in the drag coefficient at the high Mach numbers is indicative of the approaching critical speed of the wing-body combination (estimated $M_{cr}=0.66$). Comparison of the magnitude of the low-speed drag coefficients with the results obtained in reference 3 for the NACA 111 form indicated that the flow over the body was satisfactory. Tuft surveys corroborated this conclusion. It was found, however, that the addition of the body to the wing caused a local separation of the flow at the trailing edge of the wing. The effective drag of the body was therefore somewhat higher than it would have been had a more efficient wing-body juncture been employed.

NOSE-INLET OPENINGS

Pressure distribution.—The nose-inlet shapes employed in this investigation were developed in a series of tests in which the nose shape and the length for a given inlet size were progressively modified to obtain the most satisfactory drag and pressure-distribution characteristics. It was found that by taking air into the body at sufficiently high velocities the

FIGURE 31.—Variation with flow coefficient of the external-drag coefficients for nose inlet opening C combined with various tail outlet openings.

high negative-pressure peak which occurred over the noses at low flows could be greatly reduced in magnitude; for the smaller inlet sizes, the peak could be entirely eliminated. This result has the obvious beneficial effect of greatly increasing the critical compressibility speed which, as in the case of NACA cowling installations (reference 2), is generally fixed by the magnitude of the peak-negative pressures at the nose. In addition, it was found that laminar boundary layers as extensive as the ones with the streamline nose could be obtained. The design objectives then aimed at in developing noses B and C were to eliminate the pressure peak at as low an inlet-velocity ratio as possible and to obtain a uniform favorable pressure gradient similar to that of the streamline

FIGURE 32.—Comparison of the external-drag coefficients of the three nose-inlet openings tested with tail outlet opening C.

body. Figures 12 (b) and 12 (c) show that the desired results were achieved when the inlet-velocity ratios reached or exceeded 0.3 or 0.2 for noses B and C, respectively. Extensive laminar boundary layers (fig. 14) were formed even before the peak was fully eliminated with values of ΔP (fig. 16) as high as 0.2.

For the largest inlet opening, nose A, it was impossible entirely to eliminate the pressure peak, even with impractically high rates of air inlet (fig. 12 (a)). The peak was greatly reduced at practical inlet velocities but little advantage due to laminar flow was attainable (fig. 14).

Comparison of the pressure distribution of the streamline body with those for the three noses is made in figure 13 at a

FIGURE 33.—Comparison of the external-drag coefficients of tail outlet C and the annular outlet at the 63-percent station of the fuselage. Nose B.

value of the flow coefficient corresponding to high-speed flight conditions and at zero flow.

Critical speeds.—The critical Mach number corresponding to the pressure peak on the largest inlet opening, nose A, at a practical rate of air inlet for a large radial engine (fig. 13), is 0.64. With the smaller inlets, noses B and C, no pressure peak occurred, and the indicated local velocity increments were so small that the critical speed of a fuselage employing these shapes would be determined by the cockpit enclosure or the wing-fuselage juncture—that is, the highest local velocity would occur at some point other than on the nose.

External drag.—Figure 14 shows that the abrupt decreases in external-drag coefficient of noses B and C at low rates of flow occurred as a consequence of the formation of extensive low-drag laminar boundary layers. This phenomenon did not occur with nose A because, as previously discussed, the unfavorable pressure distribution near the nose precluded the possibility of appreciable laminar flow. It will be noticed, however, that the drag of nose A showed a general decrease with increasing flow coefficient as did the drags of noses B and C after the laminar boundary layers had been formed. Similar decreases occurred with transition fixed (fig. 15).

FIGURE 34.—The external-drag coefficient of the nose B and tail C combination compared with an estimate based on the drag increments obtained in the tests of the individual openings. Natural transition.

In order to aid in finding the cause of the decrease in drag with increasing air-inlet velocity, partial boundary-layer velocity profiles were measured at two stations, $0.15L$ and $0.35L$, behind nose B with fixed transition for a wide range of inlet-flow ratios. The results (fig. 17) showed a decrease in the thickness of the turbulent boundary layer as the rate of air-inlet velocity was increased in spite of slight decreases in the velocity outside of the boundary layer. Two conclusions may be drawn from this result:

- (1) The losses over the forward part of the nose are decreased as air inlet is increased.
- (2) The skin friction over the main part of the body (to the rear of the $0.15L$ station) should increase slightly with air inlet.

From the drag results (fig. 15), it is evident that the decrease in losses at the nose more than compensates for the slight increases in skin friction behind the nose because an over-all decrease in external drag with air inlet occurs.

In regard to the magnitude of the external drag with air inlet, figure 14 shows that the external drag with noses B and C was reduced to less than that of the streamline body. For the fixed transition condition, the drag of these noses was approximately the same as for the streamline body. With nose A, in both cases, the drag was considerably higher. Tests of the three noses in combination with tail outlet C

FIGURE 35.—The effect of the presence of a .50-caliber machine-gun model in the inlet opening on static-pressure distribution on top of the body. Nose B; natural transition.

(fig. 32) showed about the same relative drag characteristics as the tests of the single openings. The fact that the external drag with the openings decreased to that of the streamline body may be accounted for by the fact that the wetted area with the openings is somewhat less than that for the streamline body. In addition, the passage of air through the internal system has an effect on the external flow similar to a decrease in the effective thickness of the body.

The wake-survey results (fig. 15) show that the rate of drag decrease with air-inlet-flow coefficient was actually somewhat less than that indicated by the force-test results.

The exaggerated effect shown by the force data is believed due to leakage and possible changes in the tunnel-pressure gradient as air was removed at the nose of the body. Maximum leakage would occur where the pressure in the duct system was the greatest and may account for part of the maximum discrepancy (7 percent) between force and wake drags occurring at zero flow, where stagnation pressure existed in the ducts. At a flow coefficient of about 0.11, the mean duct pressures, and hence leakage, reached a minimum; at this point the force and wake data agree closely. At least for the range of flow covered in figure 15, leakage effects apparently predominated over possible changes in the buoyancy effect in exaggerating the rate of drag decrease with air inlet.

Inlet-opening size.—The size of the inlet opening in an actual installation should be governed by considerations of both the external and internal flow. In a consideration of the external drag, it has been shown that nose B, although twice as large in area as nose C, was equally effective, so that either nose might be employed, the choice depending on the quantity of air flow required. It has also been shown that the opening must be designed for an inlet-velocity ratio of at least 0.3 in order to permit the nose-pressure peak to be eliminated. Higher inlet velocities would be of some benefit externally.

High inlet-velocity ratios are detrimental to the internal-duct efficiency because they necessitate large expansions and make the friction and bend losses high. It is suggested in reference 7 that low inlet velocities may have an additional advantage to the internal flow in that comparatively large expansions can be made efficiently near the inlet owing to the natural spreading of the streamlines at this point.

The final compromise between the conflicting requirements of the internal and the external flows will depend on the internal arrangement and the space available for the ducts. In general, it is believed that efficient installations incorporating nose B or nose C should have inlet-velocity ratios in the range of 0.3 to 0.6.

Derivation of optimum nose profiles for arbitrary inlet-opening sizes.—The method, described in section entitled "Results," for obtaining suitable nose-inlet shapes for inlet sizes other than those tested (see figs. 20 and 21) is obviously strictly applicable only to openings on the modified 111 body form. It was thought possible, however, that the shapes obtained by this method could be applied with good results where only the basic forebody profile was similar to the 111 body form. In a subsequent investigation (reference 8) it was found that considerable stretching of the nose B profile was permissible with the stretched profile still retaining the desirable flat pressure contour and low values of the pressure peak. It was thus indicated that the profile ordinates of the present tests could be directly used in the design of nose inlets having proportions greatly different from the shapes

developed in these tests. In order to simplify the procedure of designing inlets of other proportions, it was found desirable to base the nondimensional ordinates on the distance X from the maximum diameter station ($0.4L$) to the nose rather than on the distance from the $0.25L$ station to the nose, as suggested under "Results." Reference 9, which was an outgrowth of the present work, presents high-speed-test results for related inlets derived by the foregoing method and covers a wide range of proportions.

Internal-duct shape near inlet opening.—The modifications of figure 19 consisted of a conical expansion with a 10° included angle, a large irregular expansion formed by the cut-out for the inner cowl, and a gradual (4° equivalent cone) annular expansion obtained with the inner cowl. None of these changes had a measurable effect on either the external drag or the pressure distribution. Modification B-4c of figure 18 likewise had no effects. Modifications B-4a and B-4b of figure 18, however, caused slight drag increases and disturbed the external pressures at the nose. These latter modifications are equivalent to inferior nose shapes corresponding to smaller inlet sizes than the basic nose B inlet. It will be observed that the internal-duct shapes included both satisfactory and very inefficient designs and that neither had any external effects, provided that the size of the inlet was not altered.

Angle of attack.—The effect of increase in angle of attack from 0° to 3.5° on the pressure distribution over the top of nose B can be seen in figure 35. A considerably higher air-inlet-velocity ratio is required to reduce the pressure peak at 3.5° angle of attack than at 0° angle of attack. In flight, the inlet-velocity ratio would automatically increase with angle-of-attack increases owing to decreases in the flight speed, if the engine power were assumed constant. Force-test data obtained with fixed transition on a fuselage model employing nose C (reference 8) showed that the external drag, at an inlet-velocity ratio of 0.56, was practically constant over the angle-of-attack range of 0° to 3.5° .

OUTLET OPENINGS

The outlet openings tested were not optimum shapes arrived at by a series of tests, as were the inlet openings. As previously stated, they merely represented typical practice in the design and the construction of outlets. It became apparent during the course of the tests that the openings had several undesirable characteristics, but it was not feasible at the time to extend the investigation to include modifications. Further outlet research embracing the improvements that suggested themselves in the course of this investigation are included in references 8 and 10.

Pressure distribution.—The effect on the pressure distribution of air flow from the outlets was generally unfavorable. In the case of the annular outlets (fig. 24) a negative-pressure peak occurred at the higher flow rates, owing to an effective

thickening of the body due to the flow of exhaust air in the rear of the openings. In some cases, the peak was sufficiently high to fix the critical speed of the body. The pressure disturbance at the 21-percent outlet precipitated boundary-layer transition at all outlet velocities.

The static pressure at the tail outlets (fig. 22) became more positive as the flow was increased. This effect was due to the fact that the streamlines of both the internal and the external flows were converging at the opening, so that considerable contraction of the flow in the rear of the outlet resulted. Thus, about one-third of the total pressure (measured from p_0) at the tail outlets was in the form of static pressure which, of course, increased as the flow ratio was advanced. The static pressure in the internal flow at the outlet tended to be considerably more positive than that of the external flow near the tail outlet. The high outlet pressures are believed to have caused local separation of the external flow near the tail outlets.

External drag.—The external drag with the 63-percent annular outlet (fig. 25) at first decreased as the flow rate was advanced probably because of the elimination of locally separated flow in the wake of the opening, and then it increased rapidly, probably because of the increasing skin friction over the part of the body in the wake of the outlet.

Similar drag characteristics were exhibited by the tail outlets wherever velocity ratios v/V , up to 0.5 or greater, could be attained, as in the case of tails D and F tested singly (fig. 23) and tails B, C, and E tested in combination with the nose inlets (figs. 28 to 31). The rise in drag at the higher flow rates in the combination tests is shown conclusively in figure 30 to be due to the tail outlets. When compared on the basis of tail-outlet-velocity ratio (fig. 30) instead of flow coefficient (fig. 29 (a)), the drag obtained with three outlets of widely different size shows close agreement. The drag increase at the higher tail-outlet-velocity ratios is believed to be due to local separation of the external flow as a result of the high outlet pressures.

The tail outlets were superior to the annular outlets. A comparison of tail C with the 63-percent annular outlet in combination with nose B (fig. 33) shows that in spite of a somewhat larger area the tail outlet had the lower drag throughout the range, particularly at the higher outlet velocities. As would be expected, the comparison was independent of the location of boundary-layer transition because neither opening had any appreciable effect on the transition location.

Outlet-opening design.—The outlet velocity is not arbitrary as is the inlet velocity but is fixed by the internal total-pressure losses and the pressure drop across the system. From the standpoint of the internal drag, it is desirable to have the outlet total pressure as nearly equal to the free-stream total pressure as possible so that a minimum amount

of energy will be left in the wake. In well-designed cooling systems, the internal total-pressure losses are only a few percent of the free-stream total pressure at high speeds. Under these conditions, the ideal outlet total pressure is approached and the internal drag is small. The relation between internal total-pressure loss and the internal drag was shown in the section entitled "Results." The outlet velocity at a given flight speed is readily calculable from estimates of the total-pressure losses and the pressure drop across the system. A contraction or an orifice coefficient (dependent on the outlet shape) should be applied to the velocity as computed from the pressure characteristics. With the tail outlets tested, for example, the velocity at the outlet was about 0.8 of the final velocity. For the annular outlets, the coefficient was roughly 0.9. The velocity having thus been obtained at the outlet, the size of the opening will depend on the required quantity of air flow.

The economy of passing exactly the required amount of cooling air through the internal system at all flight speeds is generally appreciated. Variation in the size of the exit opening is the most efficient method of controlling the rate of flow.

The shape of the opening is not critical as far as the internal flow is concerned, provided there are no expansions. But the present tests have indicated that the external flow may be adversely affected if the static pressures are different from those of the main stream near the outlet. The shape of the opening, therefore, should permit the internal air to exhaust at the same static pressure as exists in the external flow near the opening. A suggested optimum tail-outlet shape is sketched in figure 26, and the flow characteristics are compared with those existing at one of the outlets tested for the ideal outlet condition of free-stream total pressure in the opening. The desired conditions at the outlet are obtained in the proposed opening by eliminating the contraction of the outlet flow. The desired outlet conditions can be attained at any outlet location by making the streamlines of both internal and external flows parallel.

The optimum shape for an annular-outlet opening is not as obvious as in the case of the tail outlets. It is evident from figure 24, however, that the body fairing immediately behind the outlet should be altered to reduce the thickening of the body and thus to relieve the thickening effect of the outlet flow. Further research is recommended to determine in detail the shapes required to give the minimum disturbance to the static-pressure distribution.

In regard to the relative merits of the annular and the tail outlets for efficient internal systems, it is probable that the optimum tail outlet will be superior to the best possible annular outlet because the high-velocity flow from the annular openings will generally increase the skin friction of the portion of the body in the wake of the outlet.

INLET-OUTLET COMBINATIONS

The combination tests (figs. 28 and 34) are of principal interest in showing that the over-all external drag of the body with suitable inlet and outlet openings of practicable size was no higher than that of the basic streamline form. This result was obtained at rates of internal air flow sufficient for cooling a radial engine located at the maximum fuselage section at moderate to high-speed flight conditions.

The variation of the rate of internal flow in the combination tests was accomplished by means of varying the internal resistance. At the condition of maximum flow attainable with a given outlet size, the internal losses were very small and consequently the outlet conditions closely approached the ideal. The outlet velocities over approximately the higher 25 percent of the flow range covered with each outlet correspond to high-speed-flight outlet conditions for typical heat-exchanger installations; at lower flow rates the internal-resistance losses were considerably higher than would be encountered in present practice. The actual magnitude of the internal drag throughout the flow range covered with tail C is shown in figure 27.

The rise in drag at the higher flow rates has been shown to be due to the unfavorable outlet conditions at the higher outlet velocities (fig. 30). It is believed that by improving the outlet design as suggested in figure 26 the rise in drag at the high outlet velocities would be eliminated.

It will be observed that the drag obtained for the best combinations with fixed transition was, in general, slightly greater than for the streamline body with transition fixed at the same station. The difference may be entirely accounted for by the higher drag of the carborundum strip itself when located at the nose of the inlet openings than when located in the thicker boundary layer on the streamline body. In addition, it should be remembered that the stations selected for fixing the transition on the streamline body are entirely arbitrary. Under actual flight conditions, transition on the streamline body might occur somewhat ahead of the corresponding station on the noses owing to the greater length of the streamline body. In this case, the drag of the streamline body would be relatively higher than in the present comparisons.

The drag of the inlet openings in the presence of the outlets, and vice versa, was considerably less than it was when the openings were tested individually. (See fig. 34.) A part of this effect, particularly at low rates of internal flow, may be due to leakage in the tests of the individual openings, as has previously been pointed out. Another contributing factor of secondary importance may be the difference in the methods of restricting the internal flow—that is, the resistance plates inserted near the inlet opening in the combination tests (fig. 2) may have had some small tendency to affect the external flow. In general, however, it is reasonable to expect

that the openings, in combination, would contribute less drag than when tested individually.

Comparison with NACA cowling.—The results of reference 1 provide a comparison of the inlet-outlet combinations with the NACA cowling. In the investigation cited, the best NACA cowling shape of reference 2 was adapted in a typical fuselage installation to the NACA 111 fuselage form. This basic streamline shape was almost identical with the body employed in the present tests, and the effective body-drag coefficients with natural and fixed transition, 0.040 and 0.055, respectively, were practically equal to the corresponding drag coefficients, 0.042 and 0.054, obtained in this investigation. The flow and the boundary-layer conditions on the basic shapes employed were evidently quite similar. The drags of the cowling with fixed and natural transition as given in reference 1, with cooling air flow, were reduced about 5 percent to obtain the external drag necessary to the comparison. The results, taken at the same Mach number and at very nearly the same Reynolds number as in the present tests, are shown on each of the figures along with the results of the combination tests (figs. 28, 29, and 31) with the tail outlets.

The combinations tested were aerodynamically superior to the NACA cowling, particularly in the natural transition condition where the inlets B and C permitted extensive laminar flow and caused no increase in drag. The NACA cowling produced a drag increase of some 56 percent in this case.

The NACA cowling shape employed in the tests of reference 1 was developed (reference 2) to have the highest critical speed, $M_{cr}=0.63$, of eight typical cowling shapes of the same over-all dimensions. The critical speed of the body alone with the largest of the present inlets, nose A, was $M_{cr}=0.64$ at a practical rate of air inlet (fig. 13). With the smaller inlets the critical speed was advanced to $M_{cr}=0.84$, the critical speed of the basic 111 fuselage shape.

CONCLUSIONS

The results of this investigation of inlet and outlet openings led to the following conclusions:

1. Modification of a streamline body permitting air inlet at the nose and outlet at the tail can be accomplished without increasing the external drag.
2. Inlet profiles were developed which, with practicable rates of air flow, produced velocity distributions approaching

closely that of the basic streamline body. Consequently, the critical speed was as high as that of the streamline body and the same favorable laminar-boundary-layer-flow conditions were realized.

3. The test results indicated that outlet openings should be designed so that the static pressure of the internal flow at the outlet would be the same as the static pressure of the external flow in the vicinity of the opening.

4. The internal-duct shape near an inlet of given size had no appreciable effect on the external drag or pressure distribution.

5. The location of a simulated smooth-barrel gun in the nose-inlet opening caused no appreciable increase in drag at low angles of attack. The muzzle of the gun should be slightly rounded, and the length of barrel extending beyond the inlet should be as small as possible.

REPORT 1039

ON THE PARTICULAR INTEGRALS OF THE PRANDTL-BUSEMANN ITERATION EQUATIONS FOR THE FLOW OF A COMPRESSIBLE FLUID¹

By CARL KAPLAN

SUMMARY

The particular integrals of the second-order and third-order Prandtl-Busemann iteration equations for the flow of a compressible fluid are obtained by means of the method in which the complex conjugate variables z and $\bar{z}$ are utilized as the independent variables of the analysis. The assumption is made that the Prandtl-Glauert solution of the linearized or first-order iteration equation for the two-dimensional flow of a compressible fluid is known. The forms of the particular integrals, derived for subsonic flow, are readily adapted to supersonic flows with only a change in sign of one of the parameters of the problem.

INTRODUCTION

For the past several years iteration methods have been increasingly applied to the solution of compressible-flow problems. The most useful method from the point of view of aeronautical applications and the one discussed in this report is based on small perturbations with respect to the undisturbed flow. The Prandtl-Glauert and Ackeret solutions in two-dimensional subsonic and supersonic flow, respectively, obtained by means of the linearization of the fundamental nonlinear differential equation for compressible flow, are presumed to be known and are taken as the initial steps in this iteration process. Higher-order solutions are then obtained by retaining appropriate powers and products of the perturbation quantities. This method of iteration has been variously labeled the Ackeret iteration process and the Prandtl-Busemann small perturbation method when limited to two-dimensional subsonic flow. The procedure has been extended in recent years to both two-dimensional and axisymmetrical supersonic-flow problems.

In a recent publication (reference 1), Van Dyke succeeded in obtaining by trial the particular integral of the nonhomogeneous second-order iteration equation for the velocity potential in supersonic flow. The general solution is then easily obtained by adding solutions of the homogeneous equation with proper regard to the boundary conditions at the surface of the solid and at infinity.

The purpose of the present report is to show a procedure by means of which the particular integrals of the higher-than-first-order iteration equations can be derived in a

systematic manner. The explicit expressions obtained for the particular integrals of the second- and third-order iteration equations are believed to yield essentially the solution of the problem of high subsonic flow past an arbitrary two-dimensional profile, since it is never a difficult problem to supply the solutions of the homogeneous equation necessary for the fulfillment of the boundary conditions. It is noteworthy that the particular integrals, derived for subsonic flow, can be adapted to supersonic flow with simply a change in sign of one of the parameters.

FUNDAMENTAL EQUATIONS

The fundamental nonlinear differential equation governing the flow of a compressible fluid is

$$(c^2 - u^2) \frac{\partial u}{\partial X} + (c^2 - v^2) \frac{\partial v}{\partial Y} - uv \left(\frac{\partial v}{\partial X} + \frac{\partial u}{\partial Y} \right) = 0 \quad (1)$$

where

X, Y rectangular Cartesian coordinates in flow plane

u, v fluid velocity components along X - and Y -axis, respectively

c local speed of sound

The condition for irrotational motion is that

$$\frac{\partial u}{\partial Y} = \frac{\partial v}{\partial X}$$

and leads to a velocity potential Φ defined by

$$\left. \begin{aligned} u &= \frac{\partial \Phi}{\partial X} \\ v &= \frac{\partial \Phi}{\partial Y} \end{aligned} \right\} \quad (2)$$

If the body is held fixed in a uniform stream of velocity U , the relation between the local speed of sound c and the speed of the fluid $\sqrt{u^2 + v^2}$ is given for adiabatic processes by

$$\frac{c^2}{c_\infty^2} = 1 + \frac{\gamma - 1}{2} M_\infty^2 \left(1 - \frac{u^2 + v^2}{U^2} \right) \quad (3)$$

¹ Supersedes NACA TN 2159, "On the Particular Integrals of the Prandtl-Busemann Iteration Equations for the Flow of a Compressible Fluid" by Carl Kaplan, 1950.

where

c_∞ sound speed in undisturbed fluid

γ ratio of specific heats at constant pressure and constant volume

M_∞ Mach number of undisturbed stream (U/c_∞)

With the introduction of a characteristic length l as unit of length and the undisturbed stream velocity U as unit of velocity, the quantities X , Y , u , v , and Φ for the remainder of the analysis denote, respectively, the nondimensional quantities X/l , Y/l , u/U , v/U , and Φ/Ul , while c and c_∞ retain their original meanings. By means of equations (2), equations (1) and (3) then become, respectively,

$$\left(\frac{c^2}{c_\infty^2} - M_\infty^2 u^2\right) \Phi_{XX} + \left(\frac{c^2}{c_\infty^2} - M_\infty^2 v^2\right) \Phi_{YY} - 2M_\infty^2 \Phi_X \Phi_Y \Phi_{XY} = 0 \quad (4)$$

and

$$\frac{c^2}{c_\infty^2} = 1 + \frac{\gamma-1}{2} M_\infty^2 [1 - (u^2 + v^2)] \quad (5)$$

where the subscripts X and Y denote partial differentiations with respect to the designated variables.

In order to obtain the iteration equations based on small perturbations of the undisturbed stream, the assumption is made that the velocity potential Φ can be expanded in the form

$$\Phi = X + \Phi_1 + \Phi_2 + \Phi_3 + \dots \quad (6)$$

For the purpose of defining and controlling the iteration procedure, the function Φ_{n+1} and its derivatives are then regarded as small compared with the preceding approximation Φ_n and its derivatives.

From equations (2) and (6),

$$u = \Phi_X = 1 + \Phi_{1X} + \Phi_{2X} + \Phi_{3X} + \dots$$

and

$$v = \Phi_Y = \Phi_{1Y} + \Phi_{2Y} + \Phi_{3Y} + \dots$$

When these expressions for u , v are introduced into equation (4), together with the expression for c^2/c_∞^2 given by equation (5), and the powers and products of Φ_n and their derivatives are grouped according to the assumptions of the small perturbation method, the following iteration equations for the first three approximations Φ_1 , Φ_2 , and Φ_3 result:

$$(1 - M_\infty^2) \Phi_{1XX} + \Phi_{1YY} = 0 \quad (7)$$

$$(1 - M_\infty^2) \Phi_{2XX} + \Phi_{2YY} = M_\infty^2 [(\gamma+1) \Phi_{1X} \Phi_{1XX} + (\gamma-1) \Phi_{1X} \Phi_{1YY} + 2 \Phi_{1Y} \Phi_{1XY}] \quad (8)$$

$$(1 - M_\infty^2) \Phi_{3XX} + \Phi_{3YY} = M_\infty^2 \left\{ \left(\frac{1}{2} \Phi_{1X}^2 + \Phi_{2X} \right) [(\gamma+1) \Phi_{1XX} + (\gamma-1) \Phi_{1YY}] + \frac{1}{2} \Phi_{1Y}^2 [(\gamma-1) \Phi_{1XX} + (\gamma+1) \Phi_{1YY}] + \Phi_{1X} [(\gamma+1) \Phi_{2XX} + (\gamma-1) \Phi_{2YY}] + 2(\Phi_{1X} \Phi_{1Y} \Phi_{1XY} + \Phi_{2Y} \Phi_{1XY} + \Phi_{1Y} \Phi_{2XY}) \right\} \quad (9)$$

For slender bodies, the first few steps of this iteration process may be expected to yield an accurate result with the exception of a small region in the neighborhood of a stagnation point. Even at stagnation points, the iteration method has been shown to represent correctly the effect of compressibility (reference 2). The accuracy of the calculations obviously depends upon the number of terms determined, each additional term reducing the region of inaccuracy in the neighborhood of a stagnation point.

The iteration equations (7), (8), and (9) may be put into more familiar forms by the introduction of a new set of independent variables x and y , where

$$\left. \begin{aligned} x &= X \\ y &= Y \sqrt{1 - M_\infty^2} \end{aligned} \right\} \quad (10)$$

Thus, for $M_\infty < 1$, equation (7) is transformed into a Laplace equation; whereas equations (8) and (9) are transformed into Poisson equations with the right-hand sides composed of, respectively, double products and triple products of previously determined perturbation quantities. It is further assumed that the solution of equation (7) is available. This initial step in the approximation to the exact nonlinear solution is usually easily obtained, as it represents the Prandtl-Glauert approximation (reference 3, appendix B). The purpose of the present report is then to derive explicit expressions for the particular solutions of the second- and third-order iteration equations (8) and (9).

CALCULATION OF THE PARTICULAR INTEGRAL OF THE SECOND-ORDER ITERATION EQUATION

By introducing the independent variables x and y defined by equation (10), the second-order iteration equation (8) becomes

$$\Phi_{2xx} + \Phi_{2yy} = 2M_\infty^2 [(1 + \sigma) \Phi_{1x} \Phi_{1xx} + \Phi_{1y} \Phi_{1xy}] \quad (11)$$

where

$$\sigma = \frac{\gamma+1}{2} \frac{M_\infty^2}{\beta^2}$$

$$\beta^2 = 1 - M_\infty^2$$

and where use has been made of Laplace's equation

$$\Phi_{1xx} + \Phi_{1yy} = 0$$

The procedure for obtaining the particular integrals of the higher-order iteration equations is based on the use of the complex conjugate variables z and $\bar{z}$ as independent variables. Thus,

$$z = x + iy$$

$$\bar{z} = x - iy$$

and the equivalence of operators

$$\frac{\partial}{\partial x} = \frac{\partial}{\partial z} + \frac{\partial}{\partial \bar{z}}$$

$$\frac{\partial}{\partial y} = i \left(\frac{\partial}{\partial z} - \frac{\partial}{\partial \bar{z}} \right)$$

$$\frac{\partial^2}{\partial x^2} = \frac{\partial^2}{\partial z^2} + 2 \frac{\partial^2}{\partial z \partial \bar{z}} + \frac{\partial^2}{\partial \bar{z}^2}$$

$$\frac{\partial^2}{\partial y^2} = -\frac{\partial^2}{\partial z^2} + 2 \frac{\partial^2}{\partial z \partial \bar{z}} - \frac{\partial^2}{\partial \bar{z}^2}$$

Then equation (7) for Φ_1 becomes

$$4 \frac{\partial^2 \Phi_1}{\partial z \partial \bar{z}} = 0 \quad (12)$$

The most general real solution of this equation is

$$\Phi_1 = \frac{1}{2} [w_1(z) + \bar{w}_1(\bar{z})] \quad (13)$$

or

$$\Phi_1 = \text{R.P. } w_1(z) = \text{R.P. } \bar{w}_1(\bar{z})$$

where $w_1(z)$ is an arbitrary analytic function of z , $\bar{w}_1(\bar{z})$ is its conjugate complex, and where the symbol R.P. stands for "real part of." The imaginary part of $w_1(z)$ is a function ψ_1 , say, related to Φ_1 by means of the Cauchy-Riemann equations and hence also satisfies Laplace's equation. The function ψ_1 does not represent the stream function of the actual compressible flow and does not appear in the final expressions of the particular integrals. The following relations will be found useful and are easily verified:

$$\Phi_1 = \frac{1}{2} (w_1 + \bar{w}_1)$$

$$\Phi_{1x} = \frac{1}{2} (w_{1z} + \bar{w}_{1\bar{z}})$$

$$\Phi_{1y} = \frac{i}{2} (w_{1z} - \bar{w}_{1\bar{z}})$$

$$\Phi_{1xz} = \frac{i}{2} (w_{1zz} - \bar{w}_{1\bar{z}\bar{z}})$$

$$\Phi_{1zz} = \frac{1}{2} (w_{1zz} + \bar{w}_{1\bar{z}\bar{z}})$$

Then

$$2\Phi_{1x}\Phi_{1xz} = \text{R.P. } (w_{1z} + \bar{w}_{1\bar{z}})w_{1zz}$$

$$2\Phi_{1y}\Phi_{1zy} = -\text{R.P. } (w_{1z} - \bar{w}_{1\bar{z}})w_{1zz}$$

and equation (11) for the second approximation Φ_2 becomes

$$\begin{aligned} \Phi_{2z\bar{z}} &= \frac{1}{4} M_\infty^2 \text{R.P. } [\sigma w_{1z}w_{1zz} + (2 + \sigma) \bar{w}_{1\bar{z}}w_{1zz}] \\ &= \frac{1}{4} M_\infty^2 \text{R.P. } \left[\frac{\sigma}{2} (w_{1z}^2)_z + (2 + \sigma) (w_{1z}\bar{w}_{1\bar{z}})_z \right] \end{aligned}$$

If Φ_2 is defined to be the real part of a nonanalytic function $w_2(z, \bar{z})$, then

$$w_{2z\bar{z}} = \frac{1}{4} M_\infty^2 \left[\frac{\sigma}{2} (w_{1z}^2)_z + (2 + \sigma) (w_{1z}\bar{w}_{1\bar{z}})_z \right] \quad (14)$$

This equation can be integrated immediately by inspection and yields the general solution

$$w_2 = \frac{1}{4} M_\infty^2 \left[\frac{\sigma}{2} \bar{z} w_{1z}^2 + (2 + \sigma) \bar{w}_1 w_{1z} + F(z) \right] \quad (15)$$

where, because only the real part Φ_2 of w_2 is of interest, only one arbitrary analytic function $F(z)$ need be included. The function $F(z)$ satisfies Laplace's equation and is so chosen as to satisfy the required boundary conditions at the surface of the body and at infinity. The part of the expression on the right-hand side of equation (15), excluding the arbitrary function $F(z)$, is the particular integral of equation (14) and may be expressed in real form in the following manner:

Suppose

$$F(z) = -\frac{\sigma}{2} z w_{1z}^2 + (2 + \sigma) w_1 w_{1z} + f(z) \quad (16)$$

where $f(z)$ is again an arbitrary analytic function of z .

Then with the aid of the relation

$$w_{1z} = \frac{1}{2} \left(\frac{\partial}{\partial x} - i \frac{\partial}{\partial y} \right) (\Phi_1 + i\psi_1) = \Phi_{1x} - i\Phi_{1y}$$

where use has been made of the Cauchy-Riemann conditions

$$\Phi_{1x} = \psi_{1y}$$

$$\Phi_{1y} = -\psi_{1x}$$

the expression for Φ_2 , obtained from equation (15), becomes

$$\Phi_2 = \frac{1}{4} M_\infty^2 [-2\sigma y \Phi_{1x} \Phi_{1y} + 2(2 + \sigma) \Phi_1 \Phi_{1x} + \text{R.P. } f(z)] \quad (17)$$

The expression on the right-hand side of this equation, excluding R.P. $f(z)$, namely,

$$\Phi_2 = M_\infty^2 \left[\left(1 + \frac{\sigma}{2} \right) \Phi_1 - \frac{1}{2} \sigma y \Phi_{1y} \right] \Phi_{1x} \quad (18)$$

corresponds precisely to the particular integral obtained by Van Dyke (reference 1) for two-dimensional supersonic flow with σ replaced by $-\sigma$, where for supersonic flow the definition of σ is

$$\sigma = \frac{\gamma+1}{2} \frac{M_\infty^2}{M_\infty^2-1}$$

It is rather noteworthy that the particular integral of the second-order iteration equation (8) can be obtained for both subsonic and supersonic flows by simply interchanging the sign of the parameter σ .

CALCULATION OF THE PARTICULAR INTEGRAL OF THE THIRD-ORDER ITERATION EQUATION

In this section, the particular integral of equation (9) involving only Φ_1 , Φ_2 , and their derivatives is derived. For this purpose, the variables x, y and the parameter σ are introduced. Equation (9) then takes the following form:

$$\begin{aligned} \Phi_{3xx} + \Phi_{3yy} = 2M_\infty^2 \left\{ (1+\sigma)(\Phi_{1xx}\Phi_{2x} + \Phi_{1x}\Phi_{2xx}) + [2\beta^2(1+\sigma)-1]\Phi_{1x}\Phi_{1y}\Phi_{1xy} + (1+\sigma) \left[2\beta^2(1+\sigma) - \frac{3}{2} \right] \Phi_{1xx}\Phi_{1x}^2 + \right. \\ \left. \frac{1}{2}(\sigma\beta^2-1)\Phi_{1xx}\Phi_{1y}^2 + \Phi_{1xy}\Phi_{2y} + \Phi_{1y}\Phi_{2xy} \right\} \end{aligned} \quad (19)$$

Use is again made of the complex conjugate variables z and $\bar{z}$ as independent variables. Thus,

$$\begin{aligned} \Phi_2 &= \text{R. P. } w_2(z, \bar{z}) \\ \Phi_{2x} &= \text{R. P. } (w_{2z} + w_{2\bar{z}}) \\ \Phi_{2y} &= \text{R. P. } i(w_{2z} - w_{2\bar{z}}) \\ \Phi_{2xx} &= \text{R. P. } (w_{2zz} + 2w_{2z\bar{z}} + w_{2\bar{z}\bar{z}}) \\ \Phi_{2xy} &= \text{R. P. } i(w_{2zz} - w_{2\bar{z}\bar{z}}) \\ \Phi_{1xx}\Phi_{1x}^2 &= \text{R. P. } \frac{1}{4}(w_{1z} + \bar{w}_{1\bar{z}})^2 w_{1zz} \\ \Phi_{1xx}\Phi_{1y}^2 &= -\text{R. P. } \frac{1}{4}(w_{1z} - \bar{w}_{1\bar{z}})^2 w_{1zz} \\ \Phi_{1xx}\Phi_{2x} + \Phi_{1x}\Phi_{2xx} &= \text{R. P. } \frac{1}{2}(w_{1zz} + \bar{w}_{1\bar{z}\bar{z}})(w_{2z} + w_{2\bar{z}}) + \text{R. P. } \frac{1}{2}(w_{1z} + \bar{w}_{1\bar{z}})(w_{2zz} + 2w_{2z\bar{z}} + w_{2\bar{z}\bar{z}}) \\ \Phi_{1xy}\Phi_{2y} &= -\text{R. P. } \frac{1}{2}(w_{1zz} - \bar{w}_{1\bar{z}\bar{z}})(w_{2z} - w_{2\bar{z}}) \\ \Phi_{1y}\Phi_{2xy} &= -\text{R. P. } \frac{1}{2}(w_{1z} - \bar{w}_{1\bar{z}})(w_{2zz} - w_{2\bar{z}\bar{z}}) \\ \Phi_{1x}\Phi_{1y}\Phi_{1xy} &= -\text{R. P. } \frac{1}{4}(w_{1z}^2 - \bar{w}_{1\bar{z}}^2)w_{1zz} \end{aligned}$$

Then equation (19), with $\Phi_3 = \text{R. P. } w_3(z, \bar{z})$, can be written as follows:

$$\begin{aligned} w_{3z\bar{z}} &= \frac{1}{4}(1-\beta^2)\sigma(w_{2z}w_{1zz} + w_{2zz}w_{1z} + w_{2\bar{z}}\bar{w}_{1\bar{z}\bar{z}} + w_{2\bar{z}\bar{z}}\bar{w}_{1\bar{z}}) + \frac{1}{4}(1-\beta^2)(2+\sigma)(w_{2z}\bar{w}_{1\bar{z}\bar{z}} + w_{2zz}\bar{w}_{1\bar{z}} + w_{2\bar{z}}w_{1zz} + w_{2\bar{z}\bar{z}}w_{1z}) + \\ &\frac{1}{16}(1-\beta^2)\sigma[\beta^2(1+2\sigma)-(1-2\sigma)]w_{1z}^2w_{1zz} + \frac{1}{16}(1-\beta^2)[\beta^2(4+5\sigma+2\sigma^2)+\sigma(3+2\sigma)]\bar{w}_{1\bar{z}}^2w_{1zz} + \\ &\frac{1}{8}(1-\beta^2)[\beta^2(2+5\sigma+2\sigma^2)+(-2+\sigma+2\sigma^2)]w_{1z}\bar{w}_{1\bar{z}}w_{1zz} \end{aligned}$$

Introducing the expressions for $w_2(z, \bar{z})$ and its derivatives with respect to z and $\bar{z}$ from equation (15) yields for $w_{3z\bar{z}}$ the following equation:

$$\begin{aligned} w_{3z\bar{z}} &= \frac{1}{16}(1-\beta^2)^2\sigma^2\bar{z}(w_{1z}^2w_{1zz})_z + \frac{1}{16}(1-\beta^2)^2\sigma(2+\sigma)(\bar{z}\bar{w}_{1\bar{z}})_z(w_{1z}w_{1zz})_z + \frac{1}{16}(1-\beta^2)^2\sigma(w_{1z}F_z)_z + \frac{1}{16}(1-\beta^2)\sigma[\beta^2(2+\sigma) + \\ &(4+3\sigma)]\bar{w}_{1\bar{z}}(w_{1z}^2)_z + \frac{1}{32}(1-\beta^2)^2\sigma(2+\sigma)(w_{1z}^2)_z(\bar{z}\bar{w}_{1\bar{z}})_z + \frac{1}{16}(1-\beta^2)^2(2+\sigma)^2w_{1zz}(\bar{w}_{1\bar{z}}\bar{w}_{1\bar{z}})_z + \frac{1}{16}(1-\beta^2)^2(2+\sigma)(\bar{w}_{1\bar{z}}F_z)_{z\bar{z}} + \\ &\frac{1}{32}(1-\beta^2)^2(2+\sigma)^2(\bar{w}_{1\bar{z}}^2)_z w_{1zz} + \frac{1}{96}(1-\beta^2)\sigma^2(5+3\beta^2)(w_{1z}^3)_z + \frac{1}{32}(1-\beta^2)[\beta^2(8+10\sigma+3\sigma^2)+\sigma(6+5\sigma)]\bar{w}_{1\bar{z}}w_{1z}^2 \end{aligned} \quad (20)$$

In the derivation of this expression for $w_{3,\bar{z}}$, free use was made of the fact that insofar as the real part Φ_3 of w_3 is concerned, terms of the nature $g(z)\bar{h}(\bar{z})$ and $\bar{g}(\bar{z})h(z)$ are equivalent. It is important to note that this type of operation leaves unaltered the real part Φ_3 of w_3 . Since Φ_3 is the quantity sought in the calculations, changes in the imaginary part of w_3 are of no consequence in the final results.

Equation (20) can be integrated immediately by inspection and yields the following result:

$$\begin{aligned} w_3 = & \frac{1}{32}(1-\beta^2)^2\sigma^2\bar{z}^2w_{1z}^2w_{1zz} + \frac{1}{16}(1-\beta^2)^2\sigma\bar{z}w_{1z}F_z + \frac{1}{16}(1-\beta^2)^2\sigma(2+\sigma)\bar{z}\bar{w}_1w_{1z}w_{1zz} + \frac{1}{16}(1-\beta^2)\sigma[\beta^2(2+\sigma)+(4+3\sigma)]\bar{w}_1w_{1z}^2 + \\ & \frac{1}{32}(1-\beta^2)^2\sigma(2+\sigma)\bar{z}\bar{w}_{1z}w_{1z}^2 + \frac{1}{16}(1-\beta^2)^2(2+\sigma)\bar{w}_1\bar{w}_{1z}w_{1z} + \frac{1}{16}(1-\beta^2)^2(2+\sigma)(F\bar{w}_{1z} + F_z\bar{w}_1) + \frac{1}{32}(1-\beta^2)^2(2+\sigma)^2\bar{w}_1^2w_{1zz} + \\ & \frac{1}{96}(1-\beta^2)\sigma^2(3\beta^2+5)\bar{z}w_{1z}^3 + \frac{1}{32}(1-\beta^2)[\beta^2(8+10\sigma+3\sigma^2)+\sigma(6+5\sigma)]\bar{w}_{1z}\int w_{1z}^2dz \end{aligned} \quad (21)$$

Equation (21) is the particular integral of equation (20). The most general solution is obtained by adding an arbitrary analytic function $G(z)$, satisfying the homogeneous or Laplace equation $G_{zz}=0$. An arbitrary function of $\bar{z}$, customarily included in the general solution, need not be considered here because only the real part Φ_3 of w_3 is of interest. In fact, the omitted arbitrary function is the complex conjugate $\bar{G}(\bar{z})$.

In order to obtain the desired form of Φ_3 (the real part of w_3) from equation (21), $F(z)$ is replaced by its expression given in equation (16), and the real part of $f(z)$ in equation (17) is replaced by

$$\text{R.P. } f(z) = \frac{4}{M_\infty^2}\Phi_2 + 2\sigma y\Phi_{1x}\Phi_{1y} - 2(2+\sigma)\Phi_1\Phi_{1x}$$

The final form of the particular integral of the third-order iteration equation (9) then becomes

$$\begin{aligned} \Phi_3 = & -\frac{1}{2}(1-\beta^2)\sigma y(\Phi_{1x}\Phi_{2y} + \Phi_{1y}\Phi_{2x}) + \frac{1}{2}(1-\beta^2)(2+\sigma)(\Phi_{1x}\Phi_2 + \Phi_1\Phi_{2x}) + \\ & \frac{1}{8}(1-\beta^2)^2\sigma^2y^2\Phi_{1xx}(\Phi_{1x}^2 - \Phi_{1y}^2) - \frac{1}{4}(1-\beta^2)^2\sigma^2y^2\Phi_{1x}\Phi_{1y}\Phi_{1xy} + \frac{1}{48}(1-\beta^2)\sigma[(6+5\sigma)+3(-2+\sigma)\beta^2]y\Phi_{1y}^3 + \\ & \frac{1}{16}(1-\beta^2)\sigma[(10-\sigma)-(10+7\sigma)\beta^2]y\Phi_{1x}^2\Phi_{1y} + \frac{1}{4}(1-\beta^2)^2\sigma(2+\sigma)y\Phi_1(\Phi_{1x}\Phi_{1xy} + \Phi_{1y}\Phi_{1xz}) + \\ & \frac{1}{16}(1-\beta^2)[(-16-10\sigma+\sigma^2)+(16+22\sigma+7\sigma^2)\beta^2]\Phi_1\Phi_{1x}^2 - \frac{1}{16}(1-\beta^2)\sigma[(6+5\sigma)+3(2+\sigma)\beta^2]\Phi_1\Phi_{1y}^2 - \\ & \frac{1}{8}(1-\beta^2)^2(2+\sigma)^2\Phi_1^2\Phi_{1xx} + \frac{1}{16}(1-\beta^2)[\sigma(6+5\sigma)+(8+10\sigma+3\sigma^2)\beta^2]\Phi_{1x}\int[(\Phi_{1x}^2 - \Phi_{1y}^2)dx + 2\Phi_{1x}\Phi_{1y}dy] \end{aligned} \quad (22)$$

The corresponding expression for Φ_3 for supersonic flow is obtained by simply replacing σ by $-\sigma$ with

$$\sigma = \frac{\gamma+1}{2} \frac{M_\infty^2}{M_\infty^2-1}$$

and β^2 by $-\beta^2$ with $\beta^2 = M_\infty^2 - 1$. The physical plane variables X and Y are easily inserted into both equations (18) and (22) by means of the transformation equations (10),

$$x = X$$

$$y = \beta Y$$

It is pointed out that the forms of the two particular integrals, equations (18) and (22), derived in this report are identical for both subsonic and supersonic flow. The apparent differences are caused by a change in sign of the parameter β^2 . Thus, β^2 and σ are positive for both subsonic and supersonic flow. Actually, of course, the functions represented by Φ_1 , Φ_2 , Φ_3 , . . . are different for the two types of flow. For subsonic flow, these functions are derived from analytic and nonanalytic functions of z and $\bar{z}$; whereas for supersonic flow, they involve the real "characteristics" variables $x \pm \beta y$.

Note that the last term of the expression on the right-hand side of equation (22) contains the indefinite integral

$$I = \int [(\Phi_{1x}^2 - \Phi_{1y}^2)dx + 2\Phi_{1x}\Phi_{1y}dy] \quad (23)$$

It is obvious from the corresponding complex integral in equation (21) that the integrand of equation (23) is an exact differential. This fact can also be easily verified with the help of Laplace's equation

$$\Phi_{1xx} + \Phi_{1yy} = 0$$

Thus,

$$\frac{\partial}{\partial y} (\Phi_{1x}^2 - \Phi_{1y}^2) = \frac{\partial}{\partial x} (2\Phi_{1x}\Phi_{1y}) \quad (24)$$

Equation (24) represents the necessary and sufficient condition that the integrand of equation (23) be an exact differential. Further, according to the theory of exact differential equations, the integral I may be expressed as follows:

$$I = \int^x M dx + \int \left(N - \frac{\partial}{\partial y} \int^x M dx \right) dy \quad (25)$$

where

$$M = \Phi_{1x}^2 - \Phi_{1y}^2$$

$$N = 2\Phi_{1x}\Phi_{1y}$$

and where by $\int^x M dx$ is meant the result of integrating $M dx$ with y considered constant. The expression within the parentheses, namely

$$N - \frac{\partial}{\partial y} \int^x M dx$$

is a function of y only. This statement can be verified as

follows: Thus,

$$\frac{\partial}{\partial x} \left(N - \frac{\partial}{\partial y} \int^x M dx \right) = \frac{\partial N}{\partial x} - \frac{\partial}{\partial y} \frac{\partial}{\partial x} \int^x M dx \quad (26)$$

and because y is considered constant in the process of integrating $M dx$, it is clear that

$$\frac{\partial}{\partial x} \int^x M dx = M$$

Hence the right-hand side of equation (26) is $\frac{\partial N}{\partial x} - \frac{\partial M}{\partial y}$, which vanishes because of the condition for the existence of an exact differential.

Note that in general it is simpler to perform the complex integration $\int w_{1z}^2 dz$ rather than transform to a real integral and then perform the integration.

REPORT 1040

SPECTRA AND DIFFUSION IN A ROUND TURBULENT JET¹

By STANLEY CORRSIN and MAHINDER S. UBEROI

SUMMARY

In a round turbulent jet at room temperature, measurement of the shear correlation coefficient as a function of frequency (through band-pass filters) has given a rather direct verification of Kolmogoroff's local-isotropy hypothesis.

One-dimensional power spectra of velocity and temperature fluctuations, measured in unheated and heated jets, respectively, have been contrasted. Under the same conditions, the two corresponding transverse correlation functions have been measured and compared.

Finally, measurements have been made of the mean thermal wakes behind local (line) heat sources in the unheated turbulent jet, and the order of magnitude of the temperature fluctuations has been determined.

INTRODUCTION

At the present time there apparently exists no statistical theory of turbulent shear flow. One significant theoretical consideration has been proposed: The hypothesis of local isotropy, originated by Kolmogoroff (references 1 and 2). Kolmogoroff has suggested that the fine structure in turbulent shear flow may be isotropic; recent experiments of Townsend (references 3 and 4) in a turbulent wake seem to verify this hypothesis.

In view of this situation, the various experimental researches in the field follow two courses: First, they attempt to verify or disprove local isotropy; second, they try in all conceivable ways to make measurements that may shed light upon the basic nature of the turbulent shear flow, so that the foundations for a successful theory can be laid.

During recent years it has become evident that measurements of the intensity of turbulence alone cannot provide sufficient information about the statistical and dynamical properties of the flow fields. Such quantities as correlations, spectra, probability densities, the various terms in the turbulent kinetic-energy balance, and so forth may be expected to reveal many essential features of the problem.

The types of turbulent shear flow that have come under close experimental scrutiny are the boundary layer (references 5 and 6), the plane channel (reference 7), the plane wake (references 3 and 4), the plane single free-mixing region (reference 8), and the round jet (references 9 and 10). The present work is a continuation of that reported in references 9 and 10.

The general objectives of this investigation have been to learn something more about the flow in a fully developed round turbulent jet and about the heat transfer in such a flow. The work reported here has fallen into three phases:

(a) An attempt to establish the presence or absence of local isotropy, (b) a comparison of velocity- and temperature-fluctuation fields when the over-all boundary conditions on mean velocity and temperature are effectively the same, and (c) a study of the diffusion of heat from a local (line) source in the turbulent flow.

The only specific experimental verification of local isotropy in a turbulent shear flow to date was by Townsend in the plane wake behind a circular rod (references 3 and 4). He found that the skewness and flattening factors of the probability density of $\partial u/\partial t$ in the shear flow are very closely equal to those in the (effectively isotropic) turbulence far behind a grid. Since differentiation emphasizes the higher frequencies, his measurement shows, in essence, that the values of certain statistical quantities related to the smaller eddies in a shear flow are the same as the values for the smaller eddies in isotropic turbulence. He also found the microscale of u in the stream direction to be nearly $\sqrt{2}$ times the microscale of v in that direction, a relation which is exactly true for isotropic turbulence.

Until recently, only mean-velocity and mean-temperature distributions were measured to provide a comparison of the transfer rates of momentum and of heat in turbulent shear flows with over-all heat transfer. The previous report in this round-jet investigation (reference 10) included a beginning on the problem of direct comparison of the velocity and temperature fluctuations as well as some measurements of velocity-temperature correlations. The fluctuations in a warm turbulent wake have been studied by Townsend (reference 11).

Up to the present time, however, there appears still to be no successful hypothesis to account for the well-known fact that heat (and other scalar quantities, like material) is diffused more rapidly than momentum in a turbulent flow. Thus, more detailed study of the fluctuations seemed in order.

The first real analysis on the diffusive property (for scalar quantities) of a homogeneous turbulent field was Taylor's well-known work "Diffusion by Continuous Movements" (reference 12).

The mean thermal wake behind a line source of heat in a flowing isotropic turbulence has been carefully measured by Schubauer (reference 13) in the region close to the source, and by Simmons (measurements reported in reference 14) over an extended range. Taylor's theory of diffusion by continuous movements is directly applicable to the diffusion from a line source of heat in a homogeneous turbulent field, and he has

¹ Supersedes NACA TN 2124, "Spectrums and Diffusion in a Round Turbulent Jet" by Stanley Corrsin and Mahinder S. Uberoi, 1950.

made a generalization to permit application of the method in a decaying isotropic turbulence (reference 14).

In a turbulent shear flow, the only published measurements of the thermal wake of a local source seem to be those of Skramstad and Schubauer in a turbulent boundary layer.² These were reported by the experimenters (reference 15) and by Dryden (reference 16). The temperature distribution across the wake in shear flow is decidedly skew. On the other hand, in the isotropic turbulence, it is to all intents and purposes a Gaussian curve. Of course, in a homogeneous field this curve (measured close enough to the source so that the Lagrangian correlation coefficient is still effectively unity) is simply the probability density of the lateral velocity fluctuations. This relation may be roughly true for shear flow as well, in which case the contrasting results mentioned above would mean that the probability density of $v(t)$ is skew in shear flow, but Gaussian in decaying isotropic turbulence.

No measurements had been made of the fluctuations in these thermal wakes, and it was felt that some information on the nature of these might help further a general understanding of the diffusive process.

This investigation was conducted at the Aeronautics Department of The Johns Hopkins University under the sponsorship and with the financial assistance of the National Advisory Committee for Aeronautics. The authors would like to acknowledge many stimulating conversations with Dr. L. S. G. Kovátszay, and to thank Dr. F. H. Clauser for his helpful criticism. Donation of the hot-jet unit by Dr. C. B. Millikan, Director of the Guggenheim Aeronautical Laboratory at the California Institute of Technology, is greatly appreciated. Mr. Philip Lebowitz helped to set up much of the laboratory equipment.

SYMBOLS

d	diameter of orifice (1 in.)
x	axial distance from orifice
r	radial distance from jet axis
$\bar{U}$	axial component of mean velocity
$\bar{V}$	radial component of mean velocity
$\bar{W}$	tangential component of mean velocity
$\bar{U}_{max}$	maximum $\bar{U}$ at a cross section (on axis)
u	axial component of instantaneous velocity fluctuation
v	radial component of instantaneous velocity fluctuation
w	tangential component of instantaneous velocity fluctuation
$u' \equiv \sqrt{u^2}$	
$v' \equiv \sqrt{v^2}$	
θ	instantaneous temperature difference (measured above room temperature as reference)
$\bar{\theta}$	mean temperature difference (measured above room temperature as reference)

² Wieghardt has recently measured the diffusion of heat from a local source in a turbulent boundary layer (reference 17), but his source was flush with the solid surface and thus he was studying a different problem, that is, one more directly related to micrometeorological conditions.

$\bar{\theta}_{max}$	maximum mean temperature difference at a cross section
$\bar{\theta}_o$	maximum mean temperature in jet at orifice
ϑ	instantaneous temperature fluctuation ($\vartheta \equiv \theta - \bar{\theta}$)
$\vartheta' \equiv \sqrt{\vartheta^2}$	
t	time
e	voltage fluctuation
α, β	sensitivity of a diagonal hot-wire to u and v , respectively
R_{uv}	shear correlation coefficient ($\overline{uv}/u'v'$)
u_n, v_n	instantaneous contributions of $u(t)$ and $v(t)$, respectively, in a narrow frequency band of nominal frequency n ; in a Fourier series discussion, the n th harmonic of periodic $u(t)$ and $v(t)$, respectively
$u_n' \equiv \sqrt{u_n^2}$	
$v_n' \equiv \sqrt{v_n^2}$	
${}_nR_{uv}$	shear correlation coefficient for a narrow band of frequencies ($\overline{u_n v_n}/u_n' v_n'$); this function is referred to as the "shear-correlation spectrum" or, briefly, the "shear spectrum"
ϕ, ψ	phase angles
${}_nF_u, {}_nF_v$	in Fourier series analysis, ${}_nF_u \equiv a_n^2 / \sum_1^\infty a_n^2$, ${}_nF_v \equiv b_n^2 / \sum_1^\infty b_n^2$, where a_n and b_n are Fourier series coefficients
n	cyclic frequency in general; in particular, magnitude of radial coordinate in three-dimensional frequency space
n_1	cyclic frequency of one-dimensional spectra of $u(t)$ and $\vartheta(t)$
k	wave-number magnitude for three-dimensional spectra ($2\pi n/\bar{U}$)
k_1	wave-number magnitude for one-dimensional spectra ($2\pi n_1/\bar{U}$)
k_o	a reference constant with dimensions of wave numbers
$F_1(k_1)$	one-dimensional power spectrum of $u(t)$ in terms of wave number
$F_1^*(n_1)$	one-dimensional power spectrum of $u(t)$ in terms of frequency
$F(k)$	three-dimensional power spectrum of velocity fluctuation
$G_1(k_1)$	one-dimensional power spectrum of $\vartheta(t)$ in terms of wave number
$G_1^*(n_1)$	one-dimensional power spectrum of $\vartheta(t)$ in terms of frequency
$G(k)$	three-dimensional power spectrum of temperature fluctuation
R_y	transverse correlation function of u measured symmetrically about jet axis ($\overline{u_1 u_2}/u'^2$)
R_x	longitudinal correlation function of u
S_y	transverse correlation function of ϑ measured symmetrically about jet axis ($\overline{\vartheta_1 \vartheta_2}/\vartheta'^2$)
L_x	longitudinal scale of u -fluctuations
Λ_x	longitudinal scale of ϑ -fluctuations

L_y	lateral scale of u -fluctuations
Δ_y	lateral scale of ϑ -fluctuations
λ_x	longitudinal microscale of u -fluctuations
λ	lateral microscale of u -fluctuations
l	lateral microscale of ϑ -fluctuations
l_x	longitudinal microscale of ϑ -fluctuations
ξ	distance downstream from local heat source in x-direction
ζ	lateral distance, perpendicular to source line, from local heat source
Φ	dimensionless temperature ratio $(\bar{\theta}/\bar{\theta}_{max})$
$\eta = \zeta/\xi$	
Δ	standard deviation of mean-temperature distribution in wake behind local heat source
τ	pulse spacing
h	pulse height
j	pulse width

EQUIPMENT

AERODYNAMIC EQUIPMENT

The 1-inch hot-jet unit is shown schematically in figure 1. The centrifugal blower is driven by a $\frac{1}{2}$ -horsepower direct-current motor. Heat is added through two double banks of coils of No. 16 Nichrome wire. As can be seen in the sketch, a good part of the heated air is directed around the outside of the jet-air pipe in order to maintain a flat initial temperature distribution in the jet. A vacuum-cleaner blower is used to help the air through this secondary heating annulus, and this warm air is fed back into the intake of the main blower.

The section of relatively high velocity between heaters and final pressure box permits adequate mixing behind the grid, to insure thermally homogeneous initial jet air.

Figure 2 is a photograph of the unit as set up previously (reference 10); the present arrangement is essentially the same.

All turbulence measurements were made with an initial

FIGURE 1.—Schematic diagram of 1-inch hot-jet unit.

jet total head in the range from 3.5 to 5.0 inches of water. In free turbulent flows there is no detectable effect of jet Reynolds number over a much wider range of Reynolds numbers than this.

When the jet was run unheated, there was a slight temperature rise through the blower and duct. In the measurements of thermal wake behind a local heat source, correction for this ambient-temperature field was necessary. For all hot runs, the orifice air temperature was very close to 200° C, about 175° above room temperature.

Three different "local heat sources" were used:

(a) A straight diametrically strung wire of 0.008-inch Nichrome

(b) A 2-inch-diameter Nichrome ring

(c) A 4-inch-diameter Nichrome ring

Because of the extremely high turbulence levels encountered in a free jet, a measurable thermal wake could only be obtained by using source temperatures in the range from 300° to 700° C. This undoubtedly led to some local buoyancy effects, but, even with this order of temperatures, the thermal wake was barely detectable 1 inch downstream.

The Reynolds numbers of these heat-source wires were about as follows:

For straight wire on axis,

150, based on air temperature

22, based on wire temperature

For 2-inch-diameter ring,

110, based on air temperature

16, based on wire temperature

For 4-inch-diameter ring,

59, based on air temperature

9, based on wire temperature

No noticeable additional turbulence was generated by these wires, and no average momentum defect could be detected with a flattened total-head tube, even as close as $\frac{1}{4}$ inch downstream.

FIGURE 2.—The jet unit.

MEASURING EQUIPMENT

The measuring instruments used were: Total-head tube, Chromel-Alumel thermocouple, and hot-wire anemometer (also used as resistance thermometer).

The hot-wires were nominally 0.000635-centimeter platinum, about 1.5 millimeters in length, etched from Wollaston wire. The etched platinum was soft-soldered to the tips of small steel needle supports. A discussion of heat loss from a wire at various ambient temperatures is given in appendix A.

The basic hot-wire-anemometry equipment was purchased from Mr. Carl L. Thiele of Altadena, California. One of the two identical heating circuits is shown in figure 3.

The amplifier, with resistance-capacitance compensation network, is given in figure 4. The uncompensated gain is constant to within ± 2 percent over a frequency range from 3 to 12,000 cycles per second (fig. 5). With the wires and operating conditions used (time constants on the order of 1 millisecond), the over-all compensated response was good over the same range. Correct setting of the compensation network was determined by superimposing a square wave upon the hot-wire bridge (reference 18). Unfortunately, in a free turbulent shear flow the ambient disturbance is so great (because of the extremely high turbulence levels) that calibration cannot be made in the flow to be studied.

The vacuum-thermocouple signal output was measured

either with a millivoltmeter or by the average deflection rate of a fluxmeter.

The various spectra reported here were measured with a modified General Radio Type 760-A Sound Analyzer (reference 19). The changes in output stage (fig. 6) were made to eliminate the direct-current component and to obtain linear instead of logarithmic response. As modified, the sound analyzer had rather undesirable frequency-response characteristics, particularly a day-to-day shift in relative amplification of the higher-frequency ranges. The frequency-response calibration in figure 7 is plotted in terms of voltage squared, since this was the quantity ultimately measured.

The frequency pass band for this analyzer is far from the optimum rectangular shape. However, the slopes of the two sides are sufficiently steep that no appreciable error is attributable to noninfinite slopes with the spectra measured in this investigation. Figure 8 is an experimentally determined band shape. There was fair similarity of band shape over the entire frequency range. For computational purposes, an equivalent rectangular pass band was defined as indicated in the figure.

The instrument is a type recording constant-percent band width, measuring the product of power spectrum times frequency. This has obvious advantages in the high-frequency range where there is so little turbulent energy.

FIGURE 3.—Control circuits.

FIGURE 7.—Response of sound analyzer with modified output circuit.

FIGURE 8.—Filtration characteristics of sound analyzer with modified output circuit. Area of rectangle equals area under curve.

FIGURE 9.—Integrator and bucking circuit.

deflection point during the time of integration, and its reading at the end of this time ordinarily gave a small correction on the result.

In the highest-frequency range, overload considerations on the sound analyzer limited the signal drastically, and only a part of the thermocouple direct current was bucked.

For the determination of average wake temperatures behind the local heat sources, the thermocouple voltage was measured with a Leeds & Northrup type K-2 potentiometer.

Oscillograms were taken from a blue oscilloscope tube by means of a General Radio Type 651-AE camera, using fast film.

PROCEDURES

VELOCITY SPECTRUM

The power (or energy) spectrum of the longitudinal velocity fluctuations at a point in the unheated jet was measured by conventional hot-wire-anemometry technique,

with a continuously adjustable band-pass filter, as described under "Equipment."

TEMPERATURE SPECTRUM

The power spectrum of the temperature fluctuations in the heated jet was measured by using the hot-wire effectively as a simple resistance thermometer (reference 20). The amplified voltage signal was analyzed exactly as in the measurement of velocity spectra.

SHEAR-CORRELATION SPECTRUM

For the shear-correlation spectrum, the quantity to be measured is the correlation coefficient between a narrow frequency band of u -fluctuations and the same narrow frequency band of v -fluctuations, at the same point in the flow field.

The method, for any particular nominal frequency, was to pass the various voltage signals (e_1 , e_2 , $e_1 + e_2$, $e_1 - e_2$) from an $\times$ -type shear- (or v' -) meter through the band-pass filter after amplification. By appropriate combination of the mean-square values of these four signals (identical with total-shear measurement), there results

$${}_n R_{uv} \equiv \overline{u_n v_n} / \overline{u_n'^2 v_n'^2}$$

where the subscript n indicates the narrow band of nominal frequency n cycles per second. A justification for the validity of this procedure is obtainable by considering the two velocity-fluctuation components as periodic functions. Of course, this is not a real proof.

If a symmetrical $\times$ -meter is assumed, the two instantaneous voltage signals are

$$\begin{aligned} e_1 &= \alpha u + \beta v \\ e_2 &= \alpha u - \beta v \end{aligned} \quad (1)$$

For periodic fluctuations,

$$\left. \begin{aligned} u &= \sum_{n=1}^{\infty} a_n \cos(2\pi n t + \phi_n) \\ v &= \sum_{n=1}^{\infty} b_n \cos(2\pi n t + \psi_n) \end{aligned} \right\} \quad (2)$$

In this simple case, the correlation coefficient for any spectral line is merely

$${}_n R_{uv} = \cos(\phi_n - \psi_n) \quad (3)$$

If equations (2) are substituted into equations (1), it is easily shown that

$$\cos(\phi_n - \psi_n) = \frac{\overline{a_1^2} - \overline{a_2^2}}{\sqrt{(\overline{a_1^2} + \overline{a_2^2})(\overline{b_1^2} + \overline{b_2^2})}} \quad (4)$$

in complete analogy to the conventional method for measuring R_{uv} with an $\times$ -meter. The algebraic details are given in appendix B.

When the meter is not perfectly symmetrical ($\alpha_1 \neq \alpha_2$; $\beta_1 \neq \beta_2$), the formal processes, both algebraic and experimental, become excessively involved. Consequently, in

actual practice the effect of unavoidable unsymmetry in the $\times$ -meter was essentially nullified by taking double sets of readings at each frequency, rotating the instrument 180° about the axis of flow direction between sets.

VELOCITY CORRELATION FUNCTION

The double correlation R_v between longitudinal velocity fluctuation at pairs of points on opposite sides of the jet axis was measured only in the unheated jet. Hence the standard hot-wire-anemometry technique was used. The two hot-wires were always equidistant from the axis (on a diameter), so that they were under identical operating conditions.

TEMPERATURE CORRELATION FUNCTION

In the hot jet, the wires traversing symmetrically as for R_v were operated as simple resistance thermometers, so that the double temperature correlation S_v could be determined directly.

MEAN TEMPERATURES BEHIND LOCAL SOURCE

To determine mean temperatures behind a local source, traverses were made with a Chromel-Alumel thermocouple, whose voltage was measured with a Leeds & Northrup type K-2 potentiometer.

TEMPERATURE FLUCTUATIONS BEHIND LOCAL SOURCES

To determine temperature fluctuations behind local sources, the fine platinum wire was operated at small currents, so that it worked essentially as a resistance thermometer.

EXPERIMENTAL RESULTS

Mean-velocity and mean-temperature distributions for various orifice temperatures are presented in reference 10.

SHEAR-CORRELATION SPECTRUM

The spectrum of shear correlation coefficients ${}_n R_{uv} = \overline{u_n v_n} / \overline{u_n' v_n'}$ was measured in the unheated jet at $x/d=20$ at a radial station corresponding to maximum shear at this cross section. Figure 10 shows quite definitely that ${}_n R_{uv}(n)$ is a function decreasing monotonically to zero. Thus, the

FIGURE 10.—Variation of shear correlation coefficient ${}_n R_{uv}$ with frequency. Round turbulent jet. $x/d=20$; $\bar{U}=270$ centimeters per second.

hypothesis of local isotropy is seen to be verified in a very direct way. The value of the directly measured total-shear correlation coefficient $R_{uv} = \overline{uv} / \overline{u'v'}$ is indicated in the figure.

VELOCITY AND TEMPERATURE SPECTRA

The one-dimensional power spectrum $F_1(k_1)$ of the longitudinal velocity fluctuations $u(t)$ was measured at two radial positions in the unheated jet at $x/d=20$. Figure 11 gives the two spectra, one measured on the axis and one measured at about the maximum-shear location. Plotted against wave number ($k_1 = 2\pi n_1 / \bar{U}$), the two spectra are identical within the experimental scatter. The solid line drawn as approximation to the points is made up as follows:

- (a) For $0 < k_1 < 1.25$, it is Von Kármán's semiempirical formula (reference 21):

$$F_1\left(\frac{k_1}{k_0}\right) = \frac{\text{Constant}}{\left[1 + \left(\frac{k_1}{k_0}\right)^2\right]^{5/6}} \quad (5)$$

- (b) For $k_1 > 1.25$, a nonanalytical curve has been faired in

FIGURE 11.—One-dimensional power spectra of $u(t)$ measured in 1-inch unheated jet at $x/d=20$. Computed scales: $L_z=3.3$ centimeters for both stations, $\lambda_z=0.31$ centimeter for both stations.

The Von Kármán expression was used primarily to simplify the problem of extrapolation to $k_1=0$ and to shorten the work of transformation to three-dimensional spectra. (See "Velocity and Temperature Spectra" under "Analysis of Results.")

The corresponding one-dimensional power spectra of temperature fluctuations $G_1(k_1)$ were measured in the heated jet ($\bar{\theta}_0=170^\circ\text{C}$) at $x/d=20$. One spectrum is on the jet axis; one is at about the radial station of maximum heat transfer (and shear). From figure 12, it can be seen that they differ noticeably in the high-frequency range, but are essentially identical in the low- and moderate-frequency ranges. The curves used to approximate the experimental points are as follows: On the axis—the Von Kármán formula is used over the entire range. At the maximum-heat-transfer point—

- (a) For $0 < k_1 < 1.0$, the Von Kármán formula is used
- (b) For $k_1 > 1.0$, a nonanalytical curve has been faired in

Figures 13 and 14 contrast velocity spectra with temperature spectra at corresponding radial stations.

FIGURE 12.—One-dimensional power spectra of $\vartheta(t)$ measured in 1-inch heated jet at $x/d=20$.
Computed scales: $\Lambda_z = \frac{\pi}{2} G_1(0) = 2.18$ centimeters for both stations.

TRANSVERSE CORRELATION FUNCTIONS

The double correlation function $R_v = \overline{u_1 u_2} / u_1' u_2'$, measured symmetrically about the axis at $x/d=20$ in the unheated jet, is plotted in figure 15. Of course, since the wires are in identical flow conditions, $u_1' = u_2' = u'$ (say), and $R_v = \overline{u_1 u_2} / u_2^2$.

The double correlation function $S_v = \overline{\vartheta_1 \vartheta_2} / \vartheta_1' \vartheta_2'$ in the heated jet at $x/d=20$ is plotted in figure 16. Since this was also measured symmetrically, $S_v = \overline{\vartheta_1 \vartheta_2} / \vartheta^2$, where $\vartheta_1' = \vartheta_2' = \vartheta'$ (say).

Clearly, the range of measurable temperature correlation exceeds the range of measurable velocity correlation by an amount greater than can be attributed simply to the fact that the hot jet is wider than the unheated jet (reference 10).

MEAN THERMAL WAKES BEHIND LOCAL HEAT SOURCES

Typical radial distributions of average temperature behind a straight (diametrical) wire, a 2-inch-diameter ring, and a 4-inch-diameter ring at $x/d=20$ in the unheated jet are shown in figures 17, 18, and 19, respectively. The points in these figures are not direct experimental points, but merely

FIGURE 13.—One-dimensional spectra of $u(t)$ and $\vartheta(t)$ on axis of 1-inch jet at $x/d=20$.

serve to indicate the faired results for different distances downstream. All these have been corrected for the previously mentioned small ambient-temperature field in the unheated jet. There was rather large scatter (illustrated only in fig. 20) due to the small temperature differences measured and to the extremely large degree of fluctuation present. The 4-inch ring is slightly outside of the fully turbulent jet core (reference 9); consequently the results for this case are not of direct interest in a study of fully developed turbulence. The figures show that each of the thermal wakes possesses similarity well within the accuracy of measurement.

All of the thermal wakes spread linearly in the measured range (figs. 21, 22, and 23). From Taylor's theory of diffusion by continuous movements, this simply indicates that, for the maximum downstream station studied, the Lagrangian correlation coefficient of the v -fluctuations has still not departed appreciably from unity.

For a straight-line source at the jet axis, because of con-

FIGURE 22.—Spread of heat from 2-inch-diameter-ring source in unheated jet. $x/d=20$. $\xi_1, \xi_2=\xi$ at which $\bar{\theta}=\frac{1}{2}\bar{\theta}_{max}$.

FIGURE 23.—Spread of heat from 4-inch-diameter-ring source in unheated jet. $x/d=20$. $\xi_1, \xi_2=\xi$ at which $\bar{\theta}=\frac{1}{2}\bar{\theta}_{max}$.

servation of heat, it follows immediately from similarity and linear spread that the maximum temperature at a cross section in the wake $\bar{\theta}_{max}$ must decrease hyperbolically with increasing downstream distance. Let $\bar{\theta}/\bar{\theta}_{max}=\Phi(\eta)$, where $\eta=\xi/\delta$ and δ is some characteristic width of the wake, for example, the ξ at which $\Phi=\frac{1}{2}$; conservation of heat gives

$$\int_0^{\infty} \bar{\theta} d\xi = \text{Constant} \quad (6)$$

where the mean-velocity changes are neglected. Then,

$$\bar{\theta}_{max}\delta = \text{Constant}/I_1 \quad (7)$$

where

$$I_1 = \int_0^\infty \Phi(\eta) d\eta$$

The same is true of the annular wake in the range of ξ so small that $\delta \ll r$.

Single traverses were also made behind a straight-line heat source for two other cases:

(a) With the line source set perpendicular to r at a radius of 1 inch, a temperature traverse was made in the r -direction, at $\xi = \frac{1}{2}$ inch (fig. 24)

(b) With the line source set on a diametral line, a temperature traverse was made perpendicular to r at a radius of 1 inch; $\xi = \frac{1}{2}$ inch (fig. 25)

TEMPERATURE FLUCTUATIONS BEHIND LOCAL HEAT SOURCE

As can be anticipated, the temperature fluctuations close behind a local heat source are quite different in nature from the velocity fluctuations at the same point or from the temperature and velocity fluctuations in a turbulent flow with over-all heat transfer. Since a suitable source produces no additional turbulence,³ the velocity fluctuations should be

FIGURE 24.—Temperature behind line source of heat in unheated jet. $x/d=20$; $\xi=1/2$ inch. Line source set perpendicular to r at a radius of 1 inch. Traverse made in r -direction.

FIGURE 25.—Temperature behind line source of heat in unheated jet. $x/d=20$; $\xi=1/2$ inch. Line source set on a diametral line. Traverse made perpendicular to r at a radius of 1 inch.

³ An ideal source would also produce no average momentum defect. However, as mentioned previously, the momentum wakes of the local sources were relatively so small as to be completely undetectable as close as $\frac{1}{4}$ inch downstream.

the same as in undisturbed flow. On the other hand, the "turbulent" thermal wake close to the source must be simply a very narrow laminar thermal wake which is fluctuating in direction as $v(t)$ fluctuates. Since all of the fluid outside of this unsteady laminar wake is of constant temperature and the temperature fluctuations can only be positive, the general character of the oscillogram of $\vartheta(t)$ in figure 26 is understandable. These records were taken about $\frac{3}{8}$ inch downstream from the straight-line heat source, and about $\frac{1}{16}$ inch off the wake axis. All of the oscillograms were made with *insufficient compensation* for the hot-wire thermal lag, in order to suppress the (high frequency) noise and thus permit the basic form of $\vartheta(t)$ to stand out. From these two oscillograms of $u(t)$ and check measurements of the turbulence levels for the two cases, it appears that the source wire has made no appreciable change in the turbulence.

Measurements of the intensity of the temperature fluctuations across a section at $\xi=0.4$ inch are given in figure 27.

FIGURE 26.—Oscillograms of velocity and temperature fluctuations.

FIGURE 27.—Temperature fluctuations behind line source of heat in center of unheated jet. $x/d=20$; $\xi=0.4$ inch.

In the same vicinity the values of $u'/\bar{U}$ and $v'/\bar{U}$ are on the order of 20 percent. The extremely high values of $\vartheta'/\bar{\theta}$ are not surprising since the mean temperature difference is due only to the presence of the fluctuation. Since the simple-resistance-thermometer theory is based upon the assumption of small fluctuations compared with absolute temperature (reference 20), it is expected that these measurements are about as accurate as the measurements of much lower $\vartheta'/\bar{\theta}$ in the hot jet (reference 10).

ANALYSIS OF RESULTS

SHEAR-CORRELATION SPECTRUM

A very convenient check upon the shear-spectrum measurements can be gotten by the simple expedient of computing the total (or "net") turbulent shear correlation coefficient (which was also directly measured) from this spectrum and the turbulent-energy spectrum. Again, an elementary Fourier series treatment serves to justify (not prove) the intuitive idea that the total correlation coefficient R_{uv} is simply a weighted average of the ${}_n R_{uv}$ (i. e., the cosines of the phase angles), weighted simply by the product of the square roots of the energy spectra of u and v . The calculation is given in appendix B, and yields the relation

$$R_{uv} = \sum_{n=1}^{\infty} ({}_n F_u {}_n F_v)^{1/2} {}_n R_{uv} \quad (8)$$

Unfortunately, 25 cycles per second is the lower limit of the measured frequency range, so that some extrapolation must be made to lower frequencies which contain much of the turbulent energy. Since no theoretical basis yet exists to guide this extrapolation (like the Von Kármán formula in the case of energy spectrum), guesses had to be made as to the maximum and minimum of reasonable-looking extrapolation curves. These are plotted in figure 28, along with the energy spectrum of the u -fluctuations. Since no spectrum of the v -fluctuations was measured, the expression actually used for computing R_{uv} is

$$R_{uv} = \int_0^{\infty} \bar{F}_1(k_1) {}_n R_{uv} dk_1 \quad (9)$$

The best of the three extrapolations tried (extrapolation ③) gives $R_{uv}=0.46$, which is satisfactorily close to the directly

FIGURE 28.—Shear spectrum and power spectrum in 1-inch unheated jet at $x/d=20$ in region of maximum shear.

measured value of 0.44, especially since there is no reason to suppose that the spectrum of the v -fluctuations is identical with the spectrum of the u -fluctuations, except in the range of local isotropy.

VELOCITY AND TEMPERATURE SPECTRA

The one-dimensional spectra of velocity and temperature fluctuations, as plotted in figures 11 and 12, respectively, are area-normalized; that is, they are defined such that

$$\int_0^{\infty} \bar{F}_1(k_1) dk_1 = 1.0 \quad (10)$$

$$\int_0^{\infty} \bar{G}_1(k_1) dk_1 = 1.0 \quad (11)$$

However, the original measurements were made on an *absolute-value* basis, so that the total fluctuation levels $u'/\bar{U}$ and $\vartheta'/\bar{\theta}$ could be used as checks on the spectra. The spectra as measured were $F_1^*(n_1)$ and $G_1^*(n_1)$, defined such that, ideally,

$$\int_0^{\infty} F_1^*(n_1) dn_1 = \overline{u^2} \quad (12)$$

$$\int_0^{\infty} G_1^*(n_1) dn_1 = \overline{\vartheta^2} \quad (13)$$

Integration of F_1^* as indicated in equation (12) yielded the following:

On the axis ($r=0$),

$$\frac{1}{\bar{U}} \left(\int_0^{\infty} F_1^* dn_1 \right)^{1/2} = 0.28$$

($u'/\bar{U}=0.22$, directly measured)

In the maximum-shear region ($r=4.0$ cm),

$$\frac{1}{\bar{U}} \left(\int_0^{\infty} F_1^* dn_1 \right)^{1/2} = 0.52$$

($u'/\bar{U}=0.40$, directly measured)

Similar integration of the measured temperature spectrum in the heated jet yielded the following:

On the axis ($r=0$),

$$\frac{1}{\bar{\theta}} \left(\int_0^{\infty} G_1^* dn_1 \right)^{1/2} = 0.21$$

($\vartheta'/\bar{\theta}=0.18$, directly measured)

In the maximum-shear region ($r=4.8$ cm),

$$\frac{1}{\bar{\theta}} \left(\int_0^{\infty} G_1^* dn_1 \right)^{1/2} = 0.41$$

($\vartheta'/\bar{\theta}=0.36$, directly measured)

On the jet axis, where conventional small-perturbation hot-wire theory may still be moderately accurate, the agreement is satisfactory.

It should be noted in passing that these directly measured values of $\vartheta'/\bar{\theta}$ are appreciably higher than those reported in

reference 10. No explanation for this difference is apparent.

The longitudinal scale of u -fluctuations is obtainable approximately from the power spectrum:

$$L_x = \frac{\pi}{2} F_1(0) \quad (14)$$

which follows from the fundamental Fourier transformation,

$$F_1(k_1) = \frac{2}{\pi} \int_0^\infty R_x \cos(k_1 x) dx \quad (15)$$

in the limit $k_1 \rightarrow 0$.

An analogous treatment of a temperature-fluctuation field leads to an identical expression for the longitudinal scale of ϑ -fluctuations:

$$\Lambda_x = \frac{\pi}{2} G_1(0) \quad (16)$$

Within the accuracy of measurement, the longitudinal scale of $u(t)$ was found to be the same on the jet axis and in the maximum-shear region:

$$L_x = 3.6 \text{ centimeters}$$

The same was true of the longitudinal temperature scales in the hot jet:

$$\Lambda_x = 2.4 \text{ centimeters}$$

In all these computations the measured spectra were extrapolated to zero wave number with a parabola, as first suggested by Dryden (reference 22). Approximately the same numerical values are obtained with the Von Kármán formula illustrated in the plotted curves.

In order to compare L_x in the unheated jet with Λ_x in the heated jet, L_x may be multiplied by 1.15, the jet-width ratio at $x/d=20$ for these two initial temperatures (reference 10). The "corrected" L_x is then 4.15 centimeters.

It must be recalled that the Fourier transformation relation between time spectrum and space correlation would be exactly true only if the turbulent fluctuations at a point were due to pure rectilinear translation (by $\bar{U}$) of a fixed fluctuation pattern. For the free jet flow, the extremely high turbulence levels make such a transformation very uncertain. Therefore, equations (14) and (16) (and the resulting scales) can only be considered as crude approximations.

The longitudinal microscale,

$$\lambda_x = \left[-\frac{2}{R_x''(0)} \right]^{1/2} \quad (17)$$

may also be computed approximately from the one-dimensional power spectrum, by

$$\frac{1}{\lambda_x^2} = \frac{1}{2} \int_0^\infty k_1^2 F_1(k_1) dk_1 \quad (18)$$

(Primes signify differentiation when applied to correlations and spectra.)

Again, an analogous approach to temperature fluctuations gives

$$\frac{1}{\Lambda_x^2} = \frac{1}{2} \int_0^\infty k_1^2 G_1(k_1) dk_1 \quad (19)$$

Unfortunately, the high-frequency ranges of the G_1 's are too uncertain to permit reasonable extrapolation and the use of equation (19), although it can be seen from figure 13 that $\lambda_x > l_x$. However, equation (18) has been used to compute the longitudinal velocity microscale. Figure 29 is a plot of the integrand of equation (18). The integration and appropriate computation give

$$\lambda_x = 0.44 \text{ centimeter}$$

and the same value for both radial positions.

Since the turbulence on the axis of such a jet seems to be rather isotropic (the experimental evidence is that $\overline{uv}=0$ and $u' \approx v'$), the lateral microscale

$$\lambda = \left[-\frac{2}{R_y''(0)} \right]^{1/2} \quad (20)$$

is of the order of $\lambda_x/\sqrt{2}$; that is,

$$\lambda \approx 0.31 \text{ centimeter}$$

With the assumption of isotropic turbulence on the jet axis, it is possible to compute the three-dimensional power spectrum $F(k)$ from the one-dimensional spectrum $F_1(k_1)$. Heisenberg (reference 23) has given the inverse transformation

$$F_1(k_1) = \frac{1}{4} \int_{k_1}^\infty \frac{F(k)}{k^2} (k^2 - k_1^2) dk \quad (21)$$

and the desired $F(F_1)$ is readily found to be

$$F(k_1) = 2k_1 [k_1 F_1''(k_1) - F_1'(k_1)] \quad (22)$$

A three-dimensional spectrum computed in this way is given in figure 30.

The corresponding spectral transformations for the three-dimensional isotropic fluctuation field of a scalar quantity

FIGURE 29.—Viscous dissipation and microscale λ on axis of 1-inch jet. $x/d=20$;

$$\frac{1}{\lambda^2} = \frac{1}{2} \int_0^\infty k_1^2 F_1(k_1) dk_1; \lambda = 0.31 \text{ centimeter.}$$

FIGURE 30.—General nature of three-dimensional spectra on jet axis. $x/d=20$

(temperature, for example) are simply (reference 24)

$$G_1(k_1) = \frac{1}{2} \int_{k_1}^{\infty} \frac{G(k)}{k} dk \quad (23)$$

and

$$G(k_1) = -2k_1 G_1'(k_1) \quad (24)$$

With the assumption of isotropic temperature fluctuations on the jet axis, equation (24) has been used to compute $G(k)$.

The three-dimensional velocity and temperature spectra on the jet axis are very nearly the same—provided that the isotropy assumption is reasonably good. The curve in figure 30, which shows the general nature of both F and G , is simply the transformation of the Von Kármán approximations to F_1 and G_1 .

It must be recalled, however, that F_1 is in the unheated jet, while G_1 is in the heated jet. Although the results of references 9 and 10 indicate no essential change in the detailed dynamics of jet turbulence as a result of moderate increase in jet temperature, there is an appreciable increase in jet width at a given x/d . As mentioned earlier, the width ratio between $\bar{\theta}_0=175^\circ$ and $\bar{\theta}_0=0^\circ$ is about 1.15 at $x/d=20$.

TRANSVERSE CORRELATION FUNCTIONS

The integral area under the velocity correlation function (fig. 15) may be considered to give a sort of lateral scale of turbulence in the jet, although the result is not associated with any particular region in the jet. The conventional expression

$$L_v = \int_0^{\infty} R_v(r) dr \quad (25)$$

gives a scale, $L_v=0.67$ centimeter.

If a lateral temperature scale is defined in similar fashion,

$$\Lambda_v = \int_0^{\infty} S_v(r) dr \quad (26)$$

then for the heated jet at $x/d=20$ it turns out that $\Lambda_v=0.77$ centimeter from the function as given in figure 16.

Appropriate comparison of these transverse scales may be had if L_v is multiplied by the jet-width ratio: $1.15L_v=0.77$ centimeter, the same value as Λ_v . However, the two correlation functions that yield these net areas are still quite

different in shape. The contrast is shown in figure 31. Clearly, even though the net areas are identical, there is nonzero temperature correlation over appreciably greater distances.

A rough approximation to the microscale of turbulence can be gotten by guessing at the osculating parabola for $\Delta r=0$. In this particular case "guessing" is more appropriate than "fitting," since the job is entirely extrapolatory in nature. Figure 32 (a) shows the vertex region of R_v with the parabola that corresponds to

$$\lambda = \left[-\frac{2}{R_v''(0)} \right]^{1/2} = 0.28 \text{ centimeter} \quad (27)$$

This value is in surprisingly good agreement with the 0.31 centimeter obtained from the power spectrum on the axis. In fact, the agreement must be regarded as fortuitous, since the difference is appreciably less than the experimental uncertainty.

If the temperature-fluctuation field is again considered analogously, the transverse microscale of temperature fluctuations (fig. 32 (b)) is

FIGURE 31.—Comparison of transverse correlation functions. 1-inch heated jet.

(a) Lateral microscale of u -fluctuations.(b) Lateral microscale of θ -fluctuations.FIGURE 32.—Estimates of microscales. 1-inch jet. $x/d=20$.

$$l = \left[-\frac{2}{S_v''(0)} \right]^{1/2} = 0.43 \text{ centimeter} \quad (28)$$

For comparison, $1.15\lambda = 0.32$.

MEAN THERMAL WAKES BEHIND LOCAL HEAT SOURCES

The rate of spread of the thermal wake close behind a local source of heat was first used by Schubauer (reference 13) as a means of measuring the intensity of lateral velocity fluctuations $v'/\bar{U}$. A detailed discussion of this technique has been given by Taylor (reference 14) and need not be repeated here. The results of such a computation, compared with direct $\times$ -meter measurements of $v'/\bar{U}$, are as follows:

r (in.)	$\left(\frac{v'}{\bar{U}}\right)_{\text{wake}}$	$\left(\frac{v'}{\bar{U}}\right)_{\times\text{-meter}}$
0	0.18	0.185
1	0.22	0.20
2	0.40	0.30

The $\times$ -meter measurements were corrected for the effects of both u' and $\bar{u}v$ upon the slightly unsymmetrical meter.

It is possible to get some additional information about the fluctuation field by computation from the turbulent-heat-transfer equation. In particular, an estimate of the distribution $\bar{\theta}v$ across a section of the thermal wake behind the line source may be made as follows.

The steady turbulent-heat-transfer equation for low velocity (negligible viscous dissipation to heat), negligible molecular heat conduction, and constant density is, in Cartesian tensor notation,

$$\bar{U}_i \frac{\partial \bar{\theta}}{\partial x_i} = -\frac{\partial}{\partial x_k} (\bar{\theta} u_k) \quad (29)$$

For the region in the immediate vicinity of the jet axis, assume that conditions approximate those in a homogeneous field of turbulence; that is, $\bar{V} = \bar{W} = 0$ and $\bar{U} = \text{Constant} = \bar{U}_{\max}$.

Then equation (29) becomes simply

$$\bar{U}_{\max} \frac{\partial \bar{\theta}}{\partial \xi} \approx -\frac{\partial}{\partial \xi} (\bar{\theta} u) - \frac{\partial}{\partial \xi} (\bar{\theta} v) \quad (30)$$

The assumption of small turbulence level implies $\bar{\theta} u \ll \bar{\theta} \bar{U}_{\max}$ and hence

$$\bar{U}_{\max} \frac{\partial \bar{\theta}}{\partial \xi} \approx -\frac{\partial}{\partial \xi} (\bar{\theta} v) \quad (31)$$

This would be a good approximation in turbulence far behind a grid placed in a uniform stream, but is certainly rather crude here.

The final assumption, that of similarity in the thermal wake, is well-supported by the experimental results. Then let

$$\frac{\bar{\theta}}{\bar{\theta}_{\max}} = f\left(\frac{\xi}{\Delta}\right) \equiv f(\eta) \quad (32)$$

where Δ is the standard deviation of the mean-temperature distribution, and, according to the theory of diffusion by continuous movements, is therefore proportional to the standard deviation of the probability density of $v(t)$ as well. Specifically, for a small ξ in a homogeneous turbulent flow,

$$\Delta = \frac{v'}{\bar{U}} \xi \quad (33)$$

Similarity also implies that

$$\bar{\theta}v = \bar{\theta}_{\max} \bar{U}_{\max} \omega(\eta) \quad (\text{say}) \quad (34)$$

Equation (7) may be written

$$\bar{\theta}_{\max} \Delta = \text{Constant} \quad (7a)$$

Then, with equations (32), (34), and (7a), equation (31) may be transformed to

$$\frac{d\omega}{d\eta} = \frac{d\Delta}{d\xi} \frac{d}{d\eta} (\eta f) \quad (35)$$

or, with equation (33),

$$\frac{d\omega}{d\eta} = \frac{v'}{\bar{U}_{\max}} \frac{d}{d\eta} (\eta f) \quad (36)$$

Since $v'/\bar{U}_{\max}$ is constant in this approximation,

$$\omega(\eta) = \frac{v'}{\bar{U}_{\max}} \eta f(\eta) + \text{Constant}$$

and the boundary condition, $\omega = 0$ at $\eta = 0$, gives finally

$$\frac{\bar{\theta}v}{\bar{\theta}_{\max} \bar{U}_{\max}} = \frac{v'}{\bar{U}_{\max}} \frac{\xi}{\Delta} \frac{\bar{\theta}}{\bar{\theta}_{\max}} \quad (37)$$

which is conveniently written in the form

$$\frac{\bar{\theta}v}{\bar{\theta}_{\max} \bar{U}_{\max}} = \frac{\theta}{\bar{\theta}_{\max}} \frac{\xi}{\xi} \quad (38)$$

In figure 33 this function is plotted against ξ/ξ for the traverse $\frac{1}{2}$ inch downstream from the straight-wire heat source across the jet center.

FIGURE 33.—Thermal wake behind straight-line heat source. Temperature-velocity correlation computed from $\bar{\theta}/\bar{\theta}_{\max}$. $\xi = 0.5$ inch.

DISCUSSION

LOCAL ISOTROPY

The monotonic decrease to zero in shear correlation coefficient with increasing frequency seems to be decisive evidence for the existence of local isotropy at sufficiently high Reynolds numbers. It is interesting to note that the spectral region of negligible shear ($n_1 > 1000$ cps in the present particular determination, for example) contains only about 1.5 percent of the turbulent kinetic energy in $\bar{u}^2$. Of course, this is by no means an indication of the importance of the existence of local isotropy in a turbulent shear flow. A more pertinent comparison would be with figure 29, which shows in effect dissipation as a function of frequency. From this it appears that about 90 percent of the dissipation of turbulent kinetic energy to heat takes place in essentially isotropic turbulence. This permits the use of the Taylor expression for dissipation in isotropic turbulence (reference 25). Of course it also implies that the isotropic relation between longitudinal and lateral microscales, $\lambda_x = \sqrt{2} \lambda$, will be fairly accurate even in the region of high turbulent shear. Furthermore, it implies a universal dimensionless spectral function for all turbulent flows, in the high-frequency region. For turbulence at this Reynolds number, it appears that a universal part of the spectrum exists only for $k_1 > 7.9$, which is well beyond the point of slope $-\frac{5}{3}$. In fact, the " $-\frac{5}{3}$ point" in this spectrum is just at $k_1 = 1.0$.

At this point a few remarks on the appropriate type of measurement for verification of local isotropy may be in order. In particular, a careful distinction must be made between the shear spectrum ${}_n R_{uv}$ as presented in this report and the power spectrum of the randomly fluctuating quantity uv which might be measured with a multiplying circuit followed by a frequency analyzer.

Local isotropy specifies that restriction to a sufficiently small domain in a turbulent shear flow shows up isotropy in the various statistical properties that are studied within that domain. It implies that the frequency (or wave-number) vector must be large in magnitude. Clearly then a good indication of isotropy is zero correlation between orthogonal velocity-fluctuation components; this means that the highest-frequency parts of u , v , and w are uncorrelated with each other. Hence it is clear that if $\overline{u_n v_n}$ decreases to zero with increasing frequency faster than the product $u_n' v_n'$ decreases to zero, local isotropy exists. In terms of coefficient, this merely requires that ${}_n R_{uv}$ decrease to zero eventually.

Now consider the fluctuating quantity uv . In a turbulent shear flow $\overline{uv} \neq 0$, so that uv consists of a direct-current component with superimposed random fluctuations. Since the conventional electronic techniques eliminate the direct current, the quantity to be analyzed would be $uv - \overline{uv}$ as a function of time. If local isotropy were present, the lower frequencies of u and v would be rectified in the multiplying process, and therefore the oscillogram and power spectrum of $uv - \overline{uv}$ would have relatively great emphasis on the high-frequencies. In other words, if the naively measured power spectrum of uv were used as an indication of local isotropy, it would show a trend opposite to that of $\overline{u_n v_n}$; that is, it would

decrease more slowly than the product $u_n' v_n'$. In general, the measurement of ${}_n R_{uv}$ seems like a much more specific and direct approach than the measurement of the power spectrum of uv . Presumably, a (somewhat more complicated) Fourier series discussion like that in appendix B could also be carried out for the power spectrum of uv .

VELOCITY AND TEMPERATURE SPECTRA

The apparent identity of the velocity power spectra $F_1(k_1)$ on the jet axis and in the region of maximum shear is only approximate and has been determined only down to $k_1 = 0.1$. There still exists the possibility of measurable divergence in the lowest wave-number range. The good degree of agreement indicates that, in diffusing from the region of maximum production (near the maximum-shear region) to the region of maximum dissipation (on the jet axis), the turbulent kinetic energy has not done any gross migrating in the wave-number space.

On the other hand, the apparent decided difference between temperature power spectra measured on the axis and in the maximum-heat-transfer region seems to indicate such a migration. However, the considerable scatter at the highest measured frequencies renders definite conclusions impossible.

Somewhat more specific conclusions can be drawn from the comparison between one-dimensional velocity and temperature spectra. On the jet axis, for example, in spite of distinct differences between these two spectra, it turns out that within the experimental scatter (which is considerable) the three-dimensional power spectra may be much more nearly identical. The fact that they did in fact come out to be identical over a wide range of wave number when computed from the empirically fitted Von Kármán formula must certainly be regarded as pure chance. This is true not only because of the experimental uncertainty, but also because these spectra were measured in two similar but different flows, whose characteristic lengths probably differed by 15 percent.

KINEMATIC AND THERMAL SCALES

From the extrapolated zero-wave-number intercepts of the one-dimensional spectra, the following longitudinal scales were obtained at $x/d = 20$:

$$L_x = 4.15 \text{ centimeters}$$

$$\Lambda_x = 2.4 \text{ centimeters}$$

This L_x is 15 percent greater than the unheated-jet value, to allow for the greater width of the heated jet. Thus, $L_x/\Lambda_x = 1.7$. In a homogeneous, isotropic field of velocity and temperature fluctuations, it turns out (reference 24) that, if the three-dimensional power spectra of velocity and temperature are proportional, $L_x/\Lambda_x = 1.50$. It may also be noted that, if the measured ratio were in an isotropic field, $L_y = \frac{1}{2} L_x$ and $\Lambda_y = \Lambda_x$, so that $L_y/\Lambda_y = 0.85$. The ideal value would be 0.75. Actually, the integrals of the transverse correlation functions R_y and S_y are considerably less than the scales that would be expected, according to these relations, in a homogeneous isotropic turbulence.

On the other hand, the relative values of longitudinal and lateral kinematic microscales follow the isotropic relation,

$\lambda_x = \sqrt{2}\lambda$, at least within the experimental uncertainty. This is on the order of ± 25 percent in the case of the parabola "fitted" at the vertex of R_y .

Unfortunately, the temperature spectrum on the jet axis is not extended sufficiently far to permit computation of longitudinal microscale l_x there. The spectra in figure 13 show only that l_x is considerably less than λ_x ; that is, l_x is considerably less than 0.44 centimeter. It may be remarked in passing that isotropy for a scalar quantity means equality of longitudinal and lateral correlation functions. The lateral microscale, $l = 0.43$ centimeter, obtained by "fitting" a parabola at the vertex of S_y seems of reasonable magnitude relative to $1.15\lambda = 0.32$ centimeter.

TRANSVERSE CORRELATION FUNCTIONS

Of course, the reason L_y and Λ_y as determined by integration of functions R_y and S_y are not related isotropically to L_x and Λ_x is that over most of the range of Δr the probes are in decidedly nonisotropic turbulence. Thus, there is no reason to expect $L_y = \frac{1}{2}L_x$ or $\Lambda_y = \Lambda_x$, when L_x and Λ_x are computed from the spectra.

An examination of the behavior of these two symmetrically measured correlation functions shows that there is nonzero correlation over a considerable part of the jet, but that the relatively small scales result from the rather extensive regions of negative correlation. This behavior is emphasized by a comparison of R_y with the corresponding function in some typical isotropic turbulence downstream of 1-inch-mesh grid (reference 26). Figure 34 shows the contrast clearly.

It is conceivable that such an extended region of negative correlation is characteristic of turbulent shear flow. However, until someone establishes this in a shear flow whose transverse extent is very large compared with the maximum correlation distance, it may be safer to guess that the "excess" amount of negative correlation is simply due to a slight irregular waving of the jet as a whole. In reference 9 it was assumed that, since R_y actually goes to zero at large values of Δr , there is no over-all "whipping" of the jet. However, such a conclusion does not appear to be completely warranted.

FIGURE 34.—Transverse velocity correlation functions. $R_y = \overline{u_1 u_2} / \overline{u^2}$ in round jet; $q = \overline{u_1 u_2} / \overline{u^2}$ in isotropic turbulence.

In the section entitled "Transverse Correlation Functions" under "Analysis of Results," it was found that in the heated jet $L_y \approx \Lambda_y$. On the other hand, it is well-known that the lateral rate of transfer of heat is appreciably greater than the lateral rate of transfer of momentum, as was first found by Ruden (reference 27) from mean-velocity and mean-temperature measurements. Since diffusion is essentially Lagrangian in nature, while L and Λ are Eulerian scales, the above results are not necessarily in contradiction. The appreciably greater distance over which $S_y \neq 0$ (as contrasted with R_y) may, however, be related to the fact that the mean thermal jet diameter is appreciably greater than the mean momentum jet diameter.

PROBABILITY DENSITY OF $v(t)$ AND $w(t)$

The mean-temperature distribution close behind the straight-line heat source on the jet axis is effectively symmetrical, and closely resembles a Gaussian curve in shape (fig. 20); this shows that the probability density of $v(t)$ on the axis is more or less Gaussian, as in isotropic turbulence.

The mean-temperature distributions close behind the two ring heat sources are decidedly skew. However, some of this skewness seems to be due simply to the curvature of the line sources. Therefore, the temperature distribution across the wake of a straight wire set tangent to the circle $r=1$ inch was measured. Neglecting the effects of mean-velocity gradient, this curve (fig. 24) is proportional to the probability density of the radial velocity fluctuation $v(t)$ in the shear region. It is seen to be slightly skew; the skewness factor

$$S = \frac{\overline{v^3}}{(\overline{v^2})^{3/2}} \approx -0.1$$

is computed directly from this curve. The thermal wake measurements of Skramstad and Schubauer behind a line source in a turbulent boundary layer (reported in reference 16) show a skewness of 0.38. The differences in sign and magnitude of these two skewness factors suggest lateral turbulence-level gradient as the cause. The gradients in $v'/\overline{U}$ are of opposite sign in these two flows.

Calculation from figure 25 shows that the probability density of the tangential fluctuation $w(t)$ is symmetrical. It may be noted that on the axis of such an axially symmetric flow there is no distinction between radial and tangential velocity fluctuation; hence figure 20 also applies to $w(t)$ on the axis.

TEMPERATURE FLUCTUATIONS BEHIND LOCAL HEAT SOURCE

The extremely high temperature-fluctuation levels ($\sigma'/\bar{\theta} > 1.0$) encountered in the wake of the line heat source are easily understood from a brief consideration of the nature of the temperature field. Close behind the source, there is just a single narrow laminar thermal wake which is being blown in random deviations from the ξ -direction by the turbulent fluctuations. The gross turbulent thermal wake is simply the wedge-shaped region over which this relatively narrow wake wanders. Hence the total thermal signal at any fixed point in the gross wake consists simply

of a series of pulses, where each pulse corresponds to an occasion upon which the laminar wake swept over the point. Obviously, the frequency of occurrence of pulses will decrease monotonically with increasing transverse distance from the center of the gross wake.

If this type of temperature signal is represented schematically by periodic square pulses of height h , width j , and fundamental wave length τ (fig. 35), then it can be easily deduced that the fluctuation level is

$$\frac{\vartheta'}{\bar{\vartheta}} = \sqrt{\frac{\tau}{j} - 1}$$

where it is recalled that $\vartheta = \theta - \bar{\theta}$ by definition.

Two pulse spacings of interest are

$$(1) \tau = 2j; \text{ then } \vartheta'/\bar{\vartheta} = 1.0$$

$$(2) \tau \rightarrow \infty; \text{ then } \vartheta'/\bar{\vartheta} \rightarrow \infty$$

Hence, the measured results for $\vartheta'/\bar{\vartheta}$ seem quite reasonable in both order of magnitude and in qualitative behavior across the gross thermal wake of the local heat source.

The distribution of $\bar{\vartheta}v/\bar{\theta}_{max}\bar{U}_{max}$ computed from the thermal wake, plus the availability of the measurements of $\vartheta'/\bar{\theta}_{max}$ and $v'/\bar{U}_{max}$, suggests the computation of the heat-transfer correlation coefficient $\bar{\vartheta}v/\vartheta'v'$. Unfortunately, when the results of figures 33 and 27 are used, a part of the correlation-coefficient distribution reaches impossible values (slightly above unity). It must be concluded that the absolute values of $\bar{\vartheta}v/\bar{\theta}_{max}\bar{U}_{max}$ are too inaccurate for such a computation.

SOURCES OF ERROR

Aside from the specific instances mentioned earlier in this section, the sources of experimental error are much the same as outlined on pages 27 and 28 of reference 10. Additional uncertainties arise in the spectrum measurements, especially in the higher-frequency range, because of (a) rapid changes in the calibration of the sound analyzer (band peak response against frequency, fig. 7) and (b) slight static friction of fluxmeter bearings.

FIGURE 35.—Simulation of temperature signal close behind local heat source.

In general, it should be emphasized that measurements by conventional (small-perturbation) hot-wire anemometry in a flow of this high level of turbulence cannot be considered as accurate absolute-value measurements. Even on the jet axis, where the level is a minimum and conditions are relatively steady, there is no reason to believe that absolute values are better than within, say, ± 10 percent of the "correct" values. However, relative behaviors are undoubtedly determined, and dimensionless measures of the type of correlation coefficients are more accurate than absolute values.

None of the measurements reported here have been corrected for finite length of hot-wires.

SUMMARY OF RESULTS

From measurements in a round turbulent jet at room temperature of the shear correlation coefficient as a function of frequency, of velocity and temperature fluctuations with and without jet heating, and of the mean thermal wakes behind local heat sources, the following statements may be made:

1. The Kolmogoroff hypothesis of local isotropy is verified for the shear flow in a round, turbulent jet. This is concluded from the monotonic decrease to zero of the shear-correlation spectrum $(\overline{u_n v_n} / \overline{u_n' v_n'})$ with increasing frequency n .

2. The one-dimensional power spectra of longitudinal velocity fluctuations and of temperature fluctuations appear to be basically different.

3. The three-dimensional power spectra of velocity and temperature fluctuations on the jet axis seem to be roughly alike—if the assumption of isotropy in this region be true. It may then follow that the difference in the one-dimensional power spectra is a direct manifestation of the fact that velocity and heat are vector and scalar quantities, respectively.

4. The ratio of longitudinal to lateral scale (for both velocity and temperature fluctuations) is considerably larger than would follow from isotropy. Longitudinal scales are measured on the jet axis, while lateral scales involve a traverse of most of the fully turbulent core of the jet.

5. The ratio of longitudinal to lateral kinematic microscale on the jet axis is about equal to the isotropic value.

6. The longitudinal thermal microscale (from one-dimensional power spectra) is less than the longitudinal kinematic microscale, but the lateral microscales (from correlation measurements) have the opposite relation; that is, the thermal is greater than the kinematic.

7. The probability density of the radial fluctuation $v(t)$ on the jet axis is effectively Gaussian. The probability density in the shear region is slightly skew.

8. The temperature-fluctuation field in the wake behind a local heat source consists of a randomly waving narrow laminar thermal wake. Hence the temperature signal at a fixed point is a random-pulse type of function. Its fluctuation intensity is on the order of 100 percent on the center line, and increases toward the edges.

APPENDIX A

HEAT LOSS FROM A WIRE AT VARIOUS AMBIENT TEMPERATURES

In figure 3 of reference 20 a rough check was made on the temperature-variation first term in King's (reference 28) equation for the steady static heat loss from a cylinder perpendicular to a fluid stream, at low Reynolds numbers. The conventional form is

$$\frac{i^2 R}{R - R_a} = A + B\sqrt{U} \quad (\text{A1})$$

where

$$A = c_1 \frac{l^* k^*}{R_0 \alpha^*}$$

$$B = c_2 \frac{l^*}{R_0 \alpha^*} \sqrt{d^* c_p \rho k^*}$$

and

R	wire resistance
R_a	wire resistance at ambient fluid temperature
R_0	wire resistance at 0° C
l^*	wire length
d^*	wire diameter
α^*	temperature coefficient of change of resistivity of wire material
k^*	thermal conductivity of fluid at ambient temperature
c_p	specific heat of fluid at ambient temperature
ρ	density of fluid at ambient temperature
i	current
c_1, c_2	empirical constants

In reference 20 the check on A as a function of temperature was made by assuming the second term in equation (A1) to be exact in its temperature variation. Then each measured calibration point at any velocity and temperature led to a value for A .

The present check was carried out more completely; a full calibration curve was run for each ambient temperature. From this, both A and B were determined. Figure 36 gives the results compared with King's predicted variation, using physical constants from reference 29. Each point corresponds to a calibration. The vertical line through a

point obviously does not represent the over-all uncertainty; it simply shows the range of values that could be gotten by drawing *different* reasonable-looking straight lines through the same set of original calibration points. From the figure it can be seen that King's equation predicts the temperature variation of A quite well. The changes in B (the slope of the calibration line in the plot of $i^2 R / (R - R_a)$ against $\sqrt{U}$) are so small that the experimental scatter is as great as the changes predicted for these temperature differences.

FIGURE 36.—Variation of hot-wire constants with air temperature. ()_r, room temperature,

APPENDIX B

MEASUREMENT OF SHEAR-CORRELATION SPECTRUM

The two voltage signals from an ideal symmetrical X-meter are

$$\left. \begin{aligned} e_1 &= \alpha u + \beta v \\ e_2 &= \alpha u - \beta v \end{aligned} \right\} \quad (\text{B1})$$

Suppose that the velocity fluctuations are periodic:

$$\left. \begin{aligned} u &= \sum_{n=1}^{\infty} a_n \cos(2\pi n t + \phi_n) \\ v &= \sum_{n=1}^{\infty} b_n \cos(2\pi n t + \psi_n) \end{aligned} \right\} \quad (\text{B2})$$

Of course, there would be no loss in generality if ϕ_n or ψ_n were taken as zero.

The quantity to be measured is

$${}_n R_{uv} = \frac{\overline{u_n v_n}}{u_n' v_n'} \quad (\text{B3})$$

For two simple harmonic functions the correlation coefficient is simply the cosine of the phase angle. Thus,

$${}_n R_{uv} = \cos(\phi_n - \psi_n) \quad (\text{B4})$$

Substitution of equations (B2) into equations (B1), followed

by trigonometric transformation, gives

$$e_1 = \sum_1^{\infty} [(\alpha a_n \cos \phi_n + \beta b_n \cos \psi_n) \cos 2\pi n t - (\alpha a_n \sin \phi_n + \beta b_n \sin \psi_n) \sin 2\pi n t] \quad (\text{B5a})$$

$$e_2 = \sum_1^{\infty} [(\alpha a_n \cos \phi_n - \beta b_n \cos \psi_n) \cos 2\pi n t - (\alpha a_n \sin \phi_n - \beta b_n \sin \psi_n) \sin 2\pi n t] \quad (\text{B5b})$$

When these two signals are put separately through a narrow band-pass filter that passes only the n th harmonic, the two output voltages may be represented as

$${}_n e_1 = K [(\alpha a_n \cos \phi_n + \beta b_n \cos \psi_n) \cos 2\pi n t - (\alpha a_n \sin \phi_n + \beta b_n \sin \psi_n) \sin 2\pi n t] \quad (\text{B6a})$$

$${}_n e_2 = K [(\alpha a_n \cos \phi_n - \beta b_n \cos \psi_n) \cos 2\pi n t - (\alpha a_n \sin \phi_n - \beta b_n \sin \psi_n) \sin 2\pi n t] \quad (\text{B6b})$$

where K is an attenuation factor.

For brevity, write

$${}_n e_1 = K (A_n \cos 2\pi n t - B_n \sin 2\pi n t) \quad (\text{B6c})$$

$${}_n e_2 = K (C_n \cos 2\pi n t - D_n \sin 2\pi n t) \quad (\text{B6d})$$

These filtered signals go next into the vacuum-thermocouple unit, which puts out the mean-square values,

$$\begin{aligned} \frac{1}{K'} \overline{{}_n e_1^2} &= A_n^2 \overline{\cos^2(2\pi n t)} - 2 A_n B_n \overline{\cos(2\pi n t) \sin(2\pi n t)} + B_n^2 \overline{\sin^2(2\pi n t)} \\ \frac{1}{K'} \overline{{}_n e_2^2} &= C_n^2 \overline{\cos^2(2\pi n t)} - 2 C_n D_n \overline{\cos(2\pi n t) \sin(2\pi n t)} + D_n^2 \overline{\sin^2(2\pi n t)} \end{aligned}$$

where K' is an over-all attenuation factor.

But, $\overline{\cos^2} \approx \overline{\sin^2} \approx \frac{1}{2}$, and $\overline{\cos \sin} \approx 0$, over a large number of wavelengths. Thus,

$$\left. \begin{aligned} \overline{{}_n e_1^2} &\approx \frac{K'}{2} (A_n^2 + B_n^2) \\ \overline{{}_n e_2^2} &\approx \frac{K'}{2} (C_n^2 + D_n^2) \end{aligned} \right\} \quad (\text{B7})$$

Then, within the approximation,

$$\overline{{}_n e_1^2} - \overline{{}_n e_2^2} = \frac{K'}{2} (A_n^2 - C_n^2 + B_n^2 - D_n^2) \quad (\text{B8})$$

and when the expressions for A , B , C , and D are substituted, it turns out that

$$\overline{{}_n e_1^2} - \overline{{}_n e_2^2} = 2K' \alpha \beta a_n b_n \cos(\phi_n - \psi_n) \quad (\text{B9})$$

The necessity of determining α and β is ordinarily avoided with a symmetrical meter, if only the correlation coefficient is required.

The sum and difference of the two wire voltages are

$$\left. \begin{aligned} e_1 + e_2 &= 2\alpha u = 2\alpha \sum_1^{\infty} a_n \cos(2\pi n t + \phi_n) \\ e_1 - e_2 &= 2\beta v = 2\beta \sum_1^{\infty} b_n \cos(2\pi n t + \psi_n) \end{aligned} \right\} \quad (\text{B10})$$

Filtering gives

$${}_n(e_1 + e_2) = 2K\alpha a_n \cos(2\pi n t + \phi_n)$$

$${}_n(e_1 - e_2) = 2K\beta b_n \cos(2\pi n t + \psi_n)$$

Passage through the vacuum thermocouple gives

$$\left. \begin{aligned} \overline{{}_n(e_1 + e_2)^2} &= 2K' \alpha^2 a_n^2 \\ \overline{{}_n(e_1 - e_2)^2} &= 2K' \beta^2 b_n^2 \end{aligned} \right\} \quad (\text{B11})$$

Combination of equations (B11), (B9), and (B4) gives the final result:

$${}_n R_{uv} = \frac{\overline{{}_n e_1^2} - \overline{{}_n e_2^2}}{[\overline{{}_n(e_1 + e_2)^2} \overline{{}_n(e_1 - e_2)^2}]^{1/2}} \quad (\text{B12})$$

The computation of total-shear correlation coefficient from shear-coefficient spectrum suggests itself as a useful check possibility:

$$R_{uv} = \overline{uv} / u'v' \quad (\text{B13})$$

with the Fourier series for u and v ,

$$\left. \begin{aligned} u'^2 &\equiv \overline{u^2} = \frac{1}{2} \sum_1^{\infty} a_n^2 \\ v'^2 &\equiv \overline{v^2} = \frac{1}{2} \sum_1^{\infty} b_n^2 \end{aligned} \right\} \quad (\text{B14})$$

and the instantaneous cross product can be transformed to

$$uv = \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} a_n b_m (\cos \phi_n \cos 2\pi n t - \sin \phi_n \sin 2\pi n t) \times (\cos \psi_m \cos 2\pi m t - \sin \psi_m \sin 2\pi m t)$$

The time average of this expression is

$$\overline{uv} = \frac{1}{2} \sum_{n=1}^{\infty} a_n b_n (\cos \phi_n \cos \psi_n + \sin \phi_n \sin \psi_n)$$

or

$$\overline{uv} = \frac{1}{2} \sum_1^{\infty} a_n b_n \cos(\phi_n - \psi_n) \quad (\text{B15})$$

Thus,

$$u'v'R_{uv} = \frac{1}{2} \sum_1^{\infty} a_n b_n R_{uv}$$

In terms of the Fourier coefficients,

$$R_{uv} = \frac{\sum_1^{\infty} a_n b_n R_{uv}}{\left(\sum_1^{\infty} a_n^2 \sum_1^{\infty} b_n^2 \right)^{1/2}} \quad (\text{B16})$$

But $nF_u \equiv a_n^2 / \sum_1^{\infty} a_n^2$ and $nF_v \equiv b_n^2 / \sum_1^{\infty} b_n^2$ are simply the normalized one-dimensional energy spectra of u and v , respectively. Therefore,

$$R_{uv} = \sum_{n=1}^{\infty} (nF_u nF_v^{1/2})_n R_{nn} \quad (\text{B17})$$

REPORT 1041

EQUATIONS AND CHARTS FOR THE RAPID ESTIMATION OF HINGE-MOMENT AND EFFECTIVENESS PARAMETERS FOR TRAILING-EDGE CONTROLS HAVING LEADING AND TRAILING EDGES SWEEPED AHEAD OF THE MACH LINES¹

By KENNETH L. GOIN

SUMMARY

Existing conical-flow solutions have been used to calculate the hinge-moment and effectiveness parameters of trailing-edge controls having leading and trailing edges swept ahead of the Mach lines and having streamwise root and tip chords. Equations and detailed charts are presented for the rapid estimation of these parameters. Also included is an approximate method by which these parameters may be corrected for airfoil-section thickness.

Deflected controls are assumed to be located either at the wing tip or far enough inboard to prevent the outermost Mach lines from the controls from crossing the wing tip. For either of these locations, the innermost Mach lines are assumed not to cross the wing root chord. The method for determining control hinge moment resulting from wing angle-of-attack loading is valid for wing plan forms having the leading edges swept ahead of the Mach lines and having streamwise tips. The only additional restrictions are that the controls must not be influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

INTRODUCTION

Linearized theory, though neglecting viscosity and second-order effects existing in practice, is the most practical method now available for estimating the characteristics of control surfaces at supersonic speeds. A general application of this theory to control surfaces having edges swept either ahead of or behind the Mach lines is presented in reference 1. (Edges swept ahead of or behind the Mach lines are subsequently referred to as supersonic or subsonic edges.) Conical-flow solutions for various deflected control configurations are presented in reference 2. Such solutions were used in reference 3 to evaluate the characteristics of a restricted family of trailing-edge control surfaces.

In the present report a general analysis based on existing conical-flow solutions has been made which will apply to a broad range of trailing-edge control configurations having supersonic edges and will provide for a comprehensive coverage of control location, aspect ratio, taper ratio, and sweep. Equations and detailed charts are presented from which lift, pitching-moment, rolling-moment, and hinge-moment coefficients due to control deflection and hinge-moment

coefficient due to wing angle of attack, as predicted by linearized theory, may be determined in an estimated 5 percent of the time required without the use of such equations and charts. Also included is an approximate method by which these hinge-moment and effectiveness parameters may be corrected for airfoil-section thickness.

The equations and charts presented are applicable to control-surface plan forms that vary throughout the range in which the leading and trailing edges are supersonic and the root and tip chords are in a streamwise direction. Deflected controls are assumed to be located either at the wing tip or far enough inboard to prevent the outermost Mach lines from the controls from crossing the wing tip. For either of these locations, the innermost Mach lines are assumed not to cross the wing root chord. The method for calculating the hinge-moment coefficient due to wing angle of attack is valid for wing plan forms having straight supersonic edges and streamwise tips. This method is restricted only in that the controls must not lie in a region influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

SYMBOLS

M	free-stream Mach number
$\beta = \sqrt{M^2 - 1}$	
C_1, C_2	functions of Mach number used in calculating two-dimensional-flow characteristics
Λ	angle of sweep of wing leading edge, positive when swept back
Λ_{HL}	angle of sweep of control hinge line, positive when swept back
Λ_{TE}	angle of sweep of wing trailing edge, positive when swept back
b_f	span of control surface
c_f	root chord of control surface
c_{ft}	tip chord of control surface
λ_f	control-surface taper ratio (c_{ft}/c_f)
S_f	area of control surface
A_f	aspect ratio of control surface (b_f^2/S_f)
$A_f' = \beta A_f$	
M_a	area moment of control surface about hinge axis

¹ Supersedes NACA TN 2221, "Equations and Charts for the Rapid Estimation of Hinge-Moment and Effectiveness Parameters for Trailing-Edge Controls Having Leading and Trailing Edges Swept Ahead of the Mach Lines" by Kenneth L. Goin, 1950.

S_L	area of a loaded region	$C_l = \frac{\text{Rolling moment about wing root chord}}{2qbS}$	
S_{L_0}	area of part of deflected control surface lying in two-dimensional-flow region less area lying in region of overlap of conical-flow fields	$C_m = \frac{\text{Pitching moment about wing axis of pitch}}{qS\bar{c}}$	
m_0	moment of S_{L_0} about hinge axis	F_1	thickness correction factor for C_{L_i}' and C_{l_i}'
l_0	moment of S_{L_0} about control root chord	F_2	thickness correction factor for C_{h_i} and C_{m_i}'
$\bar{x}$	distance of center of loading from control hinge axis measured normal to hinge axis	F_3	thickness correction factor for C_{h_a}
$\bar{y}$	spanwise distance of center of loading from control root chord	Δp	difference between local pressure and stream static pressure
θ	slope of airfoil-section contour	C_p	pressure coefficient ($\Delta p/q$)
$t/2c$	one-half airfoil-thickness ratio measured in plane normal to control hinge axis	C_{p_0}	two-dimensional pressure coefficient $\left(\frac{2\delta}{57.3\beta\sqrt{1-a^2}}\right)$ or $\left(\frac{2\alpha}{57.3\beta\sqrt{1-q^2}}\right)$
$(t/c)_{max}$	maximum airfoil-thickness ratio measured in plane normal to control hinge axis	P'	local pressure ratio (C_p/C_{p_0})
x/c	chordwise position measured in plane normal to control hinge axis	P	average value of pressure ratio P' over conical-flow region $\left(\frac{\int P' dS_L}{S_L}\right)$
x_h/c	chordwise location of control hinge axis measured in plane normal to control hinge axis	τ	angle denoting arbitrary position of ray in conical-flow field
$(t/2c)', (x/c)'$	dimensions measured in plane normal to wing leading edge	$\tau' = \tau + \Delta_{TE}$	
x_f	distance of leading edge of control root chord behind wing axis of pitch	$t = \beta \tan \tau$	
y_f	distance of root chord of control from root chord of wing	$t' = \beta \tan \tau'$	
b	wing span	$r = \frac{1}{t}$	
c_r	wing root chord	n, r'	nondimensional coordinates used in integration of wing root and tip conical pressures
c_t	wing tip chord	η	angle of sweep of line intersecting conical-flow regions of wing at angle of attack
$\bar{c}$	mean aerodynamic chord of wing	Subscripts:	
S	area of semispan wing	δ, α	denote partial derivative of force and moment coefficients with respect to δ or α
$g = \frac{\tan \Lambda}{\beta}$		cp	denotes center-of-pressure ray location
$a = \frac{\tan \Lambda_{HL}}{\beta}$		Superscript:	
$d = \frac{\tan \Lambda_{TE}}{\beta}$		*	indicates that parameters $P, PS_L, PS_L\bar{x}, PS_L\bar{y}, t_{cp}'$, and r_{cp} refer to loss of loading from two-dimensional value rather than to actual loading
α	wing angle of attack, degrees		
δ	angle of control-surface deflection measured in streamwise direction, degrees		
q	free-stream dynamic pressure		
$C_L' = \frac{\text{Lift induced by deflected control}}{qS_f}$			
	Moment about control root chord induced by deflected control		
$C_l' = \frac{\text{Moment about control root chord induced by deflected control}}{qb_f S_f}$			
$C_m' = \frac{\text{Moment about hinge axis induced by deflected control}}{2qM_a}$			
$C_h = \frac{\text{Hinge moment}}{2qM_a}$			
$C_L = \frac{\text{Lift induced by deflected control}}{qS}$			

ANALYSIS

CHARACTERISTICS DUE TO DEFLECTION OF CONTROL SURFACES

Scope.—Existing solutions of the linearized equations of fluid motion have been used as a basis for calculating the characteristics due to deflection of trailing-edge control surfaces on wings in steady flight at supersonic speeds. These solutions, as presented in reference 2, are applicable to configurations for which the leading and trailing edges of the control are supersonic and the root and tip chords are streamwise. Two control-surface locations are considered.

The control is assumed to be located either at the wing tip or far enough inboard to prevent the outermost Mach line from the control from crossing the wing tip. For either of these locations, the innermost Mach lines are assumed not to cross the wing root chord. For these locations, deflected control-surface characteristics are functions only of Mach number and control-surface plan form. (The parameter C_h depends on control-surface location only when the control is located inboard from the wing tip and lies in a region influenced either by the interaction of the control-tip Mach cone with the wing tip or by the reflection from the wing root chord of the innermost control Mach line.) If the limitations previously mentioned are considered, the analysis is valid for all controls except those located at the wing tip and having the inboard conical-flow regions intersecting the tip. In such cases, the conical pressures on the control, as given in reference 2, are not applicable in the region influenced by the interaction of the Mach cone with the wing tip. Necessary corrections for this region can be determined by the method described in reference 4. Such corrections are not considered in the present report because of the prohibitive amount of computation involved. Results not including these corrections are presented, however, because they should be very useful as an indication of trends and should in many cases closely approximate the corrected result.

Method.—In order to determine control-surface characteristics, the two-dimensional region and the triangular segments of the conical-flow regions (fig. 1) are considered independently. The characteristics are obtained by summing the products of pressure ratio and nondimensional-area and moment-arm parameters for all parts (table I). The nature of conical flow is such that the pressure is constant along any ray from the origin of the flow field. Any infinitesimal triangle having the origin of the flow field as an apex, therefore, has its center of pressure located at two-thirds of the distance from the apex to the base. It follows that the summation of the loading of such infinitesimal triangles results in a finite triangle having its center of pressure lying on a line parallel to the base and located at two-thirds of the distance from the apex to the base. The center-of-pressure location and, consequently, the desired moment arms can therefore be determined from the location of the ray on which the center of pressure lies. General equations for the average pressure ratio and center-of-pressure ray location for each conical segment (tables II (a) and II (b)) were obtained by integrating the pressure equations of reference 2. (See appendix A.) Table II(c) presents equations for the nondimensional-area and moment-arm parameters (in terms of center-of-pressure ray location) for each conical segment. Equations pertaining to the two-dimensional region were obtained by treating

this region as a simple geometric area and are also included in table II(c). Results obtained by evaluating the general equations of table II when they become indeterminate at taper ratios of 1.0 are presented in table III.

For regions in which the two conical-flow fields overlap, the method of superposition must be used wherein the losses in pressure ratio from the two-dimensional value ($P'=1.0$) in the two conical-flow regions are additive; that is,

$$\begin{aligned} P' &= 1.0 - (1.0 - P_{mc_1}') - (1.0 - P_{mc_2}') \\ &= -1.0 + P_{mc_1}' + P_{mc_2}' \end{aligned}$$

(Subscripts mc_1 and mc_2 refer to inboard and outboard conical-flow regions, respectively.) The net effects of the pressure distribution in this region are obtained by adding the effects of the two conical-flow regions as though the flow regions did not overlap and by subtracting the effects of a two-dimensional pressure distribution. This subtraction is accomplished by use of the equations for the two-dimensional region (tables II (c) and III (b)). In calculating control hinge moments it was convenient to calculate the effects of regions I_c and II_c or III (fig. 1) and then to subtract the effects of the parts of these regions lying off the control. For controls located at the wing tip and having the inboard Mach cone intersecting the tip, a similar procedure was also used to reduce to zero the lift, pitching moment, and rolling moment contributed by the triangular part of the inboard conical-flow region lying beyond the tip. As previously mentioned for this case, a rigid application of linearized theory would require a correction, as described in reference 4, to the loading assumed in the region influenced by the interaction of the root Mach cone with the free edge. It should be pointed out that the areas influenced by such interactions become appreciable for extreme conditions and approximate results for such configurations should be used with caution.

HINGE MOMENT DUE TO WING ANGLE-OF-ATTACK CHANGE

Scope.—Conical-flow solutions for swept wings at supersonic speeds, as presented in reference 5, are used as a basis for the analysis. These solutions are applicable to wing plan forms having straight supersonic edges and streamwise tips.

As in the analysis for deflected control surfaces, only control surfaces having supersonic edges and streamwise root and tip chords are considered. The only restrictions regarding control location are that the control must not lie in a region influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

Method.—The method consists essentially of determining the hinge-moment parameter $PS_L\bar{x}$ for the flap by assuming two-dimensional loading and then subtracting the losses

resulting from the wing-root and wing-tip conical flows. The conical-flow losses are obtained by dividing the conical regions into a series of triangular segments, each having its apex at the origin of the Mach cone, and by summing the hinge-moment parameters $(PS_L\bar{x})^*$ for these segments as illustrated in figure 2. In determining $(PS_L\bar{x})^*$ for the triangular segments, integrations of the loading are necessary for obtaining P^* and $\bar{x}$. As has been previously explained for this type of conical-flow segment, it is sufficient to determine P^* and t_{cp} because the moment arm $\bar{x}$ can be determined from t_{cp} . The method for obtaining P^* and t_{cp} is illustrated in figure 3 and involves integrating the pressure losses along the bases of the segments. From integrations of the pressure losses between 0 and n_1 (or 0 and r_1'), values of P^* and n_{cp} (or r_{cp}') are obtained. Values of P^* and values of t_{cp} , corresponding to n_{cp} (or r_{cp}'), obtained in this manner are applicable to the triangular segment bounded by the Mach line, the ray $\tau=\tau_1$, and the section intersecting the Mach cone. Results have been obtained by numerical integration using Simpson's rule (reference 6) except in regions where the slopes of the pressure curves become infinite (fig. 3). In these regions, integrating coefficients, as presented in reference 7, have been used. Forms by which the integrations were made are presented in tables IV to VII. The upper parts of these forms are used for computing the pressure distributions $(1-P')$ along the sections intersecting the Mach cones (fig. 3). In the lower part of the form, the areas and area moments about n (or r') = 0 of the curves of $1-P'$ plotted against n (or r') are determined and are used to obtain P^* and t_{cp} for the corresponding triangular segments. Tables IV to VII can be used directly for calculating the loading distribution for intermediate cases or cases not included in the present report.

METHOD FOR APPROXIMATELY CORRECTING RESULTS OBTAINED FROM USE OF LINEARIZED THEORY FOR AIRFOIL-SECTION THICKNESS

Scope.—The method for approximately correcting the theoretical results for airfoil-section thickness is based on the assumption that, at any chordwise position on an airfoil having finite thickness, the ratio of conical to two-dimensional pressure is the same as that predicted by linearized theory for an infinitely thin flat plate. (This method is a variation of the method presented in reference 8.) The method can be logically applied only to configurations having similar sections at all spanwise positions affected. The method is expected to give most accurate results at moderate and high Mach numbers for thin controls located inboard from the wing tip and having relatively large areas over which the flow is two-dimensional.

Method.—On the basis of the preceding assumption, the method requires the determination of the following three factors:

$$F_1 = \frac{C_{L'}(\text{Two-dimensional with thickness})}{C_{L'}(\text{Two-dimensional flat plate})} = \frac{C_{l'}(\text{Two-dimensional with thickness})}{C_{l'}(\text{Two-dimensional flat plate})} \quad (1)$$

$$F_2 = \frac{C_{m'}(\text{Two-dimensional with thickness})}{C_{m'}(\text{Two-dimensional flat plate})} = \frac{C_h(\text{Two-dimensional with thickness})}{C_h(\text{Two-dimensional flat plate})} \quad (2)$$

$$F_3 = \frac{C_h(\text{Two-dimensional with thickness})}{C_h(\text{Two-dimensional flat plate})} \quad (3)$$

(The coefficients in equations (1) and (2) are for deflected controls, and the coefficients in equation (3) are those resulting from wing angle-of-attack loading.) Corrected values of $C_{L_i'}$, $C_{l_i'}$, $C_{m_i'}$, C_{h_i} , and C_{h_a} are obtained by multiplying the results obtained by use of the linearized theory for three-dimensional flat plates by the appropriate factors.

The factors are determined, as described in appendix B, by using the Busemann second-order approximation to determine the coefficients for sections having thickness. This approximation gives results which are generally in good agreement with results obtained by use of the more involved exact theories. The theory is not considered accurate, however, at Mach numbers for which the shocks become detached or at Mach numbers below about 1.3 (reference 9). For the general group of airfoil sections that are symmetrical about the chord plane, equations for the correction factors as derived in appendix B are:

$$F_1 = \frac{1}{\left(1 - \frac{x_h}{c}\right)} \int_{x_h/c}^{1.0} \left(1 + 2 \frac{C_2}{C_1} \frac{d \frac{t}{2c}}{d \frac{x}{c}}\right) d \frac{x}{c} \quad (4)$$

$$F_2 = \frac{2}{\left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) \left(1 + 2 \frac{C_2}{C_1} \frac{d \frac{t}{2c}}{d \frac{x}{c}}\right) d \frac{x}{c} \quad (5)$$

$$F_3 = \frac{2}{\left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) \left[1 + 2 \frac{C_2}{C_1} \frac{d \left(\frac{t}{2c}\right)'}{d \left(\frac{x}{c}\right)'}\right] d \frac{x}{c} \quad (6)$$

CHARTS PRESENTATION

Aside from the restrictions regarding location, the characteristics of deflected control surfaces are functions only of control plan form and Mach number. The effects of plan form and Mach number are determined from solutions to equations (tables I to III) involving the variables $\frac{\tan \Lambda_{HL}}{\beta}$, $\frac{\tan \Lambda_{TE}}{\beta}$, and λ_r . (For untapered controls the variables are $\frac{\tan \Lambda_{HL}}{\beta}$ and βA_r .) Figure 4 presents $\beta C_{L_i'}$, $\beta C_{l_i'}$, $\beta C_{m_i'}$, and βC_{h_i} as functions of these variables for controls located at the wing tip. Each chart of figure 4 presents the characteristics of a series of plan forms having a fixed hinge-line sweep angle (if the Mach number is considered to be fixed)

and varying trailing-edge sweep angles and taper ratios. The solid-line curves present the effects of varying taper ratio for plan forms having fixed hinge line and trailing-edge sweep angles. The characteristics of controls having constant aspect ratios are indicated in the charts for βC_{h_s} by dashed lines. Constant-aspect-ratio curves are not included in the charts for the other characteristics because, in many cases, they would be quite confusing. If desired, such curves can be drawn by simply determining the taper ratio at which the curve will intersect each of the curves of constant d from the following relation:

$$\lambda_f = \frac{2 - A_f'(a-d)}{2 + A_f'(a-d)}$$

For inversely tapered controls, the parameter $1/\lambda_f$ is used as a coordinate to avoid elongation of the curves. Calculations were made at values of λ_f and $\frac{1}{\lambda_f} = 0, 0.20, 0.40, 0.60, 0.80$, and 0.95 and at values of $A_f' = 0.8, 2.0, 4.0, 6.0, 8.0$, and 10.0 for untapered controls. Calculated results not included in the charts are presented in table VIII. The results not included in the charts are mainly for configurations having values of $\frac{\tan \Lambda_{TE}}{\beta}$ near $|1.0|$ and, consequently, having extremely large areas of induced loading on the wing. Results for such configurations are of little practical value because if these large areas are to lie entirely on the wing, as has been assumed, the wing must have a very large span or the control must have a very small chord.

Charts presenting the characteristics of deflected controls located inboard from the wing tip are presented in figures 5 and 6. These charts vary somewhat from those for controls located at the wing tip. Equations for $\beta C_{L_s}'$ and $\beta C_{m_s}'$ were simplified and found to be dependent only on $\frac{\tan \Lambda_{HL}}{\beta}$ and $\frac{\tan \Lambda_{TE}}{\beta}$. These equations, with results in chart form, are presented in figure 5. Charts for βC_{h_s} and $\beta C_{L_s}'$ (fig. 6) are presented only for normal taper ratios because the characteristics of inversely tapered controls can be obtained by entering the charts at $\frac{-\tan \Lambda_{HL}}{\beta}$, $\frac{-\tan \Lambda_{TE}}{\beta}$, and $1/\lambda_f$.

The computing form for C_{h_s} is presented in table IX and is self-explanatory. Supplementary charts for determining the loading distribution (P^* and t_{cp}) for the various triangular segments of the conical-flow regions are presented in figures 7 to 10. It should be pointed out that figures 8 and 10 can easily be used for determining the spanwise and chordwise loading of the wings considered in this report and will therefore be of value in making loads analyses.

USE

In order to use the charts for determining the characteristics of deflected controls, values of $\frac{\tan \Lambda_{HL}}{\beta}$, $\frac{\tan \Lambda_{TE}}{\beta}$, and λ_f for the configuration being considered must be determined.

These values are then used for entry into the charts, figures 4 or 5 and 6, depending on control location. The coefficients obtained from the charts have been made nondimensional by use of control geometric parameters. For determining the coefficients based on the usual wing parameters, the following equations are given (approximate thickness correction factors are included but can be neglected by letting the factors equal 1.0):

$$(C_{L_s})_c = F_1 C_{L_s}' \frac{S_f}{S} \quad (7)$$

$$(C_{L_s})_c = \frac{(C_{L_s})_c}{2b} \left(y_f + b_f \frac{C_{L_s}'}{C_{L_s}'} \right) \quad (8)$$

$$(C_{m_s})_c = \frac{(C_{L_s})_c}{\bar{c}} \left(\frac{F_2 C_{m_s}'}{F_1 C_{L_s}'} \frac{2M_a}{S_f} \sqrt{1 + \beta^2 a^2} - \beta a b_f \frac{C_{L_s}'}{C_{L_s}'} - x_f \right) \quad (9)$$

$$(C_{h_s})_c = F_2 C_{h_s} \quad (10)$$

(The subscript c indicates that the approximate thickness correction factors have been included.)

For determining the control hinge moment due to wing angle of attack, preliminary calculations are first made on the computing form of table IX. Results of these computations indicate positions in the charts (figs. 7 to 10) from which P^* and t_{cp} are to be obtained. Values from the charts are then inserted in table IX and the operations indicated in the computing form are completed. The approximate thickness correction factor can be applied by use of the following equation:

$$(C_{h_s})_c = F_3 C_{h_s} \quad (11)$$

ILLUSTRATIVE EXAMPLE

As an example of the use of the charts, the control-surface characteristics are determined for the configuration shown in figure 11. The wing is assumed to have 5-percent-thick symmetrical parabolic sections in planes normal to the control hinge line.

Lift and pitching-moment coefficients are obtained by entering the charts of figure 5 at values of $\frac{\tan \Lambda_{HL}}{\beta} = 0.40$ and $\frac{\tan \Lambda_{TE}}{\beta} = 0.35$. Hinge-moment and rolling-moment coefficients are obtained by entering the charts of figure 6 (g) at values of $\frac{\tan \Lambda_{TE}}{\beta} = 0.35$ and $\lambda_f = 0.713$. Coefficients obtained from the charts are $\beta C_{L_s}' = 0.0748$, $\beta C_{m_s}' = -0.0365$, $\beta C_{L_s}' = 0.0372$, and $\beta C_{h_s} = -0.0345$. The calculation of C_{h_s} for the example is presented in table IX. Preliminary calculations are made in table IX (a) and in column (1) of table IX (b). Values of n and r' calculated in column (1) are used to enter the charts (figs. 7 to 10). Values of P^* and t_{cp} obtained from the charts are inserted in columns (2) and (3) of table IX (b) and the computations are completed. The theoretical value of C_{h_s} is -0.0194 .

The equation for the section contour in a plane normal to the control hinge axis is

$$\frac{t}{2c} = 2 \left(\frac{t}{c} \right)_{\max} \left[\frac{x}{c} - \left(\frac{x}{c} \right)^2 \right] \quad (12)$$

The slope in this plane at any point along the airfoil is

$$\frac{d \frac{t}{2c}}{d \frac{x}{c}} = 2 \left(\frac{t}{c} \right)_{\max} \left(1 - 2 \frac{x}{c} \right) \quad (13)$$

Substitution of equation (13) in equations (4) and (5) yields the following equations for F_1 and F_2 :

$$F_1 = 1 - 4 \frac{C_2}{C_1} \left(\frac{t}{c} \right)_{\max} \frac{x_h}{c} \quad (14)$$

$$F_2 = 1 - \frac{4}{3} \frac{C_2}{C_1} \left(\frac{t}{c} \right)_{\max} \left(1 + 2 \frac{x_h}{c} \right) \quad (15)$$

For determining F_3 , the equation for the section contour in a plane normal to the wing leading edge is written as

$$\left(\frac{t}{2c} \right)' = \frac{2 \left(\frac{t}{c} \right)_{\max}}{\cos (\Lambda - \Lambda_{HL})} \left[\frac{\left(\frac{x}{c} \right)' - \left(\frac{x}{c} \right)^{1/2}}{1 + K \left(\frac{x}{c} \right)'} \right] \quad (16)$$

where

$$K = \tan (\Lambda - \Lambda_{HL}) \tan (\Lambda - \Lambda_{TE})$$

The slope of the airfoil contour in this plane is

$$\frac{d \left(\frac{t}{2c} \right)'}{d \left(\frac{x}{c} \right)'} = \frac{2 \left(\frac{t}{c} \right)_{\max}}{\cos (\Lambda - \Lambda_{HL})} \left\{ \frac{1 - 2 \left(\frac{x}{c} \right)' - K \left(\frac{x}{c} \right)^{1/2}}{\left[1 + K \left(\frac{x}{c} \right)' \right]^2} \right\} \quad (17a)$$

or in terms of x/c

$$\frac{d \left(\frac{t}{2c} \right)'}{d \left(\frac{x}{c} \right)'} = \frac{2 \left(\frac{t}{c} \right)_{\max}}{\cos (\Lambda - \Lambda_{HL})} \left[1 - 2 \frac{x}{c} + \frac{K}{1 + K} \left(\frac{x}{c} \right)^2 \right] \quad (17b)$$

Substitution of equation (17b) in equation (6) yields the following equation for F_3 :

$$F_3 = 1 - \frac{2 C_2 \left(\frac{t}{c} \right)_{\max}}{3 C_1 (1 + K) \cos (\Lambda - \Lambda_{HL})} \left[2 \left(1 + 2 \frac{x_h}{c} \right) - K \left(1 - \frac{x_h}{c} \right)^2 \right] \quad (18)$$

From equations (14), (15), and (18), the following correction factors are obtained for the sample configuration: $F_1 = 0.8077$, $F_2 = 0.7889$, and $F_3 = 0.7355$. It is of interest to note that these values indicate appreciable losses in loading due to airfoil-section thickness, and it might be pointed out that greater losses would be obtained for thicker airfoil sections.

The coefficients obtained from the charts and the preceding correction factors are then substituted in equations (4) to (8). The results obtained are

$$(C_{L_s})_c = 0.00411$$

$$(C_{m_s})_c = -0.00318$$

$$(C_{i_s})_c = 0.000619$$

$$(C_{h_s})_c = -0.0182$$

$$(C_{h_a})_c = -0.0143$$

LANGLEY FIELD, VA., September 8, 1950.

APPENDIX A

METHOD OF INTEGRATING PRESSURES OVER CONICAL REGIONS OF DEFLECTED CONTROLS

The pressure distributions in the conical-flow regions shown in figure 12 are given in reference 2. With suitable changes in notation these are:

For region I,

$$P' = \frac{1}{\pi} \cos^{-1} \frac{a-t}{1-at} \quad (A1)$$

For region III,

$$P' = \frac{1}{\pi} \cos^{-1} \frac{1-(2+a)t}{1+at} \quad (A2)$$

Because the flow is conical in regions I and III, integrations of the pressures along the trailing edge within these regions are representative of integrations over corresponding triangular segments having the Mach cone origin as apexes. For such integrations, a coordinate for distance along the trailing edge must be introduced. The nondimensional coordinate chosen was $t' = \beta \tan \tau'$ (fig. 12 and reference 2). The integrations required for determining average pressure ratio and center-of-pressure ray location for any segment are

$$P = \frac{\int_{t_1'}^{t_2'} P' dt'}{\int_{t_1'}^{t_2'} dt'} \quad (A3)$$

and

$$t_{cp}' = \frac{\int_{t_1'}^{t_2'} t' P' dt'}{\int_{t_1'}^{t_2'} P' dt'} \quad (A4)$$

(Subscripts 1 and 2 indicate values of t' corresponding to the end points of the part of t' over which integrations were made.)

A Mach number of $\sqrt{2}$ was assumed for convenience ($\beta=1$) in making the integrations of equations (A3) and (A4). This assumption is valid because any case of Mach number greater than 1 can readily be reduced to an equivalent case at $M=\sqrt{2}$ by an affine transformation corresponding to the Prandtl-Glauert transformation for the subsonic case (reference 5). An example of this transformation is shown in figure 13. The equivalent plan form is obtained by dividing all streamwise dimensions by β and leaving lateral dimensions unchanged; consequently, values of a , d , and t (for equivalent points) are the same. From equations (A1) and (A2), it can readily be seen that values of P' for equivalent points are the same. It follows that summation of P' over equivalent regions results in equal values of P and t_{cp} . It is apparent from figure 13, however, that values of t_{cp}' are different. This difference is of no consequence because values of t_{cp} for the equivalent wing (obtained from t_{cp}' and geometric relations) are the same as values of t_{cp} for the initial wing.

The procedures followed in the integrations of equations (A3) and (A4) are the same for regions I and III and are only shown for region I. If the Mach number is assumed to equal $\sqrt{2}$, where $\beta=1$, equation (A1) may be written in terms of t' as follows:

$$P' = \frac{1}{\pi} \cos^{-1} \frac{(a+d)-(1-ad)t'}{(1+ad)-(a-d)t'}$$

If y is substituted for $\cos \pi P'$, equations (A3) and (A4) become

$$P = \frac{\frac{-(1-a^2)(1+d^2)}{\pi} \int_{y_1}^{y_2} \frac{\cos^{-1} y}{[(1-ad)-(a-d)y]^2} dy}{\frac{-(1-a^2)(1+d^2)}{\pi} \int_{y_1}^{y_2} \frac{dy}{[(1-ad)-(a-d)y]^2}} \quad (A5)$$

$$t_{cp}' = \frac{\frac{-(1-a^2)(1+d^2)}{\pi} \int_{y_1}^{y_2} \frac{(a+d)-(1+ad)y}{[(1-ad)-(a-d)y]^3} \cos^{-1} y dy}{\frac{-(1-a^2)(1+d^2)}{\pi} \int_{y_1}^{y_2} \frac{\cos^{-1} y}{[(1-ad)-(a-d)y]^2} dy} \quad (A6)$$

Integration by parts was then employed in the solutions of equations (A5) and (A6).

For cases in which the conical-flow region overlaps the opposite parting line, the average pressure loss and center-of-pressure ray location are required for regions I_a and I_b (fig. 1). Equations (A3) and (A4) may be used in obtaining the solutions for region I_a by a slight modification requiring no additional integration. Thus,

$$P^* = \frac{\int_{t_1'}^{t_2'} (1-P') dt'}{\int_{t_1'}^{t_2'} dt'} = 1 - \frac{\int_{t_1'}^{t_2'} P' dt'}{\int_{t_1'}^{t_2'} dt'} \quad (A7)$$

$$t_{cp}' = \frac{\int_{t_1'}^{t_2'} t' (1-P') dt'}{\int_{t_1'}^{t_2'} (1-P') dt'} = \frac{\left[\frac{t'^2}{2} \right]_{t_1'}^{t_2'} - \int_{t_1'}^{t_2'} t' P' dt'}{\left[t' \right]_{t_1'}^{t_2'} - \int_{t_1'}^{t_2'} P' dt'} \quad (A8)$$

In obtaining the solutions for region I_b (fig. 1), essentially the same procedure as previously outlined was used. The parameter $r = \frac{1}{t}$ was used to represent distance along the parting line nondimensionally. Values of P^* and r_{cp} were obtained by making integrations similar to those in equations (A7) and (A8) (before simplifications).

Results of integrations over all regions shown in figure 1 are presented in tables II (a) and II (b). Results of evaluating these equations at taper ratios of 1.0, where they become indeterminate, are presented in table III (a).

APPENDIX B

METHOD FOR DETERMINING THICKNESS CORRECTION FACTORS

The pressure coefficient at any point on a two-dimensional surface as given by the Busemann second-order approximation (reference 8, with suitable changes in notation) is

$$C_p = C_1(\delta + \theta) + C_2(\delta + \theta)^2 \quad (\text{B1})$$

(The angle δ is considered positive when calculating C_p for lower surface and negative when calculating C_p for upper surface. Throughout appendix B, δ is considered to be in radians.) The constants C_1 and C_2 are functions only of Mach number. Equations for these constants and tabulated values are presented in reference 10.

The lifting pressure coefficient at any chordwise position is simply the difference between the pressure coefficients on the lower and upper surfaces. The net lift coefficient is obtained by integrating the local lifting pressure coefficients between the hinge line $\left(\frac{x}{c} = \frac{x_h}{c}\right)$ and the trailing edge $\left(\frac{x}{c} = 1.0\right)$. (See fig. 14.) Thus,

$$C_{L' \text{ thickness } (\delta)} = \frac{1}{1 - \frac{x_h}{c}} \int_{x_h/c}^{1.0} [(C_p)_L - (C_p)_U] d \frac{x}{c} \quad (\text{B2})$$

(The subscripts L and U denote lower and upper surfaces.) Similarly, the hinge-moment coefficient is obtained by integrating the products of local lifting pressure coefficient and moment arm between the hinge line and the trailing edge. Thus,

$$C_{h \text{ thickness } (\delta)} = \frac{-1}{\left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) [(C_p)_L - (C_p)_U] d \frac{x}{c} \quad (\text{B3})$$

An application of sweepback theory, as explained in reference 10, must be used for determining $C_{pL} - C_{pU}$. It is important to note that, for deflected controls, this theory requires the use of the Mach number component and the airfoil section in a plane normal to the control hinge axis. Values of C_L' and C_h thus obtained are based on the dynamic-pressure component normal to the hinge line and the deflection angle measured in a plane normal to the hinge line. Values of C_L' and C_h for a two-dimensional flat-plate control, based on the same q and δ , are obtained by considering the Mach number normal to the hinge line in determining values of C_1 . Equations for these coefficients are

$$C_{L' \text{ flat plate}} = 2C_1\delta \quad (\text{B4})$$

$$C_{h \text{ flat plate}} = -C_1\delta \quad (\text{B5})$$

The following correction factors are then determined by dividing equations (B2) and (B3) by equations (B4) and (B5), respectively:

$$F_1 = \frac{1}{2C_1\delta \left(1 - \frac{x_h}{c}\right)} \int_{x_h/c}^{1.0} [(C_p)_L - (C_p)_U] d \frac{x}{c} \quad (\text{B6})$$

$$F_2 = \frac{1}{C_1\delta \left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) [(C_p)_L - (C_p)_U] d \frac{x}{c} \quad (\text{B7})$$

If the sections are assumed to be symmetrical about the chord plane, equations (B6) and (B7) can be simplified because

$$(C_p)_L - (C_p)_U = 2\delta \left(C_1 + 2C_2 \frac{d \frac{t}{2c}}{d \frac{x}{c}} \right) \quad (\text{B8})$$

Equations (B6) and (B7) then become

$$F_1 = \frac{1}{1 - \frac{x_h}{c}} \int_{x_h/c}^{1.0} \left(1 + 2 \frac{C_2}{C_1} \frac{d \frac{t}{2c}}{d \frac{x}{c}} \right) d \frac{x}{c} \quad (\text{B9})$$

$$F_2 = \frac{2}{\left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) \left(1 + 2 \frac{C_2}{C_1} \frac{d \frac{t}{2c}}{d \frac{x}{c}} \right) d \frac{x}{c} \quad (\text{B10})$$

The equation for F_3 , may be written as equation (B7) for F_2 (substituting α for δ)

$$F_3 = \frac{1}{C_1\alpha \left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) [(C_p)_L - (C_p)_U] d \frac{x}{c} \quad (\text{B11})$$

In this case, however, the airfoil section and Mach number component in a plane normal to the wing leading edge must be used in determining values of C_1 and $(C_p)_L - (C_p)_U$.

For symmetrical sections, the equation for F_3 may be simplified in the same manner as the equivalent equation for F_2 . Thus,

$$F_3 = \frac{2}{\left(1 - \frac{x_h}{c}\right)^2} \int_{x_h/c}^{1.0} \left(\frac{x}{c} - \frac{x_h}{c}\right) \left[1 + 2 \frac{C_2}{C_1} \frac{d \left(\frac{t}{2c}\right)'}{d \left(\frac{x}{c}\right)'} \right] d \frac{x}{c} \quad (\text{B12})$$

Equation (B12) will in some cases become somewhat involved because $\frac{d(t/c)'}{d(x/c)'}$ must be determined from the equation for the airfoil section in a plane normal to the wing leading edge and must then be written in terms of x/c (unless the surfaces are plane). It should be pointed out that suitable approximations for most symmetrical biconvex airfoils (which in general require involved expressions for defining the contour) may be obtained by assuming the sections to have parabolic contours. General equations for the thickness correction factors for symmetrical sections having parabolic contours have been derived in the illustrative example of the present report.

TABLE IX.—COMPUTING FORM FOR C_{h_a}

(a) Dimensions and Preliminary Computing Form

$$M = 1.80$$

$$\beta = \sqrt{M^2 - 1} = 1.4967$$

Root case 3Tip case 3

$$g = \frac{\tan \Lambda}{\beta} = 0.5995$$

$$a = \frac{\tan \Lambda_{HL}}{\beta} = 0.3990$$

$$d = \frac{\tan \Lambda_{TE}}{\beta} = 0.3489$$

$$K_1 = \beta y_2 = 7.8577$$

$$K_2 = \beta y_1 = 2.9934$$

$$K_3 = \beta \left(\frac{b}{2} - y_1 \right) = 5.9868$$

$$K_4 = \beta \left(\frac{b}{2} - y_2 \right) = 1.1225$$

$$K_5 = \beta y_2^2 = 41.2528$$

$$K_6 = \frac{1}{\beta(1-d)} = 1.0262$$

$$K_7 = \frac{1}{\beta(1-a)} = 1.1117$$

$$K_8 = \beta y_1^2 = 5.9868$$

$$K_9 = \beta \left(\frac{b}{2} - y_1 \right)^2 = 23.9472$$

$$K_{10} = \frac{1}{\beta(1+d)} = 0.4953$$

$$K_{11} = \frac{1}{\beta(1+a)} = 0.4776$$

$$K_{12} = \beta \left(\frac{b}{2} - y_2 \right)^2 = 0.8419$$

Tapered flap:

$$2M_a 3\sqrt{1+\beta^2 a^2} = b_f \frac{c_{f_r}^3 - c_{f_t}^3}{c_{f_r} - c_{f_t}} = 5.2159$$

Untapered flap:

$$2M_a 3\sqrt{1+\beta^2 a^2} = 3b_f c_{f_r}^2 = \underline{\hspace{2cm}}$$

REPORT 1042

SOME EFFECTS OF NONLINEAR VARIATION IN THE DIRECTIONAL-STABILITY AND DAMPING-IN-YAWING DERIVATIVES ON THE LATERAL STABILITY OF AN AIRPLANE¹

By LEONARD STERNFIELD

SUMMARY

A theoretical investigation has been made to determine the effect of nonlinear stability derivatives on the lateral stability of an airplane. Motions were calculated on the assumption that the directional-stability and the damping-in-yawing derivatives are functions of the angle of sideslip. The application of the Laplace transform to the calculation of an airplane motion when certain types of nonlinear derivatives are present is described in detail. The types of nonlinearities assumed correspond to the condition in which the values of the directional-stability and damping-in-yawing derivatives are zero for small angles of sideslip.

The results of the investigation indicated that under certain conditions the nonlinear stability derivatives assumed in the analysis caused a motion which had different rates of damping for the large and small amplitudes of motion, with very little damping at the small amplitudes. In general, the period of the resultant oscillation increased with time.

INTRODUCTION

Recent flight tests of several airplanes designed for high-speed high-altitude flight have indicated neutrally damped lateral oscillations of small amplitude generally referred to as snaking. Upon examination of the flight records, the decrement of the oscillatory motion is found in some cases to be different for the large and small amplitudes of motion with a neutrally stable oscillation occurring at the small amplitudes. One of the explanations offered for the cause of this type of motion is that some of the stability derivatives are nonlinear; that is, the derivatives have different values for the large and small amplitudes of motion. The nonlinearity could be caused by boundary-layer effects or flow separation due to poor fairing at the junction of the tail surfaces.

The present report represents a preliminary investigation of the effect of the presence of two nonlinear stability derivatives, the directional-stability derivative $C_{n\beta}$ and the damping-in-yawing derivative C_{nr} , on the motion of an airplane. These derivatives were selected for the analysis since the damping of the oscillation is a function of C_{nr} and

since C_{nr} depends upon the $C_{n\beta}$ contributed by the tail. The derivatives $C_{n\beta}$ and C_{nr} were both assumed to be functions of the sideslip angle β . Calculations were made of the airplane motion due to a disturbance in sideslip for three different types of nonlinearities.

SYMBOLS AND COEFFICIENTS

ϕ	angle of roll, radians
ψ	angle of yaw, radians
β	angle of sideslip, radians except where noted in figures (v/V)
r	yawing angular velocity, radians per second ($d\psi/dt$)
p	rolling angular velocity, radians per second ($d\phi/dt$)
v	sideslip velocity along the Y-axis, feet per second
V	airspeed, feet per second
ρ	mass density of air, slugs per cubic foot
q	dynamic pressure, pounds per square foot ($\frac{1}{2} \rho V^2$)
b	wing span, feet
S	wing area, square feet
W	weight of airplane, pounds
m	mass of airplane, slugs (W/g)
g	acceleration due to gravity, feet per second per second
μ_b	relative density factor ($m/\rho S b$)
η	inclination of principal longitudinal axis of airplane with respect to flight path, positive when principal axis is above flight path at the nose, degrees
γ	angle of flight path to horizontal axis, positive in climb, degrees
k_{X_0}	radius of gyration in roll about principal longitudinal axis, feet
k_{Z_0}	radius of gyration in yaw about principal vertical axis, feet
K_{X_0}	nondimensional radius of gyration in roll about principal longitudinal axis (k_{X_0}/b)

¹ Supersedes NACA TN 2233, "Some Effects of Nonlinear Variation in the Directional-Stability and Damping-in-Yawing Derivatives on the Lateral Stability of an Airplane" by Leonard Sternfield, 1950.

K_{z_0}	nondimensional radius of gyration in yaw about principal vertical axis (k_{z_0}/b)
K_x	nondimensional radius of gyration in roll about longitudinal stability axis ($\sqrt{K_{x_0}^2 \cos^2 \eta + K_{z_0}^2 \sin^2 \eta}$)
K_z	nondimensional radius of gyration in yaw about vertical stability axis ($\sqrt{K_{z_0}^2 \cos^2 \eta + K_{x_0}^2 \sin^2 \eta}$)
K_{xz}	nondimensional product-of-inertia parameter ($(K_{z_0}^2 - K_{x_0}^2) \sin \eta \cos \eta$)
C_L	trim lift coefficient ($\frac{W \cos \gamma}{qS}$)
C_l	rolling-moment coefficient ($\frac{\text{Rolling moment}}{qSb}$)
C_n	yawing-moment coefficient ($\frac{\text{Yawing moment}}{qSb}$)
C_Y	lateral-force coefficient ($\frac{\text{Lateral force}}{qS}$)
$C_{l_\beta} = \frac{\partial C_l}{\partial \beta}$	
$C_{n_\beta} = \frac{\partial C_n}{\partial \beta}$	
$C_{Y_\beta} = \frac{\partial C_Y}{\partial \beta}$	
$C_{n_r} = \frac{\partial C_n}{\partial \left(\frac{rb}{2V}\right)}$	
$C_{n_p} = \frac{\partial C_n}{\partial \left(\frac{pb}{2V}\right)}$	
$C_{l_p} = \frac{\partial C_l}{\partial \left(\frac{pb}{2V}\right)}$	
$C_{Y_p} = \frac{\partial C_Y}{\partial \left(\frac{pb}{2V}\right)}$	
$C_{Y_r} = \frac{\partial C_Y}{\partial \left(\frac{rb}{2V}\right)}$	
$C_{l_r} = \frac{\partial C_l}{\partial \left(\frac{rb}{2V}\right)}$	
C_{n_c}	yawing-moment constant
t	time, seconds
s_b	nondimensional time parameter based on span (Vt/b)
D_b	differential operator ($\frac{d}{ds_b}$)
σ	operator in Laplace transformation
$T_{1/2}$	time for amplitude of oscillation to damp to one-half its original value, seconds

The subscript 0 is used to indicate initial conditions and a bar is used to denote variables in the operational equations.

ANALYSIS

NONLINEAR STABILITY DERIVATIVES

The assumptions made with regard to the nonlinearity of the stability derivatives C_{n_β} and C_{n_r} are shown in figure 1.

FIGURE 1.—Three types of nonlinear stability derivatives assumed in the analysis.

For all three cases presented in the figure, C_n is equal to zero for $-2^\circ < \beta < 2^\circ$, a region which is subsequently referred to as a dead spot. Thus when the airplane is within the dead spot, the value of the directional stability derivative C_{n_β} is zero. Since the damping-in-yawing derivative C_{n_r} is a direct function of C_{n_β} contributed by the tail, C_{n_r} was also assumed to be zero for values of $-2^\circ < \beta < 2^\circ$. In the region outside of the dead spot, each one of the cases represents a different type of variation of C_n with β in order to simulate the effect of several possible flow conditions on the side force acting on the vertical surface. For cases 1 and 2, $C_{n_\beta} = 0.28$ and for case 3, $C_{n_\beta} = 0.41$. The corresponding value of C_{n_r} for all three cases is -0.39 . It should be noted in figure 1 that for cases 2 and 3, $C_n = 0$ at β of 2° and -2° , whereas for case 1, C_n has a finite value at β of 2° and -2° .

METHOD OF CALCULATING MOTION

Since the nonlinearities shown in figure 1 can be treated as linear derivatives of different values within and outside of the dead spot, the airplane motion is calculated on the basis of classical linear theory. The equations of motion and the general method of calculating the motion of an airplane are given in references 1 and 2. The methods of references 1 and 2 are based on the Laplace transformation which inherently takes into account the initial conditions of the problem. Because the Laplace transformation considers the initial displacements and initial velocities of the problem, this method is directly applicable to the calculation of the motion of an airplane which has nonlinear derivatives similar to the derivatives presented in figure 1.

The nondimensional linearized lateral equations of motion, referred to the stability axes, are for rolling, for yawing, and for sideslipping, respectively:

$$\left. \begin{aligned} 2\mu_b(K_x^2 D_b^2 \phi + K_{xz} D_b^2 \psi) &= C_{l_\beta} \beta + \frac{1}{2} C_{l_p} D_b \phi + \frac{1}{2} C_{l_r} D_b \psi \\ 2\mu_b(K_z^2 D_b^2 \psi + K_{xz} D_b^2 \phi) &= C_{n_\beta} \beta + \frac{1}{2} C_{n_p} D_b \phi + \frac{1}{2} C_{n_r} D_b \psi + C_{n_c} \\ 2\mu_b(D_b \beta + D_b \psi) &= C_{Y_\beta} \beta + \frac{1}{2} C_{Y_p} D_b \phi + C_L \phi + \frac{1}{2} C_{Y_r} D_b \psi + (C_L \tan \gamma) \psi \end{aligned} \right\} \quad (1)$$

The Laplace transformation of equations (1), with the use of the symbol σ for the operator, is

$$\left. \begin{aligned} \left(2\mu_b K_X^2 \sigma^2 - \frac{1}{2} C_{l_p} \sigma\right) \bar{\phi} + \left(2\mu_b K_{XZ} \sigma^2 - \frac{1}{2} C_{l_r} \sigma\right) \bar{\psi} - C_{l_\beta} \bar{\beta} &= 2\mu_b K_X^2 [\sigma \phi_0 + (D_b \phi)_0] - \frac{1}{2} C_{l_p} \phi_0 + 2\mu_b K_{XZ} [\sigma \psi_0 + (D_b \psi)_0] - \frac{1}{2} C_{l_r} \psi_0 \\ \left(2\mu_b K_{XZ} \sigma^2 - \frac{1}{2} C_{n_p} \sigma\right) \bar{\phi} + \left(2\mu_b K_Z^2 \sigma^2 - \frac{1}{2} C_{n_r} \sigma\right) \bar{\psi} - C_{n_\beta} \bar{\beta} &= 2\mu_b K_{XZ} [\sigma \phi_0 + (D_b \phi)_0] - \frac{1}{2} C_{n_p} \phi_0 + 2\mu_b K_Z^2 [\sigma \psi_0 + (D_b \psi)_0] - \frac{1}{2} C_{n_r} \psi_0 + \frac{C_{n_c}}{\sigma} \\ \left(-\frac{1}{2} C_{Y_p} \sigma - C_L\right) \bar{\phi} + \left(2\mu_b \sigma - \frac{1}{2} C_{Y_r} \sigma - C_L \tan \gamma\right) \bar{\psi} + (2\mu_b \sigma - C_{Y_\beta}) \bar{\beta} &= -\frac{1}{2} C_{Y_p} \phi_0 + \left(2\mu_b - \frac{1}{2} C_{Y_r}\right) \psi_0 + 2\mu_b \beta_0 \end{aligned} \right\} \quad (2)$$

Equations (2) represent three simultaneous algebraic equations which can be solved for $\bar{\beta}$, $\bar{\phi}$, $\bar{\psi}$, and their derivatives by the method of determinants. For example,

$$\bar{\beta} = \frac{\bar{\Delta}_1}{\bar{\Delta}} = \frac{f(\sigma)}{F(\sigma)} \quad (3)$$

where $\bar{\Delta}$ is the characteristic lateral-stability equation

$$(A\sigma^4 + B\sigma^3 + C\sigma^2 + D\sigma + E)\sigma$$

and

$$\bar{\Delta}_1 = A_1\sigma^4 + B_1\sigma^3 + C_1\sigma^2 + D_1\sigma + E_1$$

The expressions for A , B , C , D , and E , in terms of the mass and aerodynamic parameters of the airplane, are given on pages 27 and 28 of reference 1. The coefficients of the $\bar{\Delta}_1$ equation are

$$A_1 = \beta_0 [8\mu_b^3 (K_X^2 K_Z^2 - K_{XZ}^2)]$$

$$B_1 = \phi_0 [4\mu_b^2 C_L (K_X^2 K_Z^2 - K_{XZ}^2)] + (D_b \phi)_0 [2\mu_b^2 C_{Y_p} (K_X^2 K_Z^2 - K_{XZ}^2)] + \psi_0 [4\mu_b^2 C_L \tan \gamma (K_X^2 K_Z^2 - K_{XZ}^2)] + (D_b \psi)_0 [2\mu_b^2 (C_{Y_r} - 4\mu_b) (K_X^2 K_Z^2 - K_{XZ}^2)] + \beta_0 [2\mu_b^2 (K_{XZ} C_{l_r} - K_X^2 C_{n_r}) + 2\mu_b^2 (K_{XZ} C_{n_p} - K_Z^2 C_{l_p})]$$

$$C_1 = \phi_0 [\mu_b C_L (K_{XZ} C_{l_r} - K_X^2 C_{n_r}) + \mu_b C_L (K_{XZ} C_{n_p} - K_Z^2 C_{l_p})] + (D_b \phi)_0 \left[\frac{1}{2} \mu_b K_X^2 (C_{n_p} C_{Y_r} - C_{n_r} C_{Y_p}) + 2\mu_b^2 K_X^2 (2K_Z^2 C_L - C_{n_p}) + 2\mu_b^2 K_{XZ} (C_{l_p} - 2K_{XZ} C_L) + \frac{1}{2} \mu_b K_{XZ} (C_{l_r} C_{Y_p} - C_{l_p} C_{Y_r}) \right] + \psi_0 [\mu_b C_L \tan \gamma (K_{XZ} C_{l_r} - C_{n_r} K_X^2) + \mu_b C_L \tan \gamma (K_{XZ} C_{n_p} - K_Z^2 C_{l_p})] + (D_b \psi)_0 \left[\frac{1}{2} \mu_b K_{XZ} (C_{n_p} C_{Y_r} - C_{n_r} C_{Y_p}) + \frac{1}{2} \mu_b K_Z^2 (C_{l_r} C_{Y_p} - C_{l_p} C_{Y_r}) + 4\mu_b^2 C_L \tan \gamma (K_X^2 K_Z^2 - K_{XZ}^2) + 2\mu_b^2 (K_Z^2 C_{l_p} - K_{XZ} C_{n_p}) \right] + \beta_0 \left[\frac{1}{2} \mu_b (C_{l_p} C_{n_r} - C_{l_r} C_{n_p}) \right] + C_{n_c} [-\mu_b K_{XZ} C_{Y_p} + \mu_b K_X^2 C_{Y_r} - 4\mu_b^2 K_X^2]$$

$$D_1 = \phi_0 \left[\frac{1}{4} C_L (C_{l_p} C_{n_r} - C_{l_r} C_{n_p}) \right] + (D_b \phi)_0 [\mu_b C_L \tan \gamma (K_X^2 C_{n_p} - K_{XZ} C_{l_p}) + \mu_b C_L (K_{XZ} C_{l_r} - K_X^2 C_{n_r})] + \psi_0 \left[\frac{1}{4} C_L \tan \gamma (C_{l_p} C_{n_r} - C_{l_r} C_{n_p}) \right] + (D_b \psi)_0 [\mu_b C_L (K_Z^2 C_{l_r} - K_{XZ} C_{n_r}) + \mu_b C_L \tan \gamma (K_{XZ} C_{n_p} - K_Z^2 C_{l_p})] + C_{n_c} \left[\frac{1}{4} C_{Y_p} C_{l_r} - 2\mu_b K_{XZ} C_L + 2\mu_b K_X^2 C_L \tan \gamma + \mu_b C_{l_p} - \frac{1}{4} C_{l_p} C_{Y_r} \right]$$

$$E_1 = C_{n_c} \left(\frac{1}{2} C_L C_{l_r} - \frac{1}{2} C_{l_p} C_L \tan \gamma \right)$$

The solution of equation (3), which will result in a time history of β as a function of s_b , is obtained from the Heaviside expansion theorem (reference 3):

$$\beta = \sum_{n=1}^m \frac{f(\lambda_n)}{F'(\lambda_n)} e^{\lambda_n s_b} \quad (4)$$

where λ_n are the roots of $F(\sigma)$ set equal to zero. Similar solutions are derived for ϕ , ψ , $D_b \phi$, $D_b \psi$, and $D_b \beta$. The time scale is readily converted from s_b units to t units by the equation $t = \frac{b}{V} s_b$.

The values of the stability derivatives and mass characteristics used in the calculations are presented in table I. The table is divided into two columns which differ only in the values of $C_{n\beta}$ and C_{n_r} of the airplane for the cases where the

airplane is either outside of or within the dead spot. From the analytical solution of the motion, based on the mass and aerodynamic characteristics of the first column of table I and an initial condition of $\beta=5^\circ$, the time history of β was computed for several values of s_b until the value of s_b for which $\beta=2^\circ$ was reached. For values of s_b greater than the s_b which results in $\beta=2^\circ$, this analytical solution is incorrect since the airplane has now entered into the dead spot and the values of C_{n_β} and C_{n_r} are zero. Thus, a new solution must be calculated with the use of the values given in the second column of table I with new initial conditions. The new initial conditions are determined by substituting the value of s_b at which $\beta=2^\circ$ in the original analytical solutions of ϕ , ψ , $D_b\phi$, $D_b\psi$, and $D_b\beta$. Once these initial conditions are known, another set of analytical solutions are computed for β , ϕ , ψ , and their derivatives from equations (3) and (4). This procedure is followed every time β crosses through 2° or -2° . The final resultant motion in sideslip is the sum of all the analytical solutions in β , each one of which is correct only for a particular interval of time.

The constant C_{n_c} is introduced into the yawing-moment equation of equations (1), since the value of the yawing-moment coefficient due to sideslip is $C_{n_\beta}\beta + C_{n_c}$ for the condition of the airplane having the dead spot in cases 2 and 3 of figure 1. The values of C_{n_c} are $|0.00977|$ and $|0.0143|$ for cases 2 and 3, respectively. The sign of C_{n_c} is opposite to that of β . For case 1 of figure 1, $C_{n_c}=0$.

It is apparent that the procedure employed is a time-consuming process and subject to the possibility of many computational errors due to the magnitude of the computations. The final solution can be obtained, however, in a relatively short time through the use of automatic digital computing machines.

RESULTS AND DISCUSSION

The effect of the nonlinear stability derivatives on the lateral motion was investigated for the airplane described by the mass and aerodynamic characteristics given in table I, with three different values for the damping of the lateral oscillation as calculated on the basis of derivatives constant with amplitude. Since the damping was varied arbitrarily by assuming different values for the angle of inclination of the principal longitudinal axis of the airplane to the flight path η , three values of η , -2° , 0° , and 2° , were selected which correspond to a damping of the lateral oscillation, expressed in terms of $T_{1/2}$, of 5.6, 3.0, and 1.8, respectively. The motion of the airplane in sideslip, due to an initial disturbance in sideslip of 5° , for the three values of η is shown in figure 2. Since these motions are calculated on the assumption of derivatives constant with amplitude, the amplitudes of the motion decrease exponentially with time and will eventually reduce to zero. As can be noted in the first column of table I, the C_{n_β} for cases 1 and 2 is 0.28; whereas the C_{n_β} for case 3 is 0.41. The motions presented in figure 2 are for $C_{n_\beta}=0.28$; however, the motions for $C_{n_\beta}=0.41$ would exhibit oscillations of approximately the same damping and a slightly smaller period.

The motions of the airplane in sideslip, showing the effect of the nonlinearities illustrated in figures 1(a), 1(b), and 1(c), are presented in figures 3 to 5, respectively. In all cases, an initial disturbance in sideslip of 5° was assumed. The pronounced effect of the nonlinearities on the lateral motion is noted by a comparison of figure 2 and either one of figures 3, 4, or 5. In all three figures (figs. 3 to 5) the motion for $\eta=2^\circ$, the most stable case, approaches a constant value. The analytical solution of the motion for the case of $\eta=2^\circ$ in figure 3 indicates that, within the dead spot, the airplane will oscillate at a period of 6.56 seconds and $T_{1/2}=3.38$ seconds and will eventually approach the value of $\beta=-0.0092^\circ$. Similar motions would be obtained for the case of $\eta=2^\circ$ in figures 4 and 5. As η is decreased, the damping of the oscillatory motion depends upon the nonlinearity assumed and the values of η . In figure 3, the motion for $\eta=0^\circ$ damps at a slow rate at the large amplitudes until the oscillation reaches an amplitude of approximately 2.4° where the damping of the oscillation is zero. The period of the oscillation increases from 1.5 to 1.85 seconds. For the case of $\eta=-2^\circ$, a very lightly damped oscillation is apparent within the first few seconds and the airplane may be considered to be neutrally stable at an amplitude of $\mp 4.5^\circ$. In figures 4 and 5 the motion for $\eta=0^\circ$ clearly indicates that the damping is decreasing as the amplitude decreases and the period of the oscillation increases; for $\eta=-2^\circ$, the oscillatory motion is slightly unstable. A neutrally stable oscillation would be expected to occur in figures 4 and 5 for the combinations of a value of η between 0° and -2° and the dead spot assumed in the calculations or for $\eta=-2^\circ$ and a smaller dead spot.

FIGURE 2.—Calculated motion of an airplane due to an initial disturbance in sideslip for several values of η .

FIGURE 3.—The effect of the nonlinear derivatives described in figure 1(a) on the motion of an airplane.

FIGURE 4.—The effect of the nonlinear derivatives described in figure 1(b) on the motion of an airplane.

FIGURE 5.—The effect of the nonlinear derivatives described in figure 1(c) on the motion of an airplane.

In general, the results indicate that the damping of the lateral oscillation calculated with the use of derivatives constant with amplitude is a determining factor in the type of motion obtained where nonlinear derivatives are present. As the inherent damping of the lateral oscillation decreases, a smaller dead spot will result in a neutrally stable oscillation. Obviously, if the inherent damping is zero, a neutrally stable oscillation already exists with zero dead spot.

Some additional calculations were made for the case where the airplane is disturbed within the dead spot. The motions for an initial condition of $\beta = 1^\circ$ were computed for $\eta = -2^\circ$ and 0° with the assumption of the nonlinearity described in figure 1 (b). The results are presented in figure 6. It should be noted that the only difference between figures 4 and 6 is the initial condition assumed in the calculations. In figure 6, the motion for $\eta = -2^\circ$ is unstable and gradually approaches

FIGURE 6.—The effect of the nonlinear derivatives described in figure 1(b) on the motion of an airplane. Initial disturbance in sideslip of 1° .

the amplitude and period of the motion for the case of $\eta = -2^\circ$ in figure 4. The motion for $\eta = 0^\circ$ in figure 6 is slightly unstable and will probably increase until its amplitude and period are in close agreement with the motion for the case of $\eta = 0^\circ$ in figure 4. Calculations have indicated that the oscillatory motion of the airplane within the dead spot will double amplitude about every 4 seconds for $\eta = -2^\circ$ and about every 30 seconds for $\eta = 0^\circ$. If the motion is unstable within the dead spot, either the airplane motion will be neutrally stable with an amplitude equal to or greater than the amplitude of the dead spot or the motion will be unstable.

The loss in damping and the increase in period which appeared in some of the lateral oscillations in figures 3 to 5 can be attributed to the type of nonlinearity assumed. From classical dynamic stability theory, it is well known that the damping of the oscillation is a function of C_{nr} , and the period of the oscillation is a function of $C_{n\beta}$. If the airplane is considered as a mass-spring dashpot system, $C_{n\beta}$ is the equivalent spring constant of the system and C_{nr} corresponds to the damping constant contributed by the dashpot. Thus as $C_{n\beta}$ is reduced the period increases, and as C_{nr} is reduced the damping decreases.

213637—53—65

CONCLUDING REMARKS

The results of the investigation made to determine the effect of nonlinearities assumed in the analysis on the lateral stability indicate that under certain conditions a motion is obtained which has different rates of damping for the large and small amplitudes of motion, with very little damping at the small amplitudes. In general, the period of the resultant oscillation increases with time.

REPORT 1043

A NUMERICAL METHOD FOR THE STRESS ANALYSIS OF STIFFENED-SHELL STRUCTURES UNDER NONUNIFORM TEMPERATURE DISTRIBUTIONS¹

By RICHARD R. HELDENFELS

SUMMARY

A numerical method is presented for the stress analysis of stiffened-shell structures of arbitrary cross section under nonuniform temperature distributions. The method is based on a previously published procedure that is extended to include temperature effects and multicell construction. The application of the method to practical problems is discussed, and an illustrative analysis is presented of a two-cell box beam under the combined action of vertical loads and a nonuniform temperature distribution.

INTRODUCTION

The effects of nonuniform temperature distributions, such as those produced by aerodynamic heating, are becoming of greater concern in the design of modern high-speed aircraft. The structural effects of temperature changes and the results of some analyses of a simplified structure under nonuniform distributions of temperature have been discussed in reference 1. The analytical methods considered in reference 1 were found, however, to yield inaccurate values for the secondary stresses in complicated structures, and in such cases some type of numerical approach is desirable. Numerical methods, however, usually require extensive and tedious calculations and they should be used only when satisfactory results cannot be obtained from a simplified analysis.

Several numerical methods of stress analysis have been presented in the literature, but none contains provisions for temperature changes. In the present report, one such method, the numerical procedure of reference 2, has been extended to include the effects of a nonuniform distribution of temperature. In addition, the equations developed permit the analysis of a stiffened-shell structure of arbitrary cross section with any number of internal cells. The application of the method is discussed and illustrated by analysis of a two-cell box beam under the combined action of vertical loads and a nonuniform temperature distribution.

DESCRIPTION OF THE NUMERICAL METHOD

BASIC THEORY

The structure analyzed is an idealized representation of a multicell stiffened-shell structure (see fig. 1) and has the

following characteristics:

(1) The basic unit is a rectangular panel bounded on two parallel sides by extensionally flexible stringers and on the other two sides by rigid bulkheads.

(2) The panels consist of sheet material and are assumed to carry shear stress only. The shear stress is constant within a given panel.

(3) The stringers run parallel to the direction of the primary stresses and carry axial load only.

(4) The bulkheads lie perpendicular to the stringers and are rigid in their own plane but offer no resistance to warping out of their plane.

(5) The structure is loaded only at the bulkheads.

(6) Material properties, cross-sectional dimensions, and temperature distribution do not vary along the length of a given bay.

With these assumptions about the basic elements of the structure, any type of stiffened shell can be analyzed, provided taper is excluded. The state of stress in such a structure can then be defined by suitable stress-strain relations and two types of displacements:

(1) Stringer displacements, which are displacements, at the end of a bay, of each flexible stringer in a direction parallel to the stringer

(2) Bay displacements, which are translations and rotations of the plane of each cross section defined by the rigid bulkheads

FIGURE 1.—Typical multicell, stiffened-shell wing structure.

¹ Supersedes NACA TN 2241, "A Numerical Method for the Stress Analysis of Stiffened-Shell Structures under Nonuniform Temperature Distributions" by Richard R. Heldenfels, 1950.

Once the stress-strain relations are established for the components of the idealized structure, equations of equilibrium can be used to obtain relationships between the displacements. The equilibrium equation for the forces on an individual stringer yields an expression for the stringer displacement of any panel point in terms of the surrounding stringer displacements and the displacements of the two adjacent bays. From this general expression, equations equal in number to the unknown stringer displacements are obtained. The additional equations required for the determination of the bay displacements are obtained from the equations of equilibrium of the shear forces on the cross sections. These equations then completely define the displacements of the structure. In most cases the number of equations is so large that a direct solution would be impractical and it has been found expedient to solve them by the recommended iteration procedure described in the next section. The required equations are derived in detail in the appendix.

SOLUTION OF EQUATIONS BY ITERATION

Matrix iteration often provides the easiest and quickest solution to the equations, and the procedure recommended is as follows:

The equations to be solved can be written in matrix notation as

$$[B]\{d\} = \{c\} \quad (1)$$

For purposes of iteration, these equations are rearranged to give

$$\{d\} = [C]\{d\} + \{c\} \quad (2)$$

where

$$[C] = [U] - [B]$$

$[B]$ square matrix of coefficients of general equations with diagonal terms reduced to unity

$[U]$ unit matrix

$\{d\}$ column matrix of stringer and bay displacements

$\{c\}$ column matrix of constant terms in general equation; these terms arise from applied load and thermal expansion

Initial approximate values of stringer and bay displacements $\{d_0\}$ are then selected. These values may be determined in any convenient manner; however, subsequent operations can be simplified, as explained in the appendix, if these values are chosen to correspond to elementary theory. Next, the initial displacement values are substituted into the righthand side of equation (2) to obtain a second approximation $\{d_1\}$ to the displacements

$$\{d_1\} = [C]\{d_0\} + \{c\} \quad (3)$$

and the differences between the second and initial approximate displacement values are computed from the equation

$$\{\Delta d_1\} = \{d_1\} - \{d_0\} \quad (4)$$

The iteration process is then begun by using these displacement differences. The n th difference is defined as

$$\{\Delta d_n\} = \{d_n\} - \{d_0\} \quad (5)$$

and it can be easily verified that the use of these differences leads to the following matrix equation:

$$\{\Delta d_n\} = [C]\{\Delta d_{n-1}\} + \{\Delta d_1\} \quad (6)$$

The iteration process consists of a series of solutions of equation (6), each successive solution yielding a better approximation to the displacement differences than the previous one. The process is continued until successive solutions of equation (6) yield the same result, that is, until

$$\{\Delta d_n\} = \{\Delta d_{n-1}\} \quad (7)$$

The final displacements are then determined from the final differences by using equation (5) and the initial values.

When equation (6) is being iterated, improved values should be used as soon as they are obtained; that is, each individual difference Δd_n should be substituted into the $\{\Delta d_{n-1}\}$ matrix immediately after calculation rather than at the end of the cycle. In this manner, each new value determined receives the benefit of all previous work and convergence is speeded.

The iteration of differences reduces the work required to obtain a solution because smaller numbers are involved. However, it is essential that no errors be made in the determination of the first differences $\{\Delta d_1\}$ since a single significant error will render the whole solution useless.

CONVERGENCE OF THE ITERATION PROCESS

In order to obtain more rapid convergence of the iteration process, bay displacements and loads are referred to the principal shear axes of each bay. The use of these axes greatly simplifies the equations for bay displacements by making each bay displacement independent of all other bay displacements and thus a function of the stringer displacements only. In addition, a special correction cycle is periodically introduced to bring the stringer forces on each cross section into equilibrium with the applied loads. Mathematically, the correction cycle is a special cycle that uses a certain combination of the basic equations. Its success in the particular case of the numerical method of stress analysis is a result of its physical significance, and in that respect it is similar to Southwell's "group relaxations" (reference 3).

The optimum frequency of application of the correction cycle depends largely on the characteristics of each individual problem and must be determined on a basis of experience with the method. If this frequency cannot be determined from previous experience, it can be approximated satisfactorily by one that permits the disturbances to spread their significant effect over the structure between correction cycles.

The application of the correction cycle begins at a station where the displacements are known and then proceeds outboard. The corrections required to bring the first bay into equilibrium are determined, and the stringer displacements at its outboard end are changed accordingly before the corrections required by the second bay are calculated.

EFFECT OF INTRODUCING NONUNIFORM TEMPERATURE DISTRIBUTIONS

The preceding method is applicable to any type of stress problem. Nonuniform temperature distributions do not affect the general procedure but merely change the details. These effects are of two types: A change in the effective structure due to changes in elastic properties of the material with temperature and thermal stresses resulting from restrained thermal expansion. The changes in elastic properties are easily handled if the moduli are treated as variables during the derivation of the equations. Their effect is analogous to that of variations in stringer area and panel thickness. The presence of thermal expansion requires modification of the stress-strain relationships for the stringers but does not affect those for the panels. The equations for stringer displacements contain thermal-expansion terms that are analogous to the applied-load terms. Bay-displacement equations are unaffected by thermal expansion, but thermal-expansion terms appear in the equations used for the correction cycle. If a difference solution is iterated, the elementary solution should include the distributions of thermal strain associated with the primary thermal stresses, which may be obtained from the equations derived in the appendix.

DISCUSSION OF THE NUMERICAL METHOD

The application of a method, such as that just described, always poses a number of questions; for example, what are some of the limitations of the method, would it be advantageous to use some other method of analysis, and how should the structure be idealized? Some of the factors requiring consideration, other than those mentioned in the previous section, are therefore now discussed.

VALIDITY OF BASIC ASSUMPTIONS

The assumptions upon which the method is based are commonly accepted in the analysis of stiffened shells. Comparison of theoretical and experimental results has established the fact that these assumptions will yield good results in most cases. Two important assumptions—that the bulkheads are rigid in their own plane and that the shear stress is constant in a given panel—may, however, introduce significant errors into the analysis in some cases. These assumptions are therefore examined in detail.

The assumption of rigid bulkheads is satisfactory as long as the primary stresses run perpendicular to the bulkheads, but, as demonstrated in reference 1, this assumption may not be good when dealing with problems involving thermal

stress. Large temperature gradients along the length of the structure or across the depth of a bulkhead distort the real bulkhead and make the assumption of rigidity inapplicable. In many cases, however, these effects are small and the assumption yields satisfactory results.

The numerical method could be extended to include the effects of bulkhead flexibility. Such an analysis, however, is very cumbersome and tedious and, if the equations are solved by iteration, the process is often very slowly convergent. Therefore, these extensions are not considered herein.

The assumption of constant shear stress in a given panel simplifies the development of the equations, and it yields satisfactory results if the bulkheads are reasonably close together. Cases arise, however, in which the assumption will lead to unreasonable results because the assumed constant shear stress is a poor approximation to a shear stress which should be changing rapidly in the spanwise direction. This situation is usually accompanied by slow convergence of the iteration process. This difficulty, however, can be minimized by reducing the bulkhead spacing of the idealized structure since it occurs only when the total shear stiffness of the panels joined to a stringer exceeds the extensional stiffness of that stringer.

IDEALIZATION OF AN ACTUAL STRUCTURE

The idealization process described in reference 2 is straightforward. However, it provides an opportunity for the stress analyst to exercise his engineering judgment and thus to simplify the analysis. By restricting the analysis to only a part of the structure or by using a comparatively simple idealized structure, the time required for the analysis can be substantially reduced. Such simplifications, however, can reduce the value of the results, and a compromise between speed and exactness is required.

The number and location of the idealized stringers completely define the stress-distribution shapes obtainable from the analysis. (For example, in an idealized shell of n stringers, there are n possible types of independent normal-stress distributions, three of which can be determined from elementary theory, the remaining $n-3$ being statically indeterminate.) Stringer location is thus an important part of the idealization process and in conventional problems the locations should be selected after consideration of the characteristics of the actual structure, the nature of the expected results, and the time available for the analysis. When non-uniform temperature distributions are involved, the shape of the temperature distribution should also be considered because the thermal-stress and temperature distributions will have similar shapes and the analysis will yield good results only if the idealized structure permits a stress distribution of that shape.

The bulkhead spacing usually is the same in the idealized and actual structures, but the idealized spacing should never be so large that trouble is caused by the assumption of

constant shear stress. A proper bulkhead spacing is one for which the extensional stiffness of each stringer element is greater than the sum of the shear stiffnesses of the adjacent panels so that no negative terms appear on the right-hand side of the equations for the stringer displacements.

CALCULATING PROCEDURES

All the calculations required by the numerical procedure (determining the coefficients of the equations, solving by iteration, and computing the stresses) are routine and involve only simple arithmetic. The calculations can be easily arranged in tabular form so that the bulk of the work can be done by modern automatic computing machinery or by a computer who does not need to have a knowledge of the structural theories involved.

In any problem that involves extensive numerical work, errors are very apt to occur. One of the advantages of the numerical method described herein is that a number of checking procedures can be devised to check the various steps in the calculations. No attempt is made to describe the many possible checks; a few, however, have been indicated in the illustrative example.

Solution of the equations by simple iteration also possesses another advantage with regard to errors. Values obtained from successive cycles of iteration show trends that can be observed by an experienced computer, and errors can be detected by their effects on these trends. Errors that do appear during the iteration process eventually work themselves out but may adversely affect the rate of convergence.

APPLICATION OF THE NUMERICAL METHOD

DESCRIPTION OF THE PROBLEM

The application of the numerical method is illustrated by an analysis of the idealized two-cell box beam shown in figure 2. The cross section is symmetrical about the horizontal center line and the beam is untapered; however, the stringer areas and sheet thicknesses vary from bay to bay.

The box beam is loaded by four concentrated vertical loads applied at the bulkhead stations along the inner web; in addition, it is subjected to the arbitrarily selected distribution

FIGURE 2.—Idealized structure used in illustrative example. (Stringer areas and skin thicknesses are listed in tables I and II.)

of temperature increase shown in figure 3. The temperature is highest at the tip and along the front web and decreases in both spanwise and chordwise directions, but it is constant across the depth of the beam. The beam is assumed to be constructed of 75S-T6 aluminum alloy which has the variation of elastic properties with temperature increase shown in figure 4. These data are the same as those used in reference 1.

It is assumed that no thermal stresses were present at 60° F. Since the method of analysis involves the assumption that no changes in temperature distribution occur over each element, the temperature used in the calculations was the temperature at the center of the element concerned.

FIGURE 3.—Distribution of temperature increase.

FIGURE 4.—Variation of elastic properties of 75S-T6 aluminum alloy with temperature increase (reference 1).

DETAILS OF THE ANALYSIS

Since the structure and the temperature distribution are symmetrical about the horizontal center line, the analysis can be restricted to one cover. Two solutions are required however, to determine the total stress since the thermal-stress system is symmetrical about the horizontal center line, but the load-stress system is antisymmetrical. In this way, the analysis requires the solution of two sets of equations (one of 20, the other of 24) which can be solved more easily than the set of 44 needed for a single analysis of the complete box.

The computations required are given in tabular form with most tables containing two parts—one related to the load stresses and the other related to the thermal stresses. The final solution is obtained by the superposition of these two solutions. The rectangular cross section and its symmetry permit several simplifications of the general equations. In each case the equations used are listed. The notation is described in the appendix. Methods used to check the calculations are also given in the tables. The checking methods used were determined from mathematical relationships existing between the coefficients of the equations and from equilibrium of forces.

Tables I and II present the physical characteristics and stiffness parameters of the individual stringers and panels. Table III gives the location of the principal shear axes of each bay and the coefficients of the bay-displacement equations. The location of the principal inertia axes of each bay, the coefficients used in the correction cycle, and the initial stringer displacements are given in table IV. The coefficients of the stringer-displacement equations are tabulated in table V. Table VI contains the $[C]$ matrices used for the iteration. The rows and columns have been interchanged in order that the matrix multiplications required will consist of the cumulative multiplication of the adjacent numbers in two columns. Table VII is a similar arrangement of data required for the correction cycle and also lists each correction determined. The displacements obtained from each cycle of iteration are given in table VIII and the correction cycles are indicated. Table IX contains the calculation of each type of stress and the superposition required to obtain the total stresses.

The numerical calculations in this example were done by a computer who had previous experience with the method. The following times were required:

Setting up the equations (table I to table VII).....	3 days
Solving the equations (table VIII).....	4 days
Computing stresses (table IX).....	1 day

In this example, the displacements were computed to six decimal places (five or six significant figures) in order that the stress would be accurate to 1 psi and thus would provide accurate equilibrium checks. Most practical problems will not require such numerical accuracy and a smaller number of decimal places should be used in order to speed the solution. It is estimated that the time required to solve this example could have been reduced by one-half if the number of decimal places had been reduced from six to four. This reduction would have given stresses accurate to 100 psi or about 1 percent of the maximum stress.

RESULTS OF THE CALCULATION

The results of the calculation are shown graphically in figure 5 by spanwise and chordwise plots of the stringer stresses in the top and bottom covers and a spanwise plot of shear stresses in the webs. The spanwise plots have a jagged appearance because stringer areas and sheet thicknesses are assumed constant in each bay with an abrupt change at the bulkheads. The dashed lines in the plots of stringer stresses are the values obtained from an elementary analysis.

CONCLUDING REMARKS

A numerical method for the stress analysis of stiffened-shell structures under nonuniform temperature distributions has been presented. The method is not applicable to the solution of all structural problems involving temperature effects because it requires extensive and tedious calculations and because the basic assumptions of bulkheads rigid in their own plane and constant shear stress in a given panel occasionally lead to unsatisfactory results. It is, however, a powerful tool for the solution of many structural problems because:

- (1) It is a means for accurately determining all types of secondary stresses in complicated structures that cannot be satisfactorily analyzed by simplified methods.
- (2) It is sufficiently flexible to cope with a wide variety of structural problems involving nonuniform temperature distributions.
- (3) It involves only simple arithmetic that can be handled by automatic computing machinery.

APPENDIX

DERIVATION OF GENERAL EQUATIONS

The general equations required for the numerical analysis of a stiffened shell of arbitrary cross section with any number of internal cells and under a nonuniform temperature distribution are developed. The basic assumptions and a general description of the method have been given previously and are not repeated.

SYMBOLS

A	cross-sectional area of stringer, square inches
b	width of panel on k grid line, inches
E	modulus of elasticity, psi
F	applied force, pounds
G	modulus of rigidity, psi
h	width of panel on j grid line, inches
I	moment of inertia, inches ⁴
J	shear stiffness parameters
l, m	coordinates of a special set of axes
L	length of bay, inches
M	applied moment, inch-pounds
P	axial load in stringer, positive for tensile load, pounds
Q	area moment, inches ³
r	normal distance to panel on k grid line, positive in positive z -direction, inches
T	temperature increment, measured from temperature of zero thermal stress which is 60° F in the example presented, degrees Fahrenheit
t	panel thickness, inches
u, v, w	displacements in x -, y -, and z -directions, respectively, inches
x, y, z	rectangular coordinate axes
α	coefficient of thermal expansion, inches per inch per degree Fahrenheit
β	angular rotation used in correction cycle, radians
γ	shear strain, radians
δ, Δ	increment

ϵ	normal strain, inches per inch
θ	angular rotation about x -axis, radians
λ	rotation of special set of axes, degrees or radians
ρ	normal distance to panel on j grid line, positive in positive y -direction, inches
σ	normal stress, positive for tensile stress, psi
τ	shear stress, positive in direction of associated coordinate axis when tensile stress on cross section is in positive x -direction, psi
ϕ	angle between normal line r and z -axis, degrees or radians
ψ	angle between normal line ρ and y -axis, degrees or radians

Subscripts:

i, j, k	grid system
x, y, z	coordinate axes
v, w, θ	bay displacements
0	initial value
n	cycle of iteration

A prime refers to the principal shear axes and two primes refer to the principal inertia axes. A bar over a symbol indicates an average value at the center of a bay.

NOTATION

The notation employed is illustrated in figure 6. The system adopted for designating parts of the structure is as follows:

Bulkheads divide the length of the structure into a number of bays. The subscript i is used to designate a given bulkhead or the bay between the $i-1$ and i th bulkheads.

The stringers and panels in a given cross section form the basis of a grid work which can be used to designate these elements. These grid lines are not necessarily straight, parallel, or perpendicular but follow the panels. Those grid lines that are approximately parallel to the z -axis are designated by the subscript j ; those approximately parallel to the y -axis are designated by the subscript k .

With this system, points and stringers can be uniquely located as follows:

The point on the i th bulkhead at the intersection of the

FIGURE 6.—Notation and coordinate system.

j th and k th grid lines is designated by the subscripts i, j, k .

The stringer in the i th bay at the intersection of the j th and k th grid lines is designated by the subscripts i, j, k .

In order to locate a panel, the grid line on which it lies must be known. This notation consists of underlining the appropriate subscript; for example:

The panel in the i th bay on the j th grid line and between the $k-1$ and k th grid lines is designated by the subscripts $i, \underline{j}, k$.

The panel in the i th bay on the k th grid line and between the $j-1$ and j th grid lines is designated by the subscripts $i, j, \underline{k}$.

The grid lines and bulkheads are numbered such that the numbers increase in the directions of the positive coordinate axes.

STRESS-STRAIN RELATIONSHIPS

The shear strain in a given panel is constant and is defined by the following relationships which depend upon the location of the panel:

$$\begin{aligned}\gamma_{i, \underline{j}, k} &= \left(\frac{\tau}{G} \right)_{i, \underline{j}, k} \\ &= \frac{1}{2b_{j,k}} (u_{i,j,k} + u_{i-1,j,k} - u_{i,j-1,k} - u_{i-1,j-1,k}) + \\ &\quad \frac{\Delta v_i}{L_i} \cos \phi_{j,k} + \frac{\Delta w_i}{L_i} \sin \phi_{j,k} - \frac{\Delta \theta_i}{L_i} r_{j,k}\end{aligned}\quad (A1a)$$

$$\begin{aligned}\gamma_{i, j, \underline{k}} &= \left(\frac{\tau}{G} \right)_{i, j, \underline{k}} \\ &= \frac{1}{2h_{j,k}} (u_{i,j,k} + u_{i-1,j,k} - u_{i,j,k-1} - u_{i-1,j,k-1}) - \\ &\quad \frac{\Delta v_i}{L_i} \sin \psi_{j,k} + \frac{\Delta w_i}{L_i} \cos \psi_{j,k} + \frac{\Delta \theta_i}{L_i} \rho_{j,k}\end{aligned}\quad (A1b)$$

When the shear strains are being computed, the normal distances r and ρ must be given their proper signs.

The constant shear stress produces a linearly varying strain in the stringer and its average value at the center of the bay is

$$\bar{\epsilon}_{i, j, k} = \frac{u_{i,j,k} - u_{i-1,j,k}}{L_i} = \left(\frac{\bar{P}}{AE} + \alpha T \right)_{i, j, k} \quad (A2)$$

Note that the thermal expansion is included in the relationship between stringer stress and strain.

EQUILIBRIUM OF INDIVIDUAL STRINGERS

If a half-bay length of stringer on each side of point (i, j, k) is isolated, the force system of figure 7 is obtained, and the following equilibrium equation can be written:

$$\begin{aligned}-\left(\frac{\tau t L}{2} \right)_{i, j, \underline{k}} + \left(\frac{\tau t L}{2} \right)_{i, j+1, \underline{k}} - \left(\frac{\tau t L}{2} \right)_{i, \underline{j}, k} + \left(\frac{\tau t L}{2} \right)_{i, \underline{j}, k+1} - \\ \left(\frac{\tau t L}{2} \right)_{i+1, j, \underline{k}} + \left(\frac{\tau t L}{2} \right)_{i+1, j+1, \underline{k}} - \left(\frac{\tau t L}{2} \right)_{i+1, \underline{j}, k} + \left(\frac{\tau t L}{2} \right)_{i+1, \underline{j}, k+1} + \\ \bar{P}_{i+1, j, k} - \bar{P}_{i, j, k} + (F_z)_{i, j, k} = 0\end{aligned}\quad (A3)$$

Substituting equations (A1) and (A2) into equation (A3) yields the following equation for the stringer displacement of point (i, j, k) in terms of the displacements of the adjacent bays and stringers:

$$\begin{aligned}
 u_{i,j,k} = & \frac{1}{\sum S_{i,j,k}} \left\{ u_{i-1,j-1,k} \left(\frac{GtL}{4b} \right)_{i,j,k} + u_{i-1,j,k-1} \left(\frac{GtL}{4h} \right)_{i,j,k} + \right. \\
 & u_{i-1,j,k} \left[\left(\frac{AE}{L} \right)_{i,j,k} - \left(\frac{GtL}{4b} \right)_{i,j,k} - \left(\frac{GtL}{4b} \right)_{i,j+1,k} - \left(\frac{GtL}{4h} \right)_{i,j,k} - \left(\frac{GtL}{4h} \right)_{i,j,k+1} \right] + u_{i-1,j,k+1} \left(\frac{GtL}{4h} \right)_{i,j,k+1} + \\
 & u_{i-1,j+1,k} \left(\frac{GtL}{4b} \right)_{i,j+1,k} + u_{i,j-1,k} \left[\left(\frac{GtL}{4b} \right)_{i,j,k} + \left(\frac{GtL}{4b} \right)_{i+1,j,k} \right] + u_{i,j,k-1} \left[\left(\frac{GtL}{4h} \right)_{i,j,k} + \left(\frac{GtL}{4h} \right)_{i+1,j,k} \right] + \\
 & u_{i,j,k+1} \left[\left(\frac{GtL}{4h} \right)_{i,j,k+1} + \left(\frac{GtL}{4h} \right)_{i+1,j,k+1} \right] + u_{i,j+1,k} \left[\left(\frac{GtL}{4b} \right)_{i,j+1,k} + \left(\frac{GtL}{4b} \right)_{i+1,j+1,k} \right] + u_{i+1,j-1,k} \left(\frac{GtL}{4b} \right)_{i+1,j,k} + \\
 & u_{i+1,j,k-1} \left(\frac{GtL}{4h} \right)_{i+1,j,k} + u_{i+1,j,k} \left[\left(\frac{AE}{L} \right)_{i+1,j,k} - \left(\frac{GtL}{4b} \right)_{i+1,j,k} - \left(\frac{GtL}{4b} \right)_{i+1,j+1,k} - \left(\frac{GtL}{4h} \right)_{i+1,j,k} - \left(\frac{GtL}{4h} \right)_{i+1,j,k+1} \right] + \\
 & u_{i+1,j,k+1} \left(\frac{GtL}{4h} \right)_{i+1,j,k+1} + u_{i+1,j+1,k} \left(\frac{GtL}{4b} \right)_{i+1,j+1,k} + \\

FIGURE 7.—Forces on stringer.

Equation (A4) involves no assumptions regarding equality of structural dimensions, temperatures, or elastic properties about point (i, j, k) . If any element is missing, the associated stiffness goes to zero and the general equation is still applicable. Since AE and Gt always appear as products, the variation of elastic properties with temperature is equivalent to changes in the stringer areas and sheet thicknesses of the effective structure. Furthermore, the thermal-expansion terms appear in the same manner as axial loads applied to the stringers. Thus, if desired, the effects of a nonuniform temperature distribution can be determined by applying a set of equivalent loads to a new effective structure.

BAY SHEAR AND TORQUE EQUILIBRIUM

The equations for the bay displacements (v, w, θ) can be obtained from equilibrium of the shear forces on the bay

cross section

$$(F_y)_i - \sum_j \sum_k [(\tau t b \cos \phi)_{i,j,k} - (\tau t h \sin \psi)_{i,j,k}] = 0 \quad (A5a)$$

$$(F_z)_i - \sum_j \sum_k [(\tau t b \sin \phi)_{i,j,k} + (\tau t h \cos \psi)_{i,j,k}] = 0 \quad (A5b)$$

$$(M_x)_i + \sum_j \sum_k [(\tau t b r)_{i,j,k} - (\tau t h \rho)_{i,j,k}] = 0 \quad (A5c)$$

Substitution of equations (A1) for the shear stresses in equations (A5) results in

$$(J_{vv})_i \Delta v_i + (J_{vw})_i \Delta w_i - (J_{\theta v})_i \Delta \theta_i = (F_y)_i + \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gt \cos \phi}{2} \right)_{i,j+1,k} - \left(\frac{Gt \cos \phi}{2} \right)_{i,j,k} - \left(\frac{Gt \sin \psi}{2} \right)_{i,j,k+1} + \left(\frac{Gt \sin \psi}{2} \right)_{i,j,k} \right] \quad (A6a)$$

$$(J_{vw})_i \Delta v_i + (J_{ww})_i \Delta w_i - (J_{\theta w})_i \Delta \theta_i = (F_z)_i + \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gt \sin \phi}{2} \right)_{i,j+1,k} - \left(\frac{Gt \sin \phi}{2} \right)_{i,j,k} + \left(\frac{Gt \cos \psi}{2} \right)_{i,j,k+1} - \left(\frac{Gt \cos \psi}{2} \right)_{i,j,k} \right] \quad (A6b)$$

$$-(J_{\theta v})_i \Delta v_i - (J_{\theta w})_i \Delta w_i + (J_{\theta \theta})_i \Delta \theta_i = (M_x)_i - \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gtr}{2} \right)_{i,j+1,k} - \left(\frac{Gtr}{2} \right)_{i,j,k} - \left(\frac{Gt\rho}{2} \right)_{i,j,k+1} + \left(\frac{Gt\rho}{2} \right)_{i,j,k} \right] \quad (A6c)$$

FIGURE 8.—Notation used to locate principal shear axes.

where

$$(J_{vv})_i = \sum_j \sum_k \left[\left(\frac{Gtb \cos^2 \phi}{L} \right)_{i,j,k} + \left(\frac{Gth \sin^2 \psi}{L} \right)_{i,j,k} \right]$$

$$(J_{vw})_i = \sum_j \sum_k \left[\left(\frac{Gtb \sin \phi \cos \phi}{L} \right)_{i,j,k} - \left(\frac{Gth \sin \psi \cos \psi}{L} \right)_{i,j,k} \right]$$

$$(J_{ww})_i = \sum_j \sum_k \left[\left(\frac{Gtb \sin^2 \phi}{L} \right)_{i,j,k} + \left(\frac{Gth \cos^2 \psi}{L} \right)_{i,j,k} \right]$$

$$(J_{\theta v})_i = \sum_j \sum_k \left[\left(\frac{Gtbr \cos \phi}{L} \right)_{i,j,k} + \left(\frac{Gth \rho \sin \psi}{L} \right)_{i,j,k} \right]$$

$$(J_{\theta w})_i = \sum_j \sum_k \left[\left(\frac{Gtbr \sin \phi}{L} \right)_{i,j,k} - \left(\frac{Gth \rho \cos \psi}{L} \right)_{i,j,k} \right]$$

$$(J_{\theta \theta})_i = \sum_j \sum_k \left[\left(\frac{Gtbr^2}{L} \right)_{i,j,k} + \left(\frac{Gth \rho^2}{L} \right)_{i,j,k} \right]$$

Equations (A6) can be simplified by eliminating the coupling terms if the axes used in the computations are the principal shear axes of the cross section. These axes are defined such that

$$J_{vw}' = J_{\theta v}' = J_{\theta w}' = 0 \quad (A7)$$

The relationship between the location and orientation of points and panels in two systems of coordinates, arbitrary axes (x, y, z) and the principal shear axes (x', y', z') , is shown in figure 8 and given by the following equations:

$$y' = (z - m') \sin \lambda' + (y - l') \cos \lambda' \quad (A8a)$$

$$z' = (z - m') \cos \lambda' - (y - l') \sin \lambda' \quad (A8b)$$

$$\phi' = \phi - \lambda' \quad (A9a)$$

$$\psi' = \psi - \lambda' \quad (A9b)$$

$$r' = r + l' \sin \phi - m' \cos \phi \quad (A10a)$$

$$\rho' = \rho - l' \cos \psi - m' \sin \psi \quad (A10b)$$

Then the location of the principal shear axes is

$$\tan 2\lambda' = \frac{2J_{vw}}{J_{vv} - J_{ww}} \quad (A11a)$$

$$l' = -\frac{J_{vv}J_{\theta w} - J_{vw}J_{\theta v}}{J_{vv}J_{ww} - J_{vw}^2} \quad (A11b)$$

$$m' = \frac{J_{ww}J_{\theta v} - J_{vw}J_{\theta w}}{J_{vv}J_{ww} - J_{vw}^2} \quad (A11c)$$

and, with respect to these axes,

$$J_{vv}' = J_{vv} \cos^2 \lambda' + J_{ww} \sin^2 \lambda' + 2J_{vw} \sin \lambda' \cos \lambda' \quad (A12a)$$

$$J_{ww}' = J_{vv} \sin^2 \lambda' + J_{ww} \cos^2 \lambda' - 2J_{vw} \sin \lambda' \cos \lambda' \quad (A12b)$$

$$J_{\theta \theta}' = J_{\theta \theta} + l' J_{\theta w} - m' J_{\theta v} \quad (A12c)$$

$$F_y' = F_z \sin \lambda' + F_y \cos \lambda' \quad (A13a)$$

$$F_z' = F_z \cos \lambda' - F_y \sin \lambda' \quad (\text{A13b})$$

$$M_z' = M_z + m' F_y - l' F_z \quad (\text{A13c})$$

When referred to the principal shear axes, the equations for the bay displacements become

$$\Delta v_i' = \left(\frac{1}{J_{vv'}} \right)_i \left\{ (F_y')_i + \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gt \cos \phi'}{2} \right)_{i,j+1,k} - \left(\frac{Gt \cos \phi'}{2} \right)_{i,j,k} - \left(\frac{Gt \sin \psi'}{2} \right)_{i,j,k+1} + \left(\frac{Gt \sin \psi'}{2} \right)_{i,j,k} \right] \right\} \quad (\text{A14a})$$

$$\Delta w_i' = \left(\frac{1}{J_{ww'}} \right)_i \left\{ (F_z')_i + \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gt \sin \phi'}{2} \right)_{i,j+1,k} - \left(\frac{Gt \sin \phi'}{2} \right)_{i,j,k} + \left(\frac{Gt \cos \psi'}{2} \right)_{i,j,k+1} - \left(\frac{Gt \cos \psi'}{2} \right)_{i,j,k} \right] \right\} \quad (\text{A14b})$$

$$\Delta \theta_i' = \left(\frac{1}{J_{\theta\theta'}} \right)_i \left\{ (M_z')_i - \sum_j \sum_k (u_{i,j,k} + u_{i-1,j,k}) \left[\left(\frac{Gtr'}{2} \right)_{i,j+1,k} - \left(\frac{Gtr'}{2} \right)_{i,j,k} - \left(\frac{Gtp'}{2} \right)_{i,j,k+1} + \left(\frac{Gtp'}{2} \right)_{i,j,k} \right] \right\} \quad (\text{A14c})$$

BAY THRUST AND MOMENT EQUILIBRIUM

The equations obtained from equations (A4) and (A14) are sufficient in themselves to define completely the displacements of the structure. However, if the equations are solved by iteration, it is helpful to employ a periodic correction cycle based on the gross equilibrium of axial loads in the cross section

$$(F_z)_i - \sum_j \sum_k (\bar{P})_{i,j,k} = 0 \quad (\text{A15a})$$

$$(\bar{M}_y)_i - \sum_j \sum_k (\bar{P}z)_{i,j,k} = 0 \quad (\text{A15b})$$

$$(\bar{M}_z)_i + \sum_j \sum_k (\bar{P}y)_{i,j,k} = 0 \quad (\text{A15c})$$

It can be shown that equations (A15) are satisfied by the solution of equations (A4) and (A14); however, they are not likely to be satisfied by the displacement values obtained from any given cycle of iteration. In reference 2 it was demonstrated that convergence of the iterative process can be speeded if the displacement values are periodically corrected so that the stringer displacements satisfy equations (A15).

The corrections applied to the stringer displacements are a planar distribution over the cross section and are determined as follows:

$$(u_{i,j,k})_{n+1} = (u_{i,j,k})_n + \Delta u_{i,j,k} \quad (\text{A16})$$

where

$$\Delta u_{i,j,k} = \delta u_i + \beta_{z,i} y_{j,k} + \beta_{y,i} z_{j,k}$$

Substituting equation (A16) into (A15) yields

$$(AE)_i \delta u_i + (EQ_z)_i \beta_{z,i} + (EQ_y)_i \beta_{y,i} = (LF_z)_i + L_i \sum_j \sum_k \left[(AE\alpha Tz)_{i,j,k} - (u_{i,j,k} - u_{i-1,j,k}) \left(\frac{AE}{L} \right)_{i,j,k} \right] \quad (\text{A17a})$$

$$(EQ_y)_i \delta u_i + (EI_{yz})_i \beta_{z,i} + (EI_{yy})_i \beta_{y,i} = (L\bar{M}_y)_i + L_i \sum_j \sum_k \left[(AE\alpha Ty)_{i,j,k} - (u_{i,j,k} - u_{i-1,j,k}) \left(\frac{AEy}{L} \right)_{i,j,k} \right] \quad (\text{A17b})$$

$$(EQ_z)_i \delta u_i + (EI_{zz})_i \beta_{z,i} + (EI_{yz})_i \beta_{y,i} = -(L\bar{M}_z)_i + L_i \sum_j \sum_k \left[(AE\alpha Tz)_{i,j,k} - (u_{i,j,k} - u_{i-1,j,k}) \left(\frac{AEz}{L} \right)_{i,j,k} \right] \quad (\text{A17c})$$

where

$$(AE)_i = \sum_j \sum_k (AE)_{i,j,k} \quad (EI_{yy})_i = \sum_j \sum_k (AEz^2)_{i,j,k}$$

$$(EQ_z)_i = \sum_j \sum_k (AEy)_{i,j,k} \quad (EI_{zz})_i = \sum_j \sum_k (AEy^2)_{i,j,k}$$

$$(EQ_y)_i = \sum_j \sum_k (AEz)_{i,j,k} \quad (EI_{yz})_i = \sum_j \sum_k (AEyz)_{i,j,k}$$

These equations can be simplified by elimination of the coupling terms if the computations are referred to the equivalent principal inertia axes of the cross section. These axes are referred to as equivalent because the variation of modulus of elasticity over the cross section is taken into consideration. These axes (x'' , y'' , z'') are defined such that

$$EQ_z'' = EQ_y'' = EI_{yz}'' = 0 \quad (\text{A18})$$

and then the following relationships are applicable:

$$y'' = (z - m'') \sin \lambda'' + (y - l'') \cos \lambda'' \quad (\text{A19a})$$

$$z'' = (z - m'') \cos \lambda'' - (y - l'') \sin \lambda'' \quad (\text{A19b})$$

$$\tan 2\lambda'' = \frac{2(EI_{yz} - AE l'' m'')}{(EI_{yy} - AE m''^2) - (EI_{zz} - AE l''^2)} \quad (\text{A20a})$$

$$l'' = \frac{EQ_z}{AE} \quad (\text{A20b})$$

$$m'' = \frac{EQ_y}{AE} \quad (\text{A20c})$$

$$EI_{yy}'' = (EI_{yy} - AE m''^2) \cos^2 \lambda'' + (EI_{zz} - AE l''^2) \sin^2 \lambda'' - 2(EI_{yz} - AE l'' m'') \sin \lambda'' \cos \lambda'' \quad (\text{A21a})$$

$$EI_{zz}'' = (EI_{yy} - AE m''^2) \sin^2 \lambda'' + (EI_{zz} - AE l''^2) \cos^2 \lambda'' + 2(EI_{yz} - AE l'' m'') \sin \lambda'' \cos \lambda'' \quad (\text{A21b})$$

$$F_x'' = F_x \quad (\text{A22a})$$

$$\bar{M}_y'' = \bar{M}_z \sin \lambda'' + \bar{M}_y \cos \lambda'' \quad (\text{A22b})$$

$$\bar{M}_z'' = \bar{M}_z \cos \lambda'' - \bar{M}_y \sin \lambda'' \quad (\text{A22c})$$

A further simplification of the correction cycle can be made by eliminating the load and temperature terms on the right-hand side of equations (A17). This elimination can be accomplished by iterating the difference between the exact solution and one which satisfies statics (equations (A15)) but not necessarily continuity. The iteration of differences has an additional advantage in that smaller numbers, and consequently less work, are required to obtain a solution.

An examination of equations (A17) indicates that they can be satisfied by a planar distribution of strain corresponding

to the elementary analysis of reference 1. Then the initial values of stringer displacements u can be defined as follows:

$$u_{i,j,k} = u_{i-1,j,k} + (\epsilon_0 L)_{i,j,k} \quad (A23)$$

where

$$(\epsilon_0 L)_{i,j,k} = (\delta u_i'')_0 + (\beta_{z,i}'')_0 y_{j,k}'' + (\beta_{y,i}'')_0 z_{j,k}''$$

and, with respect to the equivalent principal inertia axes,

$$(\delta u_i'')_0 = \left(\frac{L}{AE} \right)_i \left[(F_z'')_i + \sum_j \sum_k (AE \alpha T)_{i,j,k} \right] \quad (A24a)$$

$$(\beta_{z,i}'')_0 = \left(\frac{L}{EI_{zz}''} \right)_i \left[-(\bar{M}_z'')_i + \sum_j \sum_k (AE \alpha T y'')_{i,j,k} \right] \quad (A24b)$$

$$(\beta_{y,i}'')_0 = \left(\frac{L}{EI_{yy}''} \right)_i \left[(\bar{M}_y'')_i + \sum_j \sum_k (AE \alpha T z'')_{i,j,k} \right] \quad (A24c)$$

The corresponding values of the bay displacements are obtained from equations (A14) and (A23).

Then the correction-cycle equations applicable to the iterated differences are as follows:

$$\delta u_i'' = - \left(\frac{1}{AE} \right)_i \sum_j \sum_k (\Delta u_{i,j,k} - \Delta u_{i-1,j,k}) (AE)_{i,j,k} \quad (A25a)$$

$$\beta_{z,i}'' = - \left(\frac{1}{EI_{zz}''} \right)_i \sum_j \sum_k (\Delta u_{i,j,k} - \Delta u_{i-1,j,k}) (AE y'')_{i,j,k} \quad (A25b)$$

$$\beta_{y,i}'' = - \left(\frac{1}{EI_{yy}''} \right)_i \sum_j \sum_k (\Delta u_{i,j,k} - \Delta u_{i-1,j,k}) (AE z'')_{i,j,k} \quad (A25c)$$

Equations (A25) provide corrections to the stringer displacements u only. These corrections remove any unbalanced moment or thrust on the cross section but add unbalanced shear forces which are removed by correcting the

bay displacements (v, w, θ) . The corrected bay displacements are obtained from the corrected stringer displacements by application of equation (A14). These two operations constitute the complete correction cycle that brings the stringer loads into equilibrium with the external loads without changing the shear stress in any panel.

$$\sum_{j=1}^4 (119)_i - \sum_{j=1}^4 (119)_{i+1,j} = 0$$

REPORT 1044

THE METHOD OF CHARACTERISTICS FOR THE DETERMINATION OF SUPERSONIC FLOW OVER BODIES OF REVOLUTION AT SMALL ANGLES OF ATTACK ¹

By ANTONIO FERRI

SUMMARY

The method of characteristics has been applied for the determination of the supersonic-flow properties around bodies of revolution at a small angle of attack. The system developed considers the effect of the variation of entropy due to the curved shock and determines a flow that exactly satisfies the boundary conditions in the limits of the simplifications assumed. Two practical methods for numerical calculations are given.

INTRODUCTION

For the determination of aerodynamic properties of bodies of revolution at supersonic speeds, two methods have been used: a method that uses the small-disturbances theory and a method that uses the characteristics theory. Both methods are successful in the determination of the flow properties for bodies at zero angle of attack, but the precision of the small-disturbances theory decreases when a body of revolution at an angle of attack is considered.

For bodies of revolution having supersonic flow everywhere, the theory of characteristics can also be used at an angle of attack.

The method of characteristics for the determination of the flow field around bodies of revolution at an angle of attack was first used by Ferrari (reference 1) in 1936. Ferrari considers the flow as potential flow and develops a method for the analysis of the flow field around a body that in the approximation of potential flow appears to be general and can be applied to bodies of any shape and with any angle of attack. In the determination of the flow properties along the first characteristic surface from which the analysis starts, however, Ferrari analyzes the flow around a cone of revolution, and in this part of the analysis only small values of angle of attack are considered.

Sauer in 1942 (reference 2) considers the same problems and shows that, for small values of angle of attack, the analysis of the flow field around a body of revolution can be made by applying the characteristics method only in one meridian plane; and, therefore, Sauer uses characteristic lines in place of the characteristic surfaces considered by Ferrari. Sauer, in the development of his system, is interested essentially in the analysis of the flow around circular cones; and when the method is applied to bodies of revolution of shapes different from cones, the boundary conditions are

no longer satisfied. The flow obtained from the solution used, also at small angles of attack, wets a body that is not a body of revolution. The body can be obtained from the body of revolution considered initially by curving its axis of symmetry. Sauer also assumes that the flow is potential flow. With this assumption, the flow must be considered as potential flow for the case of the body at zero angle of attack also; therefore, all the effects of entropy gradients are neglected.

The flow field around circular cones at small angles of attack has been analyzed in a more exact form by Stone and Ferri. (See references 3 to 5.) In his analysis, Stone considers the flow as rotational flow and, therefore, takes into account the effect of entropy gradients on the velocity distribution. This effect exists only when the cone has an angle of attack and, at low Mach numbers, is small but of the same order as the effect of other parameters that are considered in the analysis. Ferri considers correctly the entropy distribution at the surface of the cone and found the existence of a vortical layer at the surface of the cone across which the pressure does not change although density and velocity change.

Here, the method of characteristics is extended to the analysis of the flow field around a body of revolution at small angles of attack for the case of rotational flow. The effect of entropy gradients about bodies of revolution even at small angles of attack can be important because the entropy gradients that exist in the stream for small angles of attack are due to the variation of curvature of the shock existing at zero angle of attack also, together with the fact that the shock surface does not have axial symmetry with respect to the direction of the undisturbed velocity.

The method presented permits the determination of a flow that in the assumption of small angles of attack exactly satisfies the boundary conditions and, therefore, wets the body of revolution considered. This method is given in a form that permits its application to practical problems and requires either numerical or numerical and graphical calculations of the same type as the calculations used for the analysis of the flow around bodies at zero angle of attack. The method can be applied to cases in which the entropy variations can be neglected or are zero. In these cases the terms that contain the entropy variations become zero.

EQUATION OF MOTION FOR FLOW AROUND A BODY OF REVOLUTION AT A SMALL ANGLE OF ATTACK

Consider a cylindrical coordinate system in which the x -axis is coincident with the axis of the body of revolution, the y -axis is normal to the x -axis in any meridian plane, and the position of every meridian plane is defined by the angle θ measured with respect to the meridian plane that contains the direction of the undisturbed velocity (fig. 1).

Euler's equations of motion for steady flow in cylindrical coordinates are

$$-\frac{1}{\rho} \frac{\partial p}{\partial x} = \frac{\partial u}{\partial x} u + \frac{\partial u}{\partial y} v + \frac{\partial u}{\partial \theta} w \quad (1a)$$

$$-\frac{1}{\rho} \frac{\partial p}{\partial y} = \frac{\partial v}{\partial x} u + \frac{\partial v}{\partial y} v + \frac{\partial v}{\partial \theta} w - \frac{w^2}{y} \quad (1b)$$

$$-\frac{1}{\rho} \frac{\partial p}{\partial \theta} = \frac{\partial w}{\partial x} u + \frac{\partial w}{\partial y} v + \frac{\partial w}{\partial \theta} w + \frac{vw}{y} \quad (1c)$$

The continuity equation in cylindrical coordinates can be expressed in the form

$$\frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v y)}{y \partial y} + \frac{\partial(w \rho)}{y \partial \theta} = 0 \quad (2)$$

whereas the law of conservation of energy can be written in the form

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial x} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial x} \right) = - \left(u \frac{\partial u}{\partial x} + v \frac{\partial v}{\partial x} + w \frac{\partial w}{\partial x} \right) \quad (3a)$$

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial y} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial y} \right) = - \left(u \frac{\partial u}{\partial y} + v \frac{\partial v}{\partial y} + w \frac{\partial w}{\partial y} \right) \quad (3b)$$

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial \theta} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial \theta} \right) = - \left(u \frac{\partial u}{\partial \theta} + v \frac{\partial v}{\partial \theta} + w \frac{\partial w}{\partial \theta} \right) \quad (3c)$$

If the density is eliminated from equation (2) by means of equations (1) and (3) and the quantity a is introduced as defined by

$$a^2 = \gamma \frac{p}{\rho}$$

the following equation can be obtained:

$$\begin{aligned} & \frac{\partial u}{\partial x} \left(1 - \frac{u^2}{a^2}\right) + \frac{\partial v}{\partial y} \left(1 - \frac{v^2}{a^2}\right) + \frac{\partial w}{\partial \theta} \left(1 - \frac{w^2}{a^2}\right) + \frac{v}{y} - \\ & \frac{vu}{a^2} \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) - \frac{uw}{a^2} \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial \theta}\right) - \frac{vw}{a^2} \left(\frac{\partial v}{\partial \theta} + \frac{\partial w}{\partial y}\right) = 0 \end{aligned} \quad (4)$$

In this analysis only small angles of attack will be considered, and, therefore, only the first-order effect of the angle of attack will be determined; whereas, the quantities of the same or higher order than the square of the angle of attack will be neglected. In this approximation the velocity components of the flow around the body can be expressed in the following form (references 1 to 4):

$$u = u_1 + \alpha u_2 \cos \theta \quad (5a)$$

$$v = v_1 + \alpha v_2 \cos \theta \quad (5b)$$

$$w = \alpha w_2 \sin \theta \quad (5c)$$

where u , v , and w are functions of the three coordinates x , y , and θ ; whereas u_1 , v_1 , u_2 , v_2 , and w_2 are functions only of the coordinates x and y of any meridian plane. The quantity α is the angle of attack of the body, the quantities with subscript 1 are the quantities existing at the position (x, y) for the body considered at zero angle of attack at the same Mach number, and the quantities with subscript 2 are functions that take into account the effect of angle of attack.

It will be shown in the following considerations that the form assumed in equations (5) for the velocity components permits the boundary conditions to be satisfied in the simplifications assumed. For small angles of attack equation (4) becomes

$$\frac{\partial u}{\partial x} \left(1 - \frac{u^2}{a^2}\right) + \frac{\partial v}{\partial y} \left(1 - \frac{v^2}{a^2}\right) + \frac{v}{y} - \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \frac{uv}{a^2} + \frac{\partial w}{\partial \theta} = 0 \quad (6)$$

Equation (6) is similar in form to the corresponding equation for the case of the body at zero angle of attack and differs only in the term $\frac{\partial w}{y \partial \theta}$. In order to analyze the differences between this expression and the expression for the axial symmetrical case and in order to obtain another relation that defines the quantity w , the relation between rotation of the flow and entropy gradient will now be introduced.

Between rotation of flow and entropy the following relation exists:

$$\text{curl } \mathbf{V} \times \mathbf{V} = \frac{a^2}{\gamma R} \text{grad } S \quad (7)$$

or for small angles of attack

$$\frac{\partial S}{\partial x} \frac{a^2}{\gamma R} = -v \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \quad (8a)$$

$$\frac{\partial S}{\partial y} \frac{a^2}{\gamma R} = u \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \quad (8b)$$

$$\frac{\partial S}{y \partial \theta} \frac{a^2}{\gamma R} = v \left(\frac{\partial w}{\partial y} - \frac{\partial v}{y \partial \theta}\right) + \frac{wv}{y} - u \left(\frac{\partial u}{y \partial \theta} - \frac{\partial w}{\partial x}\right) \quad (8c)$$

If n is the normal, in the meridian plane $\theta = \text{Constant}$, to the local tangent to the streamline, then

$$\begin{aligned} \frac{\partial S}{\partial n} &= -\frac{\partial S}{\partial x} \frac{v}{V} + \frac{\partial S}{\partial y} \frac{u}{V} \\ &= \frac{\gamma R}{a^2} V \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) \end{aligned} \quad (9)$$

whereas from equation (8c), when equations (5) are used, it follows that

$$\frac{1}{y} \frac{a^2}{\gamma R} \frac{\partial S}{\partial \theta} = \left[v \left(\frac{\partial w_2}{\partial y} + \frac{v_2}{y}\right) + \frac{vw_2}{y} + u \left(\frac{u_2}{y} + \frac{\partial w_2}{\partial x}\right) \right] \alpha \sin \theta \quad (10)$$

Therefore, the entropy can be expressed in the form

$$\Delta S = \Delta S_1 + \alpha \Delta S_2 \cos \theta \quad (11)$$

where ΔS_1 and ΔS_2 are functions only of x and y . Equation (11) is valid outside of the vortical layer existing at the surface of the body (see reference 5); whereas the entropy at the surface of the body is constant and equal to the value existing at the conical tip. Because no pressure gradient exists across the vortical layer, the pressure will be determined outside of the layer and equation (11) will be used in all the flow field. The presence of the layer must be considered for the velocity and density distribution at the surface of the body. At the surface of the body the entropy is constant and equal to $\Delta S_1 - \alpha \Delta S_2$. (The meridian plane $\theta = 0$ is defined as in figure 1.) From equation (11) it results

$$v \frac{\partial w_2}{\partial y} + u \frac{\partial w_2}{\partial x} = -\frac{vw_2 + vv_2 + uu_2}{y} - \frac{a^2}{y\gamma R} \Delta S_2 \quad (12)$$

Equation (6) can be written in the following form:

$$\frac{\partial u}{\partial x} \left(1 - \frac{u^2}{a^2}\right) + \frac{\partial v}{\partial y} \left(1 - \frac{v^2}{a^2}\right) + \frac{v}{y} - \frac{2uv}{a^2} \frac{\partial v}{\partial x} + \frac{uv}{V\gamma R} \frac{\partial S}{\partial n} + \frac{\partial w}{y \partial \theta} = 0 \quad (13)$$

Equation (13) together with equation (12) defines the law of motion of the flow around the body at small angles of attack. These equations will be used as a basis for the calculation of the flow field by the method of characteristics to be treated in a subsequent section.

CONDITIONS AT THE SHOCK FRONT

Equations (5) and (11) represent a stream that wets a body of revolution at a small angle of attack. In order to satisfy the boundary conditions at the surface of the body, the functions u_2 , v_2 , and w_2 must be properly selected. Equations (5) and (11) must, however, satisfy the boundary conditions at the shock surface also in order to be a solution of the problem. It is necessary, therefore, to show that a shock surface can exist across which the undisturbed stream inclined at α with respect to the axis of the body is transformed into a flow represented by equations (5) and (11).

In order to show that the shock boundary conditions can be satisfied, the following procedure will be employed. A shock surface distorted in a manner to be described is assumed. Then, the free-stream velocity ahead of the shock will be resolved into three components: v_N normal to the shock in the plane $\theta = \text{Constant}$, v_T tangent to the shock in the plane $\theta = \text{Constant}$, and w perpendicular to the plane $\theta = \text{Constant}$. Similarly, the flow behind the shock will be resolved into three components. In addition, each component of the flow behind the shock will be divided into two terms: one term for zero angle of attack and one term for the difference due to the angle of attack (for example, $u = u_1 + \alpha u_2 \cos \theta$). Then, the conditions of equilibrium at the shock will be imposed, and it will be shown that the terms u_2 , v_2 , and w_2 at the shock are independent of θ when the angle of attack is small as initially assumed; hence, the distorted shock is consistent with the field of flow behind it. Such a shock surface can be obtained by deforming the shock surface produced by the body when the angle of attack α is zero in the following way (fig. 2):

When $\alpha = 0$, the shock surface is a surface of revolution in axis with the body; therefore, if OP, OP' is the curve intersection of the shock with the meridian plane $\theta = 0$, then for $\alpha = 0$ the tangent AQ at any point Q of the curve OP is the generatrix of a circular cone having the vertex at a point A of the axis and tangent along the circle QQ' to the shock surface. The shock surface, therefore, can be considered as a surface envelope of circular cones having the axis coincident with the axis of the body but having variable

cone angle and variable position of the apex A along the axis AB of the body. For the case of $\alpha \neq 0$ the shock surface is not a surface of revolution but can still be considered, for small angles of attack, as the envelope of the same circular cones considered for the case $\alpha = 0$. These cones have the same apexes and the same cone angles as the cases for $\alpha = 0$ but do not have the axis of symmetry AB coincident with the axis of the body AB although they are rotated in the plane $\theta = 0$ with respect to the body axis. The angle η , through which each axis of the cones must rotate in the plane $\theta = 0$ with respect to the axis of the body, is not constant but varies for each cone considered. For example, the cone AQQ' tangent to the shock surface for $\alpha = 0$, when $\alpha \neq 0$, must be rotated by an angle η to the position AQ_1Q_1' ; the axis AB_1 remains in the plane $\theta = 0$.

The shock surface so generated is consistent with the flow represented by equations (5) and (11), and this can be shown in the following way:

Consider a point P of the shock produced by the body at an angle of attack, and consider the cone tangent to the shock at the point P (fig. 3). Call σ the semiangle of the cone with respect to its axis of symmetry. The axis of this cone is inclined at an angle η with respect to the axis of the body and lies in the plane $\theta = 0$.

The uniform velocity V_0 ahead of the shock is decomposed in the three components: v_N' in the direction PB normal to the shock, v_T' in the direction AP along the generatrix of the cone, and w' in the direction normal to the plane APB . These components are, at small angles of attack,

$$v_N' = V_0 \sin \sigma - V_0(\alpha - \eta) \cos \sigma \cos \theta \quad (14a)$$

$$v_T' = V_0 \cos \sigma + V_0(\alpha - \eta) \sin \sigma \cos \theta \quad (14b)$$

$$w' = -V_0(\alpha - \eta) \sin \theta \quad (14c)$$

Strictly, in equations (14) ψ must be written in place of θ ; but, for small angles of attack in equations (14), the difference between ψ and θ can be neglected. Indeed,

$$\psi = \delta + \theta'$$

where δ is of the order of α , and θ' differs from θ by a quantity of the order of α .

FIGURE 3.—The velocity components in front of and behind the shock.

FIGURE 2.—The shock surface at $\alpha = 0$ and $\alpha \neq 0$.

The velocity components behind the shock are (fig. 3)

$$v_N'' = u \sin \sigma - v \cos \sigma + \eta \cos \theta (v \sin \sigma + u \cos \sigma) \quad (15a)$$

$$v_T'' = u \cos \sigma + v \sin \sigma + \eta \cos \theta (v \cos \sigma - u \sin \sigma) \quad (15b)$$

$$w'' = w + \eta (u - v \cot \sigma) \sin \theta \quad (15c)$$

where u , v , and w are the velocity components behind the shock in cylindrical coordinates in axis with the body at the point P considered.

The velocity components u , v , and w at the point P can be expressed in the form given by equations (5), in which the components u_1 and v_1 are the quantities obtained at the point P for the condition of $\alpha=0$ and are direct functions only of x and y . The point P, however, is a point of the shock, and its coordinates x and y change when the coordinate θ changes; therefore, the velocity components u_1 and v_1 at P also change with θ_1 . In order to separate the part of the components u , v , and w dependent on θ from the part independent of θ , the velocity components u_1 and v_1 at P will now be expressed as a function of the flow properties at a point P_1 near P, having a constant value of x and y for every value of θ .

Now, it has been assumed that the angle of the cone σ tangent to the shock at the point P is equal to the angle of the cone tangent to the shock for the condition of zero angle of attack at the point P_1 (fig. 4). The point P_1 is obtained on the shock by rotating the cone APQ tangent to the shock for the condition $\alpha=0$ through an angle η around the axis AN normal to the plane $\theta=0$ at the apex A of the cone. Because for the condition of zero angle of attack the velocity components u_1 and v_1 are independent of the coordinate θ , the velocity components u_1 and v_1 at P (x_P, y_P) (fig. 4) are equal to the velocity components at $P_2(x_P, y_P)$ in the plane AP_1C . Therefore, if ΔN is the distance P_2P_1 ,

$$u_{1P} = u_{1P_1} + \left(\frac{\partial u_1}{\partial N} \right)_{P_1} \Delta N \quad (16a)$$

$$v_{1P} = v_{1P_1} + \left(\frac{\partial v_1}{\partial N} \right)_{P_1} \Delta N \quad (16b)$$

where (fig. 4)

$$\Delta N = \frac{x_{P_1} \eta}{\cos \sigma} \cos \theta \quad (17)$$

Substituting equations (5), (16), and (17) in equations (15) results in

$$v_N'' = (u_1 \sin \sigma - v_1 \cos \sigma)_{P_1} + \alpha \cos \theta (u_2 \sin \sigma - v_2 \cos \sigma)_{P_1} + \eta \cos \theta (u_1 \cos \sigma + v_1 \sin \sigma)_{P_1} + \frac{x_{P_1} \eta}{\cos \sigma} \cos \theta \left(\frac{\partial u_1}{\partial N} \sin \sigma - \frac{\partial v_1}{\partial N} \cos \sigma \right)_{P_1} \quad (18a)$$

$$v_T'' = (u_1 \cos \sigma + v_1 \sin \sigma)_{P_1} + \alpha \cos \theta (u_2 \cos \sigma + v_2 \sin \sigma)_{P_1} - \eta \cos \theta (u_1 \sin \sigma - v_1 \cos \sigma)_{P_1} + \frac{x_{P_1} \eta}{\cos \sigma} \cos \theta \left(\frac{\partial u_1}{\partial N} \cos \sigma + \frac{\partial v_1}{\partial N} \sin \sigma \right)_{P_1} \quad (18b)$$

$$w'' = \alpha w_{2P_1} \sin \theta + \eta (u_1 - v_1 \cot \sigma)_{P_1} \sin \theta \quad (18c)$$

FIGURE 4.—The velocity components behind the shock for $\alpha \neq 0$ as a function of the velocity components behind the shock for $\alpha=0$.

For the condition of zero angle of attack at P_1

$$v_{N_1}'' = u_1 \sin \sigma - v_1 \cos \sigma \quad (19a)$$

$$v_{T_1}'' = u_1 \cos \sigma + v_1 \sin \sigma \quad (19b)$$

and for the condition of the equilibrium at the shock at zero angle of attack

$$V_0 \cos \sigma = v_{T_1}'' \quad (20a)$$

$$v_{N_1}'' V_0 \sin \sigma = \frac{\gamma-1}{\gamma+1} (V_0^2 - v_{T_1}''^2) \quad (20b)$$

At the point P for the case of a small angle of attack,

$$(v_N' v_N'')_P = \frac{\gamma-1}{\gamma+1} (V_0^2 - v_T''^2)_P \quad (21a)$$

$$v_{TP}'' = v_{TP}' \quad (21b)$$

$$w'' = w' \quad (21c)$$

If equations (19) are used, equations (18a) and (18b) can be written in the form

$$(v_N'')_P = (v_{N_1}'')_{P_1} + \alpha \cos \theta (v_{N_2}'')_{P_1} + \eta \cos \theta (v_{T_1}'')_{P_1} +$$

$$\frac{x_{P_1} \eta}{\cos \sigma} \cos \theta \left(\frac{\partial v_{N_1}''}{\partial N} \right)_{P_1}$$

$$(v_T'')_P = (v_{T_1}'')_{P_1} + \alpha \cos \theta (v_{T_2}'')_{P_1} - \eta \cos \theta (v_{N_1}'')_{P_1} +$$

$$\frac{x_{P_1} \eta}{\cos \sigma} \cos \theta \left(\frac{\partial v_{T_1}''}{\partial N} \right)_{P_1}$$

Therefore, from equations (14), (20), and (21),

$$-(\alpha - \eta) V_0 \cos \sigma (v_{N_1}'')_{P_1} +$$

$$V_0 \sin \sigma \left(\alpha v_{N_2}'' + \eta v_{T_1}'' + \frac{x_{P_1} \eta}{\sin \sigma} \frac{\partial v_{N_1}''}{\partial N} \right)_{P_1} = -\frac{2(\gamma-1)}{\gamma+1} (\alpha - \eta) V_0^2 \cos \sigma \sin \sigma \quad (22a)$$

$$(\alpha - \eta) V_0 \sin \sigma = (v_{T_2}'')_{P_1} \alpha - \eta (v_{N_1}'')_{P_1} +$$

$$\frac{x_{P_1} \eta}{\sin \sigma} \left(\frac{\partial v_{T_1}''}{\partial N} \right)_{P_1} \quad (22b)$$

or

$$\left(\frac{v_{T_2}''}{V_0}\right)_{P_1} = \left(1 - \frac{\eta}{\alpha}\right) \sin \sigma + \frac{\eta}{\alpha} \left(\frac{v_{N_1}''}{V_0}\right)_{P_1} - \frac{\eta}{\alpha} \frac{x_{P_1}}{\sin \sigma} \frac{1}{V_0} \left(\frac{\partial v_{T_1}''}{\partial N}\right)_{P_1} \quad (23a)$$

$$\left(\frac{v_{N_2}''}{V_0}\right)_{P_1} = \frac{1}{\tan \sigma} \left[-2 \left(\frac{\gamma-1}{\gamma+1}\right) \left(1 - \frac{\eta}{\alpha}\right) \sin \sigma + \left(1 - \frac{\eta}{\alpha}\right) \left(\frac{v_{N_1}''}{V_0}\right)_{P_1} - \frac{\eta}{\alpha} \sin \sigma - \frac{\eta}{\alpha} \frac{x_{P_1}}{\cos \sigma} \frac{1}{V_0} \left(\frac{\partial v_{N_1}''}{\partial N}\right)_{P_1} \right] \quad (23b)$$

$$\left(\frac{w_2}{V_0}\right)_{P_1} = -\left(1 - \frac{\eta}{\alpha}\right) + \left(\frac{-u_1 + v_1 \cot \sigma}{V_0}\right)_{P_1} \frac{\eta}{\alpha} \quad (23c)$$

In equations (23) the coordinate θ does not appear; therefore, for the shock considered the functions u_2 , v_2 , and w_2 are independent of θ , and equations (5) represent a flow condition in agreement with the conditions at the shock.

The ratio η/α which appears in equations (23) is independent of α ; therefore, for a given point P_1 , η/α remains constant in all the range of angle of attack in which the simplifications assumed are valid. (Indeed, u_2 , v_2 , and w_2 are also independent of the angle of attack (equations (5)). The values of u_2 , v_2 , w_2 , and η/α must therefore be determined only for one value of the angle of attack.

METHOD OF CHARACTERISTICS FOR FLOW AROUND A BODY OF REVOLUTION AT A SMALL ANGLE OF ATTACK

In this section the method of characteristics is applied to equation (13) to establish equations which will permit the flow field behind the shock to be calculated by a point-by-point process. If the flow is anywhere supersonic, equations (12) and (13) permit the determination of the flow around a body of revolution at a small angle of attack by using the method of characteristics. Equation (13) can be written in the following form:

$$H \frac{\partial u}{\partial x} + L \frac{\partial v}{\partial y} + 2K \frac{\partial w}{\partial x} + Z = 0$$

where

$$\left. \begin{aligned} H &= 1 - \frac{u^2}{a^2} \\ L &= 1 - \frac{v^2}{a^2} \\ K &= -\frac{uv}{a^2} \\ Z &= \frac{uv}{V} \frac{1}{\gamma R} \frac{\partial S}{\partial n} + \frac{\partial w}{y \partial \theta} + \frac{v}{y} \end{aligned} \right\} \quad (24)$$

If ϕ is the angle between the velocity V and the x -axis and β is the Mach angle,

$$\tan \phi = \frac{\sqrt{v^2 + w^2}}{u}$$

$$\sin \beta = \frac{a}{V}$$

or for small angles of attack

$$\tan \phi = \frac{v}{u}$$

and

$$\sin \beta = \frac{a}{\sqrt{v^2 + u^2}}$$

The tangent to the line intersection of a characteristic surface with the meridian plane $\theta = \text{Constant}$ is

$$\left. \begin{aligned} \lambda_a &= \tan(\phi + \beta) = \frac{K}{H} - \frac{1}{H} \sqrt{K^2 - HL} \\ \lambda_b &= \tan(\phi - \beta) = \frac{K}{H} + \frac{1}{H} \sqrt{K^2 - HL} \end{aligned} \right\} \quad (25)$$

where λ_a is the tangent to a line corresponding to the characteristic surface of the first family and λ_b is the tangent to a line corresponding to the characteristic surface of the second family. The terms λ_a and λ_b are solutions of the equations (reference 6)

$$H\lambda^2 - 2K\lambda + L = 0 \quad (26)$$

Because u , v , V , and a can be considered to be given by an equation of the type of equations (5), ϕ and β can also be written in the form

$$\phi = \phi_1 + \alpha \phi_2 \cos \theta$$

$$\beta = \beta_1 + \alpha \beta_2 \cos \theta$$

The characteristic surfaces are not, therefore, surfaces of revolution but can be obtained, as was true for the case of the shock, as an envelope of circular cones with their apexes at the axis of the body and their axis of symmetry in the plane $\theta = 0$ and inclined with the axis of the body.

The determination of the u and v components of the velocity in any point of the flow can be obtained from equation (13) by performing a transformation in order to obtain a law of variation along the characteristic lines (reference 6). Indeed, for every point of any meridian plane (for example, of the meridian plane $\theta = 0$, or $\theta = \pi$) two characteristic lines can be obtained as the intersection of two characteristic surfaces with the meridian plane. Along these lines the variation of the u and v velocity components is determined by the equations of characteristics that can be derived from equation (13). Assume that at two points P_1 and P_2 (fig. 5) of the meridian plane $\theta = \text{Constant}$ (for example, $\theta = 0$, or $\theta = \pi$) the velocity components are known. From equations (25) the tangents to the characteristic surfaces in this meridian plane can be drawn and the velocity components u and v at the point P_3 , intersection of the two tangents, can be obtained in the first approximation.

The equations of characteristics can be obtained by analyzing equation (13) along the characteristic lines given by equation (25) in the following way: If du and dv are the variations along the characteristic lines,

$$\frac{du}{dx} = \frac{\partial u}{\partial x} + (\lambda_a, \lambda_b) \frac{\partial u}{\partial y}$$

FIGURE 5.—The analysis of the flow with the characteristics system.

or (see equation (9))

$$\frac{du}{dx} = \frac{\partial u}{\partial x} + (\lambda_a, \lambda_b) \frac{\partial v}{\partial x} - (\lambda_a, \lambda_b) \frac{a^2}{\gamma R V} \frac{\partial S}{\partial n}$$

$$\frac{dv}{dx} = \frac{\partial v}{\partial x} + (\lambda_a, \lambda_b) \frac{\partial v}{\partial y} \quad (27a)$$

then

$$\frac{du}{dx} = \frac{\partial u}{\partial x} + \lambda \frac{dv}{dx} - \lambda^2 \frac{\partial v}{\partial y} - \lambda \frac{a^2}{\gamma R V} \frac{\partial S}{\partial n} \quad (27b)$$

If equations (27a) and (27b) are substituted in equation (13) and equation (26) is used, along the characteristic line of the first family defined by

$$\frac{dy}{dx} = \lambda_a = \tan(\beta + \phi) \quad (28a)$$

there results

$$\frac{du}{dx} + \lambda_b \frac{dv}{dx} - \frac{a^2}{\gamma R V} \frac{dS}{dn} \left(\frac{K}{H} - \lambda_a \right) + \left(\frac{v}{y} + \frac{\partial w}{y \partial \theta} \right) \frac{1}{H} = 0 \quad (28b)$$

and along the characteristic line of the second family defined by

$$\frac{dy}{dx} = \lambda_b = \tan(\phi - \beta) \quad (28c)$$

there results

$$\frac{du}{dx} + \lambda_a \frac{dv}{dx} - \frac{a^2}{\gamma R V} \frac{dS}{dn} \left(\frac{K}{H} - \lambda_b \right) + \left(\frac{v}{y} + \frac{\partial w}{y \partial \theta} \right) \frac{1}{H} = 0 \quad (28d)$$

Equations (28b) and (28d) contain the term $\frac{\partial w}{y \partial \theta}$, but at small angles of attack

$$\frac{\partial w}{y \partial \theta} = \frac{w_2 \alpha}{y} \cos \theta = \frac{w}{y} \cot \theta$$

and, therefore, $\frac{\partial w}{y \partial \theta}$ is known at the points P_1 and P_2 . The value of the entropy is also known at the points P_1 and P_2 and, therefore, the value of $\frac{dS}{dn}$ can be determined (reference 6)

$$\frac{dS}{dn} = \frac{\Delta S_{P_2} - \Delta S_{P_1}}{(x_{P_3} - x_{P_1}) \left[\frac{\sin \beta}{\cos(\beta + \phi)} \right]_{P_1} + (x_{P_3} - x_{P_2}) \left[\frac{\sin \beta}{\cos(\phi - \beta)} \right]_{P_2}} \quad (29)$$

From equations (28) and (29) the values of u and v can be determined in the first approximation for the point P_3 . In order to determine the value of w at P_3 , the following Procedure can be used:

If s is the projection of the streamline in the meridian plane considered (fig. 5) and P_3 is a point near P_1 and P_2 ,

$$\frac{dw_2}{ds} = \frac{\partial w_2}{\partial y} \sin \phi + \frac{\partial w_2}{\partial x} \cos \phi$$

$$= \frac{\partial w_2}{\partial y} \frac{v}{V} + \frac{\partial w_2}{\partial x} \frac{u}{V}$$

or from equation (12)

$$\frac{\partial w_2}{\partial s} = - \frac{v w_2 + v v_2 + u u_2}{y V} - \frac{\sin^2 \beta V \Delta S_2}{\gamma R y} \quad (30)$$

Now (fig. 5)

$$w_{2E} = w_{2P_1} + \left(\frac{dw_2}{ds} \right)_{P_1} (x_{P_3} - x_{P_1}) \left[\frac{\cos \beta}{\cos(\beta + \phi)} \right]_{P_1} \quad (31a)$$

$$w_{2F} = w_{2P_2} + \left(\frac{dw_2}{ds} \right)_{P_2} (x_{P_3} - x_{P_2}) \left[\frac{\cos \beta}{\cos(\phi - \beta)} \right]_{P_2} \quad (31b)$$

and

$$\left(\frac{dw_2}{dn} \right)_E = \frac{w_{2F} - w_{2E}}{(x_{P_3} - x_{P_1}) \left[\frac{\sin \beta}{\cos(\phi + \beta)} \right]_{P_1} + (x_{P_3} - x_{P_2}) \left[\frac{\sin \beta}{\cos(\phi - \beta)} \right]_{P_2}} \quad (32)$$

Therefore,

$$w_{2P_3} = w_{2E} + \left(\frac{\partial w_2}{\partial n} \right)_E (x_{P_3} - x_{P_1}) \left[\frac{\sin \beta}{\cos(\phi + \beta)} \right]_{P_1} \quad (33)$$

The values of u , v , w , ΔS , u_1 , v_1 , and ΔS_1 are known at the points P_1 and P_2 ; therefore, the values of u_2 , v_2 , w_2 , and ΔS_2 at the same points can be calculated from equations (5) and (11). (The values of u_1 , v_1 , and ΔS_1 at those points are known from the determination of the flow for $\alpha=0$.) Therefore, from equations (30) to (33) the value of w_2 at P_3 can be determined.

After the velocity components u , v , and w at P_3 have been determined in the first approximation, a second approximation can be determined by assuming the average values between the corresponding values at the points P_2 and P_3 or P_1 and P_3 for all the coefficients. After the velocity components at a point P_3 have been obtained, the velocity components at any other point having the same x and y coordinates as

P_3 but a different coordinate θ can be calculated from equations (5).

For practical calculations, equations (28) can be transformed in the following form:

$$\lambda_a = \tan(\beta + \phi) \quad (34a)$$

$$\frac{dV}{V} - d\phi \tan \beta - \left[\left(\frac{\sin \phi}{y} + \frac{\partial w}{yV \partial \theta} \right) \tan \beta - \frac{\sin^2 \beta}{\gamma R} \frac{dS}{dn} \right] \frac{\sin \beta}{\cos(\phi + \beta)} dx = 0 \quad (34b)$$

$$\lambda_b = \tan(\phi - \beta) \quad (34c)$$

$$\frac{dV}{V} + d\phi \tan \beta - \left[\left(\frac{\sin \phi}{y} + \frac{\partial w}{yV \partial \theta} \right) \tan \beta + \frac{\sin^2 \beta}{\gamma R} \frac{dS}{dn} \right] \frac{\sin \beta}{\cos(\phi - \beta)} dx = 0 \quad (34d)$$

$$\frac{1}{V} \frac{dw_2}{ds} = -\frac{1}{y} \frac{V_2}{V} - \frac{w_2}{Vy} \sin \phi - \frac{\sin^2 \beta}{\gamma R} \frac{\Delta S_2}{y} \quad (34e)$$

and

$$\phi = \phi_1 + \alpha \phi_2 \cos \theta \quad (35)$$

where

$$\phi_2 = \frac{v_2}{V_1} \cos \phi_1 - \frac{u_2}{V_1} \sin \phi_1 \quad (36)$$

and

$$V = V_1 + \alpha V_2 \cos \theta \quad (37)$$

where

$$V_2 = u_2 \cos \phi_1 + v_2 \sin \phi_1 \quad (38)$$

At the surface of the body outside of the vortical layer the calculations are similar to the case of zero angle of attack because the entropy at the surface of the body is known in every meridian plane and the value of θ is given. Equation (34e) gives the variation of w_2 along the body outside of the layer; therefore, the value of w_2 can be obtained directly from another point on the body in the same meridian plane.

At the surface of the shock the system of calculations is similar to the system for zero angle of attack. In figure 6 the point P_3 is at the intersection of the tangents to the first characteristic surface at P_1 and to the shock at P_2 in the meridian plane $\theta = \text{Constant}$. The equations of the shock and equation (34b) must be verified at P_3 , which is assumed as a point of the shock in the first approximation.

In the plane $\theta = 0$, w is zero and the values of V , ΔS , and ϕ behind the shock are functions only of the value of Ω ; and for any value of Ω , the values of V , ΔS , and ϕ can be obtained from the equations of the shock

$$\frac{\cos(\Omega - \alpha)}{\cos(\Omega - \phi)} = \frac{V}{V_0} = \frac{V/V_1}{V_0/V_1} \quad (39a)$$

$$\frac{1}{\tan(\phi - \alpha)} = \left[\frac{\gamma + 1}{2} \frac{M_0^2}{M_0^2 \sin^2(\Omega - \alpha) - 1} - 1 \right] \tan(\Omega - \alpha) \quad (39b)$$

FIGURE 6.—Determination of a point of the shock.

$$\Delta S = \frac{R}{\gamma - 1} \log_e \gamma \left(\frac{2}{\gamma + 1} \right)^{\gamma + 1} \left[M_0^2 \sin^2(\Omega - \alpha) - \frac{\gamma - 1}{2\gamma} \right] \left[\frac{1}{M_0^2 \sin^2(\Omega - \alpha)} + \frac{\gamma - 1}{2} \right]^\gamma \quad (39c)$$

and

$$\frac{V_1^2}{V_0^2} = 1 + \frac{2}{\gamma - 1} \frac{1}{M_0^2} \quad (39d)$$

If the plane $\theta = \pi$ is considered, the sign of α in equations (39) must be reversed.

From equations (39) the values of V and ΔS can be determined as a function of ϕ ; then $\frac{dV}{d\phi}$ and $\frac{d\Delta S}{d\phi}$ as a function of ϕ can be evaluated. Now, if ϕ_{P_1} is the direction of the velocity at P_1 , the velocity at P_3 will have the direction

$$\phi_{P_3} = \phi_{P_1} + \Delta \phi$$

Therefore, the velocity at P_3 must correspond to a deviation across the shock of $\phi_{P_3} - \alpha$ and can be expressed as

$$V_{P_3} = V_{\phi_{P_1}} + \left(\frac{dV}{d\phi} \right)_{\phi_{P_1}} \Delta \phi$$

where $V_{\phi_{P_1}}$ is the velocity behind the shock corresponding to the direction ϕ_{P_1} . In a similar way,

$$\Delta S_{P_3} = \Delta S_{\phi_{P_1}} + \left(\frac{d\Delta S}{d\phi} \right)_{\phi_{P_1}} \Delta \phi$$

Therefore, equation (34b) at the point P_1 becomes

$$\begin{aligned} \frac{V_{\phi_{P_1}}}{V_{P_1}} - 1 + \frac{1}{V_{P_1}} \left(\frac{\partial V}{\partial \phi} \right)_{\phi_{P_1}} \Delta \phi - \tan \beta_{P_1} \Delta \phi - \\ \left[\left(\frac{\sin \phi}{y} + \frac{w_2 \alpha \cos \theta}{yV} \right) \frac{\sin \beta \tan \beta}{\cos(\beta + \phi)} \right]_{P_1} dx + \\ \left[\Delta S_{\phi_{P_1}} - \Delta S_{P_1} + \left(\frac{d\Delta S}{d\phi} \right)_{\phi_{P_1}} \Delta \phi \right] \frac{\sin^2 \beta_{P_1}}{\gamma R} = 0 \end{aligned} \quad (40)$$

In equation (40), $\Delta \phi$ is the only unknown and, therefore, can be determined. From the value of ϕ the value of Ω_{P_3}

and the value of V_{P_3} can be determined; a second approximation for the position of P_3 and its value of the velocity can be calculated if the corresponding average values between P_3 and P_1 are assumed for ϕ , β , and all the coefficients of equation (40):

The value of w at P can be obtained from equation (23c) in which η is given by figure 6 as

$$\eta = \frac{dN}{y_{P_3}} \sin \Omega$$

where $\eta = \Omega - \sigma$ for $\theta = 0$ and $\eta = \sigma - \Omega$ for $\theta = \pi$. The value of σ corresponding to the point P_4 on the shock for $\alpha = 0$ is given by the relation

$$\frac{y_{P_4}}{\sin \sigma} = \frac{y_{P_3}}{\sin \Omega}$$

and $y_{P_4} = f(\sigma_{P_4})$ is the curve that represents the shock for $\alpha = 0$

PRACTICAL APPLICATION OF THE CHARACTERISTIC SYSTEM

GRAPHICAL NUMERICAL METHOD

The analytical part of the characteristic system used for determining the flow field about a body of revolution at an angle of attack is similar to the system used for a body of revolution at zero angle of attack (reference 6), but the practical numerical application is slightly more involved. In equation (34e) the values of V_2 and ΔS_2 must be known in order to determine the value of w_2 and must be determined from equations (37), (36), and (11), where the values of V_1 and ΔS_1 are considered known in the entire flow field and given by the determination from the case of zero angle of attack. In the practical case, however, the values of V_1 , ϕ_1 , and ΔS_1 have been obtained with the characteristic system only in a finite number of points at the intersections of the characteristic net, and the characteristic net for the case of zero angle of attack is different from the net used for the case of a body with a small angle of attack. In order, therefore, to obtain the values of V_1 and ΔS_1 at the intersections of the characteristic lines for the case with a given angle of attack, a lengthy interpolation of the values V_1 and ΔS_1 would be necessary if the two characteristic nets for zero angle of attack and for a given angle of attack were constructed independently.

In order to reduce the numerical work to a minimum, the two following methods can be used, the first of which is practical when a graphical numerical calculation is performed, whereas the second can be more convenient when automatic computing machines are used.

In both cases the calculations start with the determination of the flow at an angle of attack around a cone when the body considered is a pointed-nose body of revolution or with the determination of the shock at the lip of the body if the body is an open-nose body of revolution. (The tangent to the

shock at the lip can be determined with the two-dimensional theory.) The flow around a cone at an angle of attack has been determined and tabulated in reference 3; whereas the flow for zero angle of attack has been tabulated in reference 7. A different method for determining the flow around a circular cone at an angle of attack is given in the appendix. It can be assumed, therefore, that the flow along the first characteristic line of the first family at the end of the conical region in the plane $\theta = \text{Constant}$ (for example, $\theta = \pi$) is known (fig. 7).

For the practical numerical calculations a value of the angle of attack must be selected. In order to obtain higher precision, it is convenient to select a relatively high value of the angle of attack because in this way the differences between V and V_1 and ΔS and ΔS_1 are large and, therefore, can be determined with sufficient precision.

Usually, when the determination of the flow field for the case of zero angle of attack is made with a graphical numerical process, in order to avoid numerical errors of computations, the value of the intensity and direction of the velocity are plotted as a function of the position along the characteristic lines for both families of characteristic lines. The velocity distribution and the entropy-variation distribution along the characteristic lines and along the surface of the body for the case of zero angle of attack can therefore be considered known. If the distribution is not given, the values of V_1 and ΔS_1 must be determined as a function of x along each characteristic line of a given family (for example, of the second family) along the body.

Then the construction of the characteristic net for the selected angle of attack must start by drawing the first characteristic line $P_0P_2P_8$ over the design of the characteristic net for zero angle of attack (fig. 7).

From equations (34c), (34d), and (34e) the flow at P_1 can be determined. From P_1 and P_2 the point P_3 can be obtained in the first approximation as the intersection of the tangents at P_2 and P_1 to the characteristic lines. By using equations (34b), (34d), and (29), V , ϕ , and ΔS can be obtained in P_3

FIGURE 7.—Scheme of the characteristic net.

as for the case of zero angle of attack (reference 6). From the variations $\frac{dV}{dx}$, $\frac{d\phi}{dx}$, and $\frac{d\Delta S}{dx}$ along the line P_1P_3 the values of V , ϕ , and ΔS at the point P_4 can be obtained, where P_4 is obtained from the intersection of the characteristic line P_1P_3 with a characteristic line of the second family in the net for zero angle of attack. At the point P_4 , V_1 , ΔS_1 , and ϕ_1 are known and, therefore, ϕ_2 , V_2 , ΔS_2 , and w_2 can be obtained. From the values obtained from the first approximation a second approximation can be obtained. From P_4 and P_5 the point P_6 can be determined in a similar way, and the flow at P_7 can be calculated. By proceeding in a similar way, all the flow field can be analyzed.

NUMERICAL METHOD

The equation of motion (13) can be transformed by means of equations (5) and (11) in a system of equations that permits a numerical determination of the quantities V_2 , ϕ_2 , and ΔS_2 . This system is numerically more involved; however, the characteristic net determined for zero angle of attack is used. For a small angle of attack,

$$\frac{1}{a^2} = \frac{1}{a_1^2} \left[1 + \frac{\gamma-1}{a_1^2} (u_1 u_2 + v_1 v_2) \alpha \cos \theta \right]$$

where

$$\frac{\gamma-1}{a_1^2} (u_1 u_2 + v_1 v_2) = \frac{\gamma-1}{a_1^2} V_1 V_2 = \frac{\gamma-1}{\sin^2 \beta} \frac{V_2}{V_1} \equiv A \quad (41)$$

Therefore,

$$\frac{1}{a^2} = \frac{1}{a_1^2} (1 + A \alpha \cos \theta)$$

Substituting equations (5) in equations (6) results in the following expression if higher-order terms are neglected:

$$\begin{aligned} & \frac{\partial u_1}{\partial x} \left(1 - \frac{u_1^2}{a_1^2} \right) + \frac{\partial v_1}{\partial y} \left(1 - \frac{v_1^2}{a_1^2} \right) - \frac{u_1 v_1}{a_1^2} \left(\frac{\partial u_1}{\partial y} + \frac{\partial v_1}{\partial x} \right) + \frac{v_1}{y} \\ &= -\alpha \cos \theta \left[\frac{v_2}{y} + \frac{w_2}{y} - \frac{\partial u_1}{\partial x} \left(\frac{2u_2 u_1 + u_1^2 A}{a_1^2} \right) + \right. \\ & \quad \frac{\partial u_2}{\partial x} \left(1 - \frac{u_1^2}{a_1^2} \right) - \frac{\partial v_1}{\partial y} \left(\frac{2v_2 v_1 + v_1^2 A}{a_1^2} \right) + \frac{\partial v_2}{\partial y} \left(1 - \frac{v_1^2}{a_1^2} \right) - \\ & \quad \left. \frac{u_1 v_1 A + u_1 v_2 + v_1 u_2}{a_1^2} \left(\frac{\partial u_1}{\partial y} + \frac{\partial v_1}{\partial x} \right) - \frac{u_1 v_1}{a_1^2} \left(\frac{\partial u_2}{\partial y} + \frac{\partial v_2}{\partial x} \right) \right] \quad (42) \end{aligned}$$

Because the left-hand side of equation (42) must be zero for the conditions at zero angle of attack,

$$\frac{\partial u_2}{\partial x} \left(1 - \frac{u_1^2}{a_1^2} \right) + \frac{\partial v_2}{\partial y} \left(1 - \frac{v_1^2}{a_1^2} \right) + \frac{v_2}{y} + \frac{w_2}{y} - \frac{u_1 v_1}{a_1^2} \left(\frac{\partial u_2}{\partial y} + \frac{\partial v_2}{\partial x} \right) + Q = 0 \quad (43)$$

where

$$Q = -\frac{1}{2} \left(\frac{\partial u_1^2}{\partial x} + \frac{\partial v_1^2}{\partial x} \right) \frac{2u_2 + u_1 A}{a_1^2} - \frac{1}{2} \left(\frac{\partial v_1^2}{\partial y} + \frac{\partial u_1^2}{\partial y} \right) \frac{2v_2 + v_1 A}{a_1^2} - \left(\frac{\partial v_1}{\partial x} - \frac{\partial u_1}{\partial y} \right) \frac{u_1 v_2 - u_2 v_1}{a_1^2} \quad (44)$$

or, from equations (9) and (36),

$$Q = -V_1 \frac{\partial V_1}{\partial x} \frac{2u_2 + u_1 A}{a_1^2} - V_1 \frac{\partial V_1}{\partial y} \frac{2v_2 + v_1 A}{a_1^2} - \frac{\phi_2 V_1}{\gamma R} \frac{\partial S_1}{\partial n_1} \quad (45)$$

The value of all the coefficients at the points P_1 and P_2 in equation (43) can be considered known because $\frac{\partial V_1}{\partial x}$ and $\frac{\partial V_1}{\partial y}$ can be considered known from the calculations for the case of zero angle of attack. Therefore, equation (43) can be considered an equation in which the characteristic lines are equal to the characteristic lines for zero angle of attack because the coefficients of the partial derivatives $\frac{\partial u_2}{\partial x}$, $\frac{\partial u_2}{\partial y}$, $\frac{\partial v_2}{\partial x}$, and $\frac{\partial v_2}{\partial y}$ are the same in both cases. Thus,

$$\left(\frac{dy}{dx} \right) = \lambda_{1a} = \tan (\phi_1 + \beta_1) \quad (46a)$$

$$\left(\frac{dy}{dx} \right) = \lambda_{1b} = \tan (\phi_1 - \beta_1) \quad (46b)$$

Equation (43) can be transformed by introducing the entropy gradient $\frac{\partial S_2}{\partial n}$, and the equation of motion along each characteristic line can be obtained. From equations (9) and (11) by means of equations (5) and (37), the following relation can be obtained:

$$\begin{aligned} \frac{\partial S}{\partial n} &= \frac{\partial S_1}{\partial n} + \frac{\partial S_2}{\partial n} \alpha \cos \theta \\ &= -\left(\frac{\partial S_1}{\partial x} + \frac{\partial S_2}{\partial x} \alpha \cos \theta \right) \frac{v_1 + v_2 \alpha \cos \theta}{V_1 + V_2 \alpha \cos \theta} + \\ & \quad \left(\frac{\partial S_1}{\partial y} + \frac{\partial S_2}{\partial y} \alpha \cos \theta \right) \frac{u_1 + u_2 \alpha \cos \theta}{V_1 + V_2 \alpha \cos \theta} \end{aligned}$$

or, for small angles of attack,

$$\begin{aligned} \frac{\partial S}{\partial n} &= \frac{\partial S_1}{\partial n_1} + \frac{\partial S_2}{\partial n_1} \alpha \cos \theta + \left[-\frac{\partial S_1}{\partial x} (v_2 V_1 - v_1 V_2) + \right. \\ & \quad \left. \frac{\partial S_1}{\partial y} (u_2 V_1 - u_1 V_2) \right] \frac{\alpha \cos \theta}{V_1^2} \quad (47) \end{aligned}$$

From equations (36) and (38)

$$u_2 = V_2 \cos \phi_1 - \phi_2 V_1 \sin \phi_1 \quad (48a)$$

$$v_2 = V_2 \sin \phi_1 + \phi_2 V_1 \cos \phi_1 \quad (48b)$$

and

$$v_1 = V_1 \sin \phi_1$$

$$u_1 = V_1 \cos \phi_1$$

Therefore,

$$\begin{aligned} & -\frac{\partial S_1}{\partial x} (v_2 V_1 - v_1 V_2) + \frac{\partial S_1}{\partial y} (u_2 V_1 - u_1 V_2) \\ & = -\phi_2 V_1^2 \left(\frac{\partial S_1}{\partial x} \frac{u_1}{V_1} + \frac{\partial S_1}{\partial y} \frac{v_1}{V_1} \right) \end{aligned}$$

Because the term in parentheses on the right-hand side of this equation represents the variation of entropy along the streamline, which is zero, equation (47) becomes

$$\frac{\partial S}{\partial n} = \frac{\partial S_1}{\partial n_1} + \frac{\partial S_2}{\partial n_1} \alpha \cos \theta \quad (49)$$

Then, from equations (9), (41), and (49)

$$\frac{\partial v_2}{\partial x} - \frac{\partial u_2}{\partial y} = \frac{a_1^2}{\gamma R V_1} \frac{\partial S_2}{\partial n_1} - \left(\frac{V_2}{V_1} + A \right) \frac{a_1^2}{\gamma R V_1} \frac{\partial S_1}{\partial n_1} \quad (50)$$

The equations of motion along the characteristic lines defined by equations (46) can be obtained by means of transformations similar to those of equations (27) and are

$$du_2 + \lambda_{1b} dv_2 + D_1 dx = 0 \quad (51)$$

$$\lambda_{1a} = \frac{dy}{dx} = \tan(\phi_1 + \beta_1) \quad (52)$$

$$du_2 + \lambda_{1a} dv_2 + D_2 dx = 0 \quad (53)$$

$$\lambda_{1b} = \frac{dy}{dx} = \tan(\phi_1 - \beta_1) \quad (54)$$

where

$$\begin{aligned} D_1 = & \left(\frac{w_2}{y} + \frac{v_2}{y} + Q \right) \frac{a_1^2}{a_1^2 - u_1^2} + \\ & \left(\frac{u_1 v_1}{a_1^2 - u_1^2} + \lambda_{1a} \right) \frac{V_1}{\gamma R} \sin^2 \beta_1 \left[\frac{\partial S_2}{\partial n_1} - \frac{V_2}{V_1} \left(1 + \frac{\gamma - 1}{\sin^2 \beta_1} \right) \frac{\partial S_1}{\partial n_1} \right] \end{aligned} \quad (55a)$$

$$\begin{aligned} D_2 = & \left(\frac{w_2}{y} + \frac{v_2}{y} + Q \right) \frac{a_1^2}{a_1^2 - u_1^2} + \\ & \left(\frac{u_1 v_1}{a_1^2 - u_1^2} + \lambda_{1b} \right) \frac{V_1}{\gamma R} \sin^2 \beta_1 \left[\frac{\partial S_2}{\partial n_1} - \frac{V_2}{V_1} \left(1 + \frac{\gamma - 1}{\sin^2 \beta_1} \right) \frac{\partial S_1}{\partial n_1} \right] \end{aligned} \quad (55b)$$

In equations (51) and (53) the coefficients D_1 and D_2 contain the derivatives $\frac{\partial V_1}{\partial x}$ and $\frac{\partial V_1}{\partial y}$ that must be obtained from the analysis of the case with zero angle of attack. Now, for every point P the variation of V_1 along the characteristic line of the first family for the case of zero angle of attack is

$$\left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} = \frac{\partial V_1}{\partial x} + \lambda_{1a} \frac{\partial V_1}{\partial y} \quad (56a)$$

whereas along the characteristic line of the second family

$$\left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} = \frac{\partial V_1}{\partial x} + \lambda_{1b} \frac{\partial V_1}{\partial y} \quad (56b)$$

At every point P given by the intersection of two characteristic lines λ_{1a} and λ_{1b} in the characteristic net, the values $\left(\frac{dV_1}{dx} \right)_{\lambda_{1a}}$ and $\left(\frac{dV_1}{dx} \right)_{\lambda_{1b}}$ are known, having been obtained from the evaluation of the following equations (reference 5):

$$\frac{dy}{dx} = \lambda_{1a} = \tan(\phi_1 + \beta_1) \quad (57a)$$

$$\begin{aligned} & \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} - \tan \beta_1 \left(\frac{d\phi_1}{dx} \right) - \frac{\sin \phi_1 \sin \beta_1 \tan \beta_1}{\cos(\phi_1 + \beta_1)} \frac{1}{y} + \\ & \frac{dS_1}{dn_1} \frac{1}{\gamma R} \frac{\sin^3 \beta_1}{\cos(\phi_1 + \beta_1)} = 0 \end{aligned} \quad (57b)$$

$$\frac{dy}{dx} = \lambda_{1b} = \tan(\phi_1 - \beta_1) \quad (57c)$$

$$\begin{aligned} & \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} + \tan \beta_1 \left(\frac{d\phi_1}{dx} \right) - \frac{1}{y} \frac{\sin \phi_1 \sin \beta_1 \tan \beta_1}{\cos(\phi_1 - \beta_1)} - \\ & \frac{dS_1}{dn_1} \frac{1}{\gamma R} \frac{\sin^3 \beta_1}{\cos(\phi_1 - \beta_1)} = 0 \end{aligned} \quad (57d)$$

Therefore, the values

$$\frac{\partial V_1}{\partial x} = \frac{\lambda_{1b}}{\lambda_{1b} - \lambda_{1a}} \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} - \frac{\lambda_{1a}}{\lambda_{1b} - \lambda_{1a}} \left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} \quad (58a)$$

and

$$\frac{\partial V_1}{\partial y} = \frac{1}{\lambda_{1b} - \lambda_{1a}} \left[\left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} - \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} \right] \quad (58b)$$

can be calculated directly for every point of intersection of the characteristic line (equations (57a) and (57c)).

After substituting the expressions of equations (48) and (58) in equations (51) and (53) after some simplifications and trigonometric transformations, the following equations can be obtained:

$$\lambda_{1a} = \frac{dy}{dx} = \tan(\phi_1 + \beta_1) \quad (59a)$$

$$\frac{dV_2}{V_1} - \tan \beta_1 d\phi_2 + \left[\frac{\sin^3 \beta_1}{\cos(\phi_1 + \beta_1)} \frac{1}{\gamma R} \frac{\partial S_2}{\partial n_1} + \phi_2 A_1 + \frac{V_2}{V_1} P_1 - \frac{w_2}{V_1} \frac{1}{y} \frac{\tan \beta_1 \sin \beta_1}{\cos(\phi_1 + \beta_1)} \right] dx = 0 \quad (59b)$$

$$\lambda_{1b} = \frac{dy}{dx} = \tan(\phi_1 - \beta_1) \quad (59c)$$

$$\frac{dV_2}{V_1} + \tan \beta_1 d\phi_2 - \left[\frac{\sin^3 \beta_1}{\cos(\phi_1 - \beta_1)} \frac{1}{\gamma R} \frac{\partial S_2}{\partial n_1} + \phi_2 A_2 - \frac{V_2}{V_1} P_2 + \frac{w_2}{V_1} \frac{1}{y} \frac{\tan \beta_1 \sin \beta_1}{\cos(\phi_1 - \beta_1)} \right] dx = 0 \quad (59d)$$

where

$$A_1 = \frac{1}{\cos \beta_1 \cos(\phi_1 + \beta_1)} \left[\frac{\sin \beta_1}{y} \sin(\phi_1 - \beta_1) + \frac{\sin^4 \beta_1}{\gamma R} \frac{\partial S_1}{\partial n_1} - \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} \frac{\cos(\phi_1 - \beta_1)}{\sin \beta_1} \right] \quad (60a)$$

$$A_2 = \frac{1}{\cos \beta_1 \cos(\phi_1 - \beta_1)} \left[\frac{\sin \beta_1}{y} \sin(\phi_1 + \beta_1) - \frac{\sin^4 \beta_1}{\gamma R} \frac{\partial S_1}{\partial n_1} - \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} \frac{\cos(\phi_1 + \beta_1)}{\sin \beta_1} \right] \quad (60b)$$

$$P_1 = \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} \left(\frac{T}{\cos^2 \beta_1} - 1 \right) - T \left[\frac{2 \sin^3 \beta_1}{\gamma R \cos(\phi_1 + \beta_1)} \frac{\partial S_1}{\partial n_1} - \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} \frac{\cos(\phi_1 - \beta_1)}{\cos^2 \beta_1 \cos(\phi_1 + \beta_1)} \right] \quad (60c)$$

$$P_2 = \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1b}} \left(\frac{T}{\cos^2 \beta_1} - 1 \right) + T \left[\frac{2 \sin^3 \beta_1}{\gamma R \cos(\phi_1 - \beta_1)} \frac{\partial S_1}{\partial n_1} + \frac{1}{V_1} \left(\frac{dV_1}{dx} \right)_{\lambda_{1a}} \frac{\cos(\phi_1 + \beta_1)}{\cos^2 \beta_1 \cos(\phi_1 - \beta_1)} \right] \quad (60d)$$

$$T = 1 + \frac{\gamma - 1}{2 \sin^2 \beta_1} \quad (60e)$$

The coefficients A_1 and A_2 and the value of $\frac{dS_1}{dn_1}$ have been determined for the flow at zero angle of attack and

$$\begin{aligned} \frac{dS_2}{dn_1} &= \frac{S_{2P_2} - S_{2P_1}}{(x_{P_3} - x_{P_2}) \left[\frac{\sin \beta_1}{\cos(\phi_1 - \beta_1)} \right]_{P_2} + (x_{P_3} - x_{P_1}) \left[\frac{\sin \beta_1}{\cos(\phi_1 + \beta_1)} \right]_{P_1}} \\ &= \frac{dS_1}{dn_1} \frac{S_{2P_2} - S_{2P_1}}{S_{1P_2} - S_{1P_1}} \end{aligned} \quad (61)$$

The practical use of equations (59) is identical to the use of the corresponding equations (57) for the case of zero angle of attack. (See reference 6.)

CONCLUDING REMARKS

The method of characteristics has been applied to bodies of revolution at a small angle of attack. Only the first-order effects of the angle of attack have been considered. The system developed takes into account the effects of the entropy variations on the flow phenomena and determines a flow that exactly satisfies the boundary conditions within the limits of the simplifications assumed.

The application of the method to practical problems has been discussed and two systems are given. The first method is numerical and analytical and requires less numerical computation but requires the construction of another characteristic net; whereas the second method is only numerical and uses the characteristic net and some of the numerical computations made for the calculations for zero angle of attack.

LANGLEY FIELD, VA., November 22, 1948.

APPENDIX

DETERMINATION OF FLOW PROPERTIES AROUND A CIRCULAR CONE AT A SMALL ANGLE OF ATTACK

Assume a polar coordinate system r, ψ, θ . Call v_r the velocity in radial direction, v_n the velocity in normal direction to r in the meridian plane $\theta = \text{Constant}$, and w the component normal to the meridian plane (fig. 8); that is,

$$v_r = \frac{dr}{dt}$$

$$v_n = \frac{r d\psi}{dt}$$

$$w = \frac{r d\theta \sin \psi}{dt}$$

If the phenomenon is conical,

$$\frac{\partial v_r}{\partial r} = 0$$

$$\frac{\partial v_n}{\partial r} = 0$$

$$\frac{\partial w}{\partial r} = 0$$

and

$$\frac{\partial p}{\partial r} = 0$$

$$\frac{\partial \rho}{\partial r} = 0$$

Therefore, Euler's equations are

$$\frac{v_n}{r} \frac{\partial v_r}{\partial \psi} + \frac{w}{r \sin \psi} \frac{\partial v_r}{\partial \theta} - \frac{v_n^2 + w^2}{r} = 0 \quad (62a)$$

$$\frac{v_n}{r} \frac{\partial v_n}{\partial \psi} + \frac{w}{r \sin \psi} \frac{\partial v_n}{\partial \theta} + \frac{1}{\rho r} \frac{\partial p}{\partial \psi} + \frac{v_r v_n - w^2 \cot \psi}{r} = 0 \quad (62b)$$

$$\frac{v_n}{r} \frac{\partial w}{\partial \psi} + \frac{w}{r \sin \psi} \frac{\partial w}{\partial \theta} + \frac{1}{r \rho \sin \psi} \frac{\partial p}{\partial \theta} + \frac{v_r w + v_n w \cot \psi}{r} = 0 \quad (62c)$$

The continuity equation is

$$2\rho v_r \sin \psi + v_n \sin \psi \frac{\partial \rho}{\partial \psi} + \rho \sin \psi \frac{\partial v_n}{\partial \psi} + v_n \rho \cos \psi + w \frac{\partial \rho}{\partial \theta} + \frac{\partial w}{\partial \theta} = 0 \quad (63)$$

and the energy equation is

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial \theta} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial \theta} \right) = - \left(v_r \frac{\partial v_r}{\partial \theta} + v_n \frac{\partial v_n}{\partial \theta} + w \frac{\partial w}{\partial \theta} \right) \quad (64a)$$

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial \psi} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial \psi} \right) = - \left(v_r \frac{\partial v_r}{\partial \psi} + v_n \frac{\partial v_n}{\partial \psi} + w \frac{\partial w}{\partial \psi} \right) \quad (64b)$$

FIGURE 8.—Polar coordinates and velocity components.

Combining equations (62) to (64) results in

$$\begin{aligned} v_r \left(2 - \frac{v_n^2 + w^2}{a^2} \right) + v_n \cot \psi + \frac{\partial v_n}{\partial \psi} \left(1 - \frac{v_n^2}{a^2} \right) + \\ \frac{\partial w}{\sin \psi \partial \theta} \left(1 - \frac{w^2}{a^2} \right) - \frac{2wv_n}{a^2} \frac{\partial v_n}{\sin \psi \partial \theta} + \\ \frac{wv_n}{a^2} \left(\frac{\partial v_n}{\sin \psi \partial \theta} - \frac{\partial w}{\partial \psi} \right) = 0 \end{aligned} \quad (65)$$

For small angles of attack the velocity components can be expressed in the form (references 1 and 3)

$$\left. \begin{aligned} v_r &= v_{r_1} + \alpha v_{r_2} \cos \theta \\ v_n &= v_{n_1} + \alpha v_{n_2} \cos \theta \\ w &= \alpha w_2 \sin \theta \end{aligned} \right\} \quad (66)$$

when the second- and higher-order terms of the angle of attack have been neglected. Equation (65) at small angles of attack becomes

$$v_r \left(2 - \frac{v_n^2}{a^2} \right) + v_n \cot \psi + \frac{\partial v_n}{\partial \psi} \left(1 - \frac{v_n^2}{a^2} \right) + \frac{\partial w}{\sin \psi \partial \theta} = 0 \quad (67)$$

The shock is a circular conical shock having its axis inclined at an angle η with the axis of the cone. The quantities with subscript 1 are the quantities corresponding to the case of zero angle of attack. (Indeed, the cone is a particular body of revolution and, therefore, the considerations made for the case of bodies of revolution are still valid.)

From equations (62a), (62b), and (64b), there results at small angles of attack

$$\frac{1}{p} \frac{\partial p}{\partial \psi} - \frac{\gamma}{\rho} \frac{\partial \rho}{\partial \psi} = 0$$

In the meridian plane $\theta = \text{Constant}$, therefore, the transformation behind the shock is isentropic for small angles of attack. If $-\alpha \Delta S_2 \sin \theta$ is the variation of entropy in a direction normal to the meridian plane $\theta = \text{Constant}$ (reference 5),

$$\frac{\partial S}{\sin \psi \partial \theta} = -\alpha \Delta S_2 \sin \theta$$

where ΔS_2 is constant and independent of ψ outside of the vortical layer. From equations (62c) and (64a)

$$-\frac{a^2}{\gamma R} \Delta S_2 = v_n \frac{\partial w_2}{\partial \psi} \sin \psi + w_2 (v_r \sin \psi + v_n \cos \psi) + v_r v_{r_2} + v_n v_{n_2} \quad (68)$$

If the variation of entropy is small and the term ΔS_2 can be neglected, equation (68) becomes

$$w_2 \sin \psi = -v_{r_2} \quad (69)$$

Equation (67) can be written in the following form:

$$\left(v_r + \frac{\partial v_n}{\partial \psi} \right) \left(1 - \frac{v_n^2}{a^2} \right) = -v_r - v_n \cot \psi - \frac{\alpha w_2 \cos \theta}{\sin \psi} \quad (70)$$

By use of equation (67) and by considering the conditions for zero angle of attack, equation (70) becomes

$$\begin{aligned} & \left(v_{r_2} + \frac{\partial v_{n_2}}{\partial \psi} \right) \left(1 - \frac{v_{n_1}^2}{a_1^2} \right) \\ &= -v_{n_2} \left[\cot \psi + \left(\frac{2v_{n_1}}{a_1^2} + \frac{\gamma-1}{a_1^4} v_{n_1}^3 \right) \frac{v_{r_1} + v_{n_1} \cot \psi}{1 - \frac{v_{n_1}^2}{a_1^2}} \right] - \\ & \quad v_{r_2} \left(1 + \frac{\gamma-1}{a_1^4} \frac{v_{r_1} + v_{n_1} \cot \psi}{1 - \frac{v_{n_1}^2}{a_1^2}} v_{r_1} v_{n_1}^2 \right) - \frac{w_2}{\sin \psi} \quad (71) \end{aligned}$$

Equations (68), (70), and (71) permit the determination of the flow around the cone at an angle of attack by means of a step-by-step calculation when the calculation for $\alpha=0$ has been performed. Consider the hodograph plane uv , and consider the variation of velocity components v_r and v_n in a meridian plane $\theta = \text{Constant}$ (fig. 9). Assume that for a given value of ψ_a and θ_a the velocity components v_r , v_n , and

FIGURE 9.—The hodograph diagram.

w are known. Point P_a of the hodograph diagram represents the velocity vector OP_a corresponding to the velocity at every point of the space of coordinate ψ_a in the plane $\theta_a = \text{Constant}$; whereas OQ_a represents the values of $(v_n)_{P_a}$ and Q_aP_a represents the values of $(v_r)_{P_a}$. Now, the radius of curvature R_a of the hodograph diagram is along the line Q_aP_a and has a value given by (reference 1)

$$R_a = \left(v_r + \frac{\partial v_n}{\partial \psi} \right)_{P_a}$$

and, therefore, can be determined from equation (70). At P_0 the values of v_{r_1} and v_{n_1} are known from the calculation for $\alpha=0$; therefore, αv_{r_2} and αv_{n_2} can be determined from equations (66). Equation (71) can be used in place of equation (70) in the following way: The vectors OQ_a and Q_aP_a represent the values of v_{n_2} and v_{r_2} at P_a ; the vector OP_a in the hodograph diagram gives the values of V_2 ; therefore,

$$R_{2a} = \left(v_{r_2} + \frac{\partial v_{n_2}}{\partial \psi} \right)_{P_a}$$

can be obtained from equation (71).

Now at any point P_a the radius R_a , given from equation (70), or the radius R_{2a} , given from equation (71), is known; therefore, from the quantities at P_a the quantities at P_b of coordinate $\psi_b = \psi_a + \Delta \psi$ can be obtained by constructing a circle of center C_a (where $C_aP_a = R_a$ or R_{2a}) through the point

P_a until the point P_b along the line $C_a P_b$ which is a straight line from C_a , is inclined by $\psi_a + \Delta\psi$ with the u -axis. Therefore,

$$(v_n)_{\psi+\Delta\psi} = (v_n)_\psi \cos \Delta\eta + (R-v_r)_\psi \sin \Delta\eta$$

$$(v_r)_{\psi+\Delta\psi} = (v_n)_\psi \sin \Delta\eta - (R-v_r)_\psi \cos \Delta\eta + R_\psi$$

Inasmuch as the values of v_r and v_n at P_b have been obtained, the values of v_{r_2} and v_{n_2} can be determined by differences from the values for $\alpha=0$ with the use of equations (66). (If equation (71) is used, the values of v_{r_2} and v_{n_2} are obtained directly.) With equation (68) the value of $\frac{\partial w_2}{\partial \psi}$ can be calculated at P_a , and the value of w_2 at P_b can be obtained. Indeed, ΔS_2 is constant and has been determined from the conditions at the shock. In a similar way, all the hodograph diagram can be constructed. If necessary, for every point P_b a second approximation can be determined.

The calculation of all the flow field must start at the shock. For the calculations it is convenient to choose a coordinate system having the axis of the conical shock as the axis of polar coordinates. In this case, the velocity components v_r , v_n , and w behind the shock can still be expressed in the form of equations (66). Indeed, from equations (15) and (19),

$$\begin{aligned} v_{n_s} &= \left[v_{n_1} + \alpha \cos \theta \left(v_{n_2} + \frac{\eta}{\alpha} \frac{\partial v_{n_1}}{\partial \psi} \right) \right]_b \\ &= v_{n_{1_2}} + (\alpha - \eta) v_{n_{2_2}} \cos \theta \end{aligned} \quad (72a)$$

$$\begin{aligned} v_{r_s} &= \left[v_{r_1} + \alpha \cos \theta \left(v_{r_2} + \frac{\eta}{\alpha} v_{n_1} \right) \right]_b \\ &= v_{r_{1_2}} + (\alpha - \eta) v_{r_{2_2}} \cos \theta \end{aligned} \quad (72b)$$

$$\begin{aligned} w_s &= \alpha \sin \theta \left(w_2 - \frac{1}{\sin \psi} \frac{\eta}{\alpha} v_{n_1} \right)_b \\ &= (\alpha - \eta) w_{2_s} \sin \theta \end{aligned} \quad (72c)$$

where v_{n_s} , v_{r_s} , and w_s are the components referred to the axis of the conical shock, whereas the components v_{n_b} , v_{r_b} , and w_b are referred to the axis of the body. Indeed, η/α is constant.

The calculations start at the shock. After determining the flow field for zero angle of attack, the angle of the conical shock ψ_s is known and the velocity components v_{n_1} and v_{r_1} with respect to the axis of the shock for every value of ψ are also known. In order to determine the flow for the case of a small angle of attack, the direction of the undisturbed velocity must be rotated at a small angle $\alpha - \eta$ with respect to the axis of the shock (fig. 10). The value assumed for $\alpha - \eta$ fixes the value of α for which the calculations are performed. (This value of α is not yet known but is obtained as a result of the calculation.)

FIGURE 10.—Choice of the axis for the hodograph diagram.

For a unitary value of $\alpha - \eta$, the component v_{r_s} behind the shock can be determined from equation (14b) ($v_{r_s} = v_{r'}$) and the component w_s , from equation (14c) ($w' = w_s$); whereas v_{n_s} can be determined from equation (21a) ($v_{n_s} = -v_{N''}$) and $v_{N'}$ is given by equation (14a). The value of entropy $(\alpha - \eta)\Delta S_2 \cos \theta$ can also be determined from the equation of the shock, for example, from the difference between ΔS and ΔS_1 . When v_{r_s} , v_{n_s} , w_{2_s} , and ΔS_2 are known behind the shock, all the flow field can be obtained by means of equations (68) and (70) or (71). The hodograph diagram can be constructed, for example, in the plane $\theta = \pi$.

The axis u has been chosen in the direction of the undisturbed velocity for zero angle of attack that corresponds to the axis of the shock for $\alpha = 0$. For α the undisturbed velocity has been rotated at $\alpha - \eta$ with respect to the u -axis (fig. 10); therefore, the axis of the shock has not been changed. The velocity OP_a behind the shock of figure 9 must be decomposed into (1) a component $P_a Q_a$ inclined at ψ_s and corresponding to v_{r_s} if equation (70) is used or to $v_{r_{2_s}}$ if equation (71) is used and (2) a component $O_a Q_a$ corresponding to v_{n_s} or $v_{n_{2_s}}$.

In this way, the values of v_{r_1} and v_{n_1} that must be used in equations (68), (70), and (71) are the values obtained from the calculations for zero angle of attack at the same value of ψ (that is, $\psi = \psi_s$ for P_a). Because the calculations start at the shock, the construction of the hodograph diagram must be performed in the direction of decreasing values of ψ .

At the surface of the body for $\theta=\pi$, the component v_n must be zero; therefore, when the radius of the hodograph diagram passes at the origin of coordinates u and v , the corresponding value of ψ is equal to $\psi_0+\eta$ where ψ_0 is the angle of the cone (fig. 10). Because ψ_0 is known, the value of η and, therefore, of α can be determined.

The components v_r and v_n in the plane $\theta=0$ or $\theta=\pi$ do not change when, for the axis of reference, the axis of the body is assumed; but the corresponding value of ψ is increased at η (fig. 10). The value of w_2 changes; the value of w_2'' can be determined from the value of w_2 by means of equation (72c).

For practical calculations it is convenient to use nondimensional coefficients obtained by dividing all the velocity components by the limiting velocity V_i . The expression a/V_i can be obtained from equation (39d).

For small values of α , the values of v_{r_2} , v_{n_2} , w_2 , and η/α are independent of α and, therefore, the flow for every other value of α can be obtained from this determination. The calculations can be graphical or analytical.

REPORT 1045

SUPERSONIC FLOW AROUND CIRCULAR CONES AT ANGLES OF ATTACK¹

By ANTONIO FERRI

SUMMARY

The flow around cones without axial symmetry and moving at supersonic velocity is analyzed. Singular points are shown to exist in the flow around the cone if no axial symmetry exists. The results of the analysis are applied to the determination of flow around circular cones at small angles of attack. The concept of a vortical layer around the cone at small angles of attack is introduced, and the correct values of the first-order terms of the velocity components are determined.

The method used is applied to cones at finite angles of attack, and it is shown that good agreement with experimental results can be obtained from the first-order theory if the complete equation for the pressure distribution is used.

INTRODUCTION

The flow around a cone having a circular cross section and moving at supersonic speed has been determined by means of the assumption of small disturbances or by means of more rigorous methods that consider the existence of the shocks. The latter methods can be applied for any Mach number larger than unity and have been developed by several authors, at first by assuming all the flow as potential flow (references 1 and 2) and later by also considering the variation of entropy due to the change in angle of attack (reference 3). By means of the development given in reference 3, values of flow properties around circular cones at an angle of attack have been tabulated in reference 4. The method has been extended in reference 5 to larger angles of attack.

In the method given in references 3, 4, and 5, the flow properties were considered continuous and were developed in Fourier series in terms of the angle of attack; however, the existence of a singular point at the surface of the cone was neglected. The derivatives of the flow properties were obtained by differentiating the Fourier series term by term, and the terms of the series that represent the derivatives were assumed to be of the same order as the corresponding terms of the integral quantities. For this reason, an erroneous distribution of the entropy at the surface of the cone was obtained.

In this report, the flow around the cone in the general case is discussed, the existence of singular points in the flow is proved, and a different procedure for determining the flow around cones at small, but finite, angles of attack is developed. This procedure shows the way in which the values tabulated in reference 4 can be used if a simple correction is introduced. The values obtained in this way are compared with experimental results at several values of angle of attack.

SYMBOLS

r, ψ, θ	polar coordinates (see fig. 1)
v_r	polar velocity component in radial direction (along r), referred to limiting velocity (see fig. 1)
v_n	polar velocity component normal to v_r in meridian plane $\theta = \text{Constant}$, referred to limiting velocity (fig. 1)
w	polar velocity component normal to meridian plane $\theta = \text{Constant}$, referred to limiting velocity (fig. 1)
t	time
p	pressure
ρ	density
S	entropy
γ	ratio of specific heats (c_p/c_v)
$R = c_p - c_v$	
c_p	specific heat at constant pressure
c_v	specific heat at constant volume
a	speed of sound
L	projection of streamline on sphere $r = \text{Constant}$ with center at center of the polar coordinate system
V	local velocity
V_1	undisturbed velocity, referred to limiting velocity
V_i	limiting velocity (velocity for expansion in the vacuum)
σ	semiapex angle of conical shock
δ	inclination of axis of conical shock with respect to free-stream direction
η	inclination of axis of conical shock with respect to axis of body
α	angle of attack
Subscripts:	
1	stream conditions
a	zero-order terms of Fourier series (part independent from angle of attack)
b	first-order terms of Fourier series (part proportional to angle of attack)
c	higher-order terms of Fourier series or quantities at surface of cone
e	quantities at external surface of vortical layer
s	quantities for polar coordinate system having axis coincident with axis of conical shock

¹Supersedes NACA TN 2236, "Supersonic Flow around Circular Cones at Angles of Attack" by Antonio Ferri, 1950.

A prime is used to designate the terms of zero order in the power series in $\Delta\theta$ for the quantities in the neighborhood of the meridian plane $\theta=\pi$; two primes are used to designate the factor of the term containing $\Delta\theta^2/2$ in the same power series.

THE FLOW FIELD FOR CONICAL FLOW WITHOUT AXIAL SYMMETRY

In order to analyze the flow field for conical flow without axial symmetry at supersonic speeds, assume a polar coordinate system (r, ψ, θ) . Call v_r the velocity component in the radial direction, v_n the velocity component in the direction normal to r in the meridian plane $\theta=\text{Constant}$, and w the component normal to the meridian plane (fig. 1); that is,

$$v_r = \frac{dr}{dt}$$

$$v_n = \frac{r d\psi}{dt}$$

$$w = \frac{r d\theta}{dt} \sin \psi$$

If the flow is conical,

$$\frac{\partial v_r}{\partial r} = 0 \quad \frac{\partial v_n}{\partial r} = 0 \quad \frac{\partial w}{\partial r} = 0$$

$$\frac{\partial p}{\partial r} = 0 \quad \frac{\partial \rho}{\partial r} = 0 \quad \frac{\partial S}{\partial r} = 0$$

For these conditions Euler's equations become

$$v_n \frac{\partial v_r}{\partial \psi} + \frac{w}{\sin \psi} \frac{\partial v_r}{\partial \theta} - v_n^2 - w^2 = 0 \quad (1a)$$

$$v_n \frac{\partial v_n}{\partial \psi} + \frac{w}{\sin \psi} \frac{\partial v_n}{\partial \theta} + \frac{1}{\rho} \frac{\partial p}{\partial \psi} + v_r v_n - w^2 \cot \psi = 0 \quad (1b)$$

$$v_n \frac{\partial w}{\partial \psi} + \frac{w}{\sin \psi} \frac{\partial w}{\partial \theta} + \frac{1}{\rho \sin \psi} \frac{\partial p}{\partial \theta} + v_r w + v_n w \cot \psi = 0 \quad (1c)$$

and the continuity equation becomes

$$2\rho v_r \sin \psi + v_n \sin \psi \frac{\partial \rho}{\partial \psi} + \rho \sin \psi \frac{\partial v_n}{\partial \psi} + v_n \rho \cos \psi + w \frac{\partial \rho}{\partial \theta} + \rho \frac{\partial w}{\partial \theta} = 0 \quad (2)$$

Because the energy in the flow is constant, the following relations must apply:

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial \theta} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial \theta} \right) = - \left(v_r \frac{\partial v_r}{\partial \theta} + v_n \frac{\partial v_n}{\partial \theta} + w \frac{\partial w}{\partial \theta} \right) \quad (3a)$$

$$\frac{\gamma}{\gamma-1} \left(\frac{1}{\rho} \frac{\partial p}{\partial \psi} - \frac{p}{\rho^2} \frac{\partial \rho}{\partial \psi} \right) = - \left(v_r \frac{\partial v_r}{\partial \psi} + v_n \frac{\partial v_n}{\partial \psi} + w \frac{\partial w}{\partial \psi} \right) \quad (3b)$$

FIGURE 1.—The polar coordinate system.

Combining equations (1), (2), and (3) results in

$$v_r \left(2 - \frac{v_n^2 + w^2}{a^2} \right) + v_n \cot \psi + \frac{\partial v_n}{\partial \psi} \left(1 - \frac{v_n^2}{a^2} \right) + \frac{\partial w}{\sin \psi \partial \theta} \left(1 - \frac{w^2}{a^2} \right) - \frac{w v_n}{a^2} \left(\frac{\partial v_n}{\sin \psi \partial \theta} + \frac{\partial w}{\partial \psi} \right) = 0 \quad (4)$$

The entropy at any point of the flow can be expressed as

$$S = \frac{R}{\gamma-1} \log_e \frac{p}{p_1} \left(\frac{\rho_1}{\rho} \right)^\gamma + \text{Constant}$$

where p and ρ are the local quantities and p_1 and ρ_1 the stream quantities. Therefore,

$$\left. \begin{aligned} \frac{\gamma-1}{R} \frac{\partial S}{\partial \theta} &= \frac{1}{p} \frac{\partial p}{\partial \theta} - \gamma \frac{1}{\rho} \frac{\partial \rho}{\partial \theta} \\ \frac{\gamma-1}{R} \frac{\partial S}{\partial \psi} &= \frac{1}{p} \frac{\partial p}{\partial \psi} - \gamma \frac{1}{\rho} \frac{\partial \rho}{\partial \psi} \end{aligned} \right\} \quad (5)$$

Combining equations (5) with equations (1), (2), and (3) results in the following expressions:

$$\left. \begin{aligned} \frac{a^2}{\gamma R} \frac{\partial S}{\partial \theta} &= v_n \sin \psi \frac{\partial w}{\partial \psi} - v_r \frac{\partial v_r}{\partial \theta} - v_n \frac{\partial v_n}{\partial \theta} + v_r w \sin \psi + v_n w \cos \psi \\ \frac{a^2}{\gamma R} \frac{\partial S}{\partial \psi} &= -v_r \frac{\partial v_r}{\partial \psi} - w \frac{\partial w}{\partial \psi} + \frac{w}{\sin \psi} \frac{\partial v_n}{\partial \theta} + v_r v_n - w^2 \cot \psi \end{aligned} \right\} \quad (6)$$

Equations (6) combined with equation (1a) give

$$v_n \sin \psi \frac{\partial S}{\partial \psi} = -w \frac{\partial S}{\partial \theta} \quad (7)$$

Equation (7) is general for any conical flow and defines the lines of constant entropy, which correspond to the streamlines. In fact, if L is the streamline projection on the sphere given by $r=\text{Constant}$,

$$\frac{dS}{dL} = \frac{\partial S}{\partial \psi} \frac{d\psi}{dL} + \frac{\partial S}{\partial \theta} \frac{d\theta}{dL} = 0$$

and, from equation (7),

$$\left(\frac{d\theta}{d\psi}\right)_L = \frac{w}{v_n \sin \psi} \quad (8)$$

At the surface of any conical body the component of velocity in the direction normal to the surface is zero and the stream moves tangentially to the body; therefore, the entropy at the surface of the body must be constant or must change in a discontinuous way (in which case equations (7) and (8) are not valid).

THE PROPERTIES OF CONICAL FLOW WITHOUT AXIAL SYMMETRY

In order to analyze the properties of conical flow without axial symmetry, consider first a polar coordinate system having its axis coincident with the axis of a circular cone at a small angle of attack (fig. 2) and assume that the direction of the undisturbed velocity V_1 is in the plane $\theta=0$, $\theta=\pi$. In this case, the plane $\theta=0$, $\theta=\pi$ is a plane of symmetry of the flow and, in this plane,

$$w=0$$

$$v_n \neq 0$$

and

$$\frac{\partial v_r}{\partial \theta} = 0 \quad \frac{\partial v_n}{\partial \theta} = 0 \quad \frac{\partial S}{\partial \theta} = 0$$

Therefore, equation (7) shows that in the plane $\theta=0$, $\theta=\pi$ the entropy is constant. At the surface of the cone ($\psi=\psi_c$), the normal component v_n is zero and $w \neq 0$; therefore, equation (7) shows that the entropy remains constant also along the surface of the cone ($\psi=\psi_c$). Only at points A and B, (defined by $\theta=0$, $\theta=\pi$, and $\psi=\psi_c$) $v_n \rightarrow 0$ and $w \rightarrow 0$; therefore,

equation (7) is indeterminate. Because the body is at an angle of attack, the axis of conical shock does not remain coincident with the direction of the velocity V_1 , and the entropy in the plane $\theta=0$ must be different from the entropy in the plane $\theta=\pi$. The entropy at the cone surface therefore must be different from the entropy at the plane $\theta=0$, from the entropy at the plane $\theta=\pi$, or from both. In this case, where $w=0$ and $v_n=0$, a discontinuity of entropy must exist either at A or B or both points.

In order to find a relation between the value of the entropy at the surface of the cone and the values of the entropy in the meridian plane $\theta=0$, $\theta=\pi$, the following considerations can be used: In the meridian plane ($\theta=0$, $\theta=\pi$), w , $\frac{\partial S}{\partial \theta}$, and $\frac{\partial v_n}{\partial \theta}$ are zero because the plane is a plane of symmetry of the flow field and, from equation (7), $\frac{\partial S}{\partial \psi} = 0$. Therefore, in the plane of symmetry in the zone outside of the singular points A and B,

$$\frac{\partial}{\partial \psi} \left(\frac{\partial^2 S}{\partial \theta^2} \right) = - \frac{2}{v_n \sin \psi} \frac{\partial w}{\partial \theta} \frac{\partial^2 S}{\partial \theta^2} \quad (9)$$

For the case considered, the velocity component v_n is negative at the shock or at the Mach cone and remains negative throughout the field, until it becomes zero at the surface of the cone; therefore, the value of $\frac{\partial^2 S}{\partial \theta^2}$ tends to increase in absolute value as ψ decreases from the value corresponding to the value at the surface of the shock to the value at the surface of the cone when $\frac{\partial w}{\partial \theta}$ is negative and tends to decrease when $\frac{\partial w}{\partial \theta}$ is positive.

FIGURE 2.—The singular points at the surface of the cone.

Because the entropy remains constant along each streamline, the decrease of the absolute value of $\frac{\partial^2 S}{\partial \theta^2}$ as ψ decreases corresponds to a departure of projection of the streamlines on the sphere $r=\text{Constant}$ from the plane of symmetry; but, if $\frac{\partial}{\partial \psi} \left(\frac{\partial^2 S}{\partial \theta^2} \right)$ is of sign opposite to $\frac{\partial^2 S}{\partial \theta^2}$, the projection of the streamlines on the sphere $r=\text{Constant}$ tends to converge toward the plane of symmetry as ψ decreases from the value at the shock to the value at the surface of the cone.

Now, with the convention used in figure 2, the component w is negative throughout the field and is zero at $\theta=0$ and $\theta=\pi$. Therefore, $\frac{\partial w}{\partial \theta}$ is negative in the zone $\theta=0$ but is positive in the zone $\theta=\pi$, and the streamline projection tends to converge toward the zone of point A and diverge from the zone of point B. Because of the departure of the streamlines from the plane $\theta=\pi$, the entropy in zone B remains constant and, therefore, the entropy at the surface of the cone is equal to the entropy at the meridian plane $\theta=\pi$; at point A a discontinuity of entropy exists from the value corresponding to the plane $\theta=0$ to the larger value existing in the plane $\theta=\pi$. All the projections of the streamlines converge at point A where the entropy is not single-valued. Because v_n approaches zero near the cone, equation (8) shows that all the streamline projections tend to become parallel to the line $\psi=\text{Constant}$ in the zone near the cone and converge at A. The value of v_n in the meridian plane $\theta=0$ can change sign and can be positive in the neighborhood of the point A (case of large angles of attack). In this case the right-hand side of equation (9) changes sign and the singular point moves away from A in the meridian plane $\theta=0$ and occurs at the other point of the meridian plane where v_n is also zero. (At the shock or at the Mach wave v_n is negative; therefore, another singular point where $v_n=0$ must exist.)

It is interesting to observe that singular points must exist in any supersonic conical flow without axial symmetry. Considerations similar to those used for the case of circular cones at an angle of attack can be extended to other cases, and it can be shown that the streamlines that are tangent to the body start from points of the shock and meet the body at points where the component of velocity perpendicular to the radius and tangent to the body vanishes and has a positive derivative in the streamline direction (equiva-

lent to the condition of positive $\frac{\partial w}{\partial \theta}$). Convergency of streamlines occurs and, therefore, the points are singular at the points where this component vanishes and has a negative derivative in the direction tangent to the body, while the component normal to the body also vanishes and has a negative derivative in the direction normal to the body (equivalent to $v_n=0$ and $\frac{\partial v_n}{\partial \psi}$ negative).

For example, the conical body of figure 3 has two planes of symmetry, AA' and BB' when w and v_n are zero, but at the points BB', $\frac{\partial w}{\partial \theta}$ is positive, while at AA', it is negative.

Therefore, because $\frac{\partial v_n}{\partial \psi}$ is negative at AA' and BB', the points AA' are singular points and the entropy at the surface of the body is determined by the shock strength at the points CC'.

DETERMINATION OF THE FLOW AROUND CIRCULAR CONES AT SMALL ANGLES OF ATTACK

In order to determine the flow around circular cones at small angles of attack, consider a polar coordinate system, the axis of which is coincident with the body axis. At the surface of the body the velocity component v_n is zero and in the neighborhood of the body is very small; therefore, the terms v_n^2/a^2 can be neglected with respect to unity.

If the angle of attack is small, the component w is also small and the terms w^2/a^2 can also be neglected. On the basis of this approximation, in the neighborhood of the body equation (4) can be expressed as

$$2v_r + v_n \cot \psi + \frac{\partial v_n}{\partial \psi} + \frac{\partial w}{\sin \psi \partial \theta} = 0 \quad (10)$$

This equation permits a particular solution of this type chosen from physical considerations

$$\left. \begin{aligned} v_r &= v_{r_a} + \alpha v_{r_b} \cos \theta + \sum v_{r_c} \cos m\theta \\ v_n &= v_{n_a} + \alpha v_{n_b} \cos \theta + \sum v_{n_c} \cos m\theta \\ w &= \alpha w_b \sin \theta + \sum w_c \cos m\theta \end{aligned} \right\} \quad (11)$$

where $v_{r_{a,b,c}}$, $v_{n_{a,b,c}}$, and $w_{b,c}$ are functions only of ψ , are constant for constant values of ψ , and must be chosen in a form that satisfies the boundary conditions.

Consider now a conical shock having circular cross section and semiapex angle σ (fig. 4). Consider the cone inclined at an angle δ with respect to the undisturbed velocity with a polar coordinate system, the axis of which is coincident with the axis of the conical shock. If v_r , v_n , and w are the velocity components referred to the limiting velocity V_1 in the new coordinate system (r_s , ψ_s , θ_s), from the shock-wave relations the following equations result:

$$v_{r_s} = V_1 \cos \delta \cos \sigma + V_1 \sin \delta \sin \sigma \cos \theta_s$$

$$w_s = -V_1 \sin \delta \sin \theta_s$$

$$-v_{n_s} = \frac{\gamma-1}{\gamma+1} \frac{1-v_{r_s}^2-w_s^2}{V_1 \cos \delta \sin \sigma - V_1 \sin \delta \cos \sigma \cos \theta_s}$$

If δ is assumed to be small and terms of the order of δ^2 are neglected, these equations become

$$\left. \begin{aligned} v_{r_s} &= V_1 \cos \sigma + \delta V_1 \sin \sigma \cos \theta_s \\ w_s &= -V_1 \delta \sin \theta_s \\ v_{n_s} &= -\frac{\gamma-1}{\gamma+1} \left(\frac{1-V_1^2 \cos^2 \sigma}{V_1 \sin \sigma} \right) - \frac{\gamma-1}{\gamma+1} \delta \cos \sigma \left(-2V_1 + \frac{1-V_1^2 \cos^2 \sigma}{V_1 \sin^2 \sigma} \right) \cos \theta_s \end{aligned} \right\} \quad (12)$$

FIGURE 3.—The singular points at the surface of a cone in supersonic flow without axial symmetry.

FIGURE 4.—The position of the conical shock with respect to the conical body.

The flow behind a circular conical shock inclined at a small angle δ with respect to the undisturbed stream can therefore be expressed in the form

$$\left. \begin{aligned} v_{rs} &= v_{ra_s} + \delta v_{rb_s} \cos \theta_s \\ v_{ns} &= v_{na_s} + \delta v_{nb_s} \cos \theta_s \\ w_s &= \delta w_{bs} \sin \theta_s \end{aligned} \right\} \quad (13)$$

where all the terms containing v_{rb} , v_{nb} , and w_b are small, that is, of the order of δ .

If the axis of the conical coordinates is rotated at an angle η of the same order as the angle δ and terms of the order of δ^2

are neglected, the velocity components v_r , v_n , and w referred to the new axis (fig. 4) become

$$\left. \begin{aligned} v_r &= v_{ra_s} + \left(\frac{\partial v_{ra_s}}{\partial \psi_s} \eta + \delta v_{rb_s} \right) \cos \theta \\ v_n &= v_{na_s} + \left(\frac{\partial v_{na_s}}{\partial \psi_s} \eta + \delta v_{nb_s} \right) \cos \theta \\ w &= \left(\delta w_{bs} - \frac{v_{na_s} \eta}{\sin \psi_s} \right) \sin \theta \end{aligned} \right\} \quad (14)$$

where θ , the coordinate referred to the new axis, is given by

$$\cos \theta = \cos \theta_s - \eta \cot \psi_s \sin^2 \theta_s$$

Equations (14) show that the flow behind a circular conical shock inclined at a small angle δ with respect to the direction of the undisturbed stream and at an angle η with respect to a conical body can also be expressed in the form given in equations (11) where, if the angles η and δ are small and the terms of the order of η^2 and δ^2 are neglected, only the terms having the subscripts a and b must be considered. Therefore, equations (11), when the terms with the subscript c are neglected, are valid for small angles of attack ($\alpha = \delta - \eta$), and a conical circular shock is consistent with the solution chosen for the flow around the body. At the surface of the cone the assumption that w^2 is small corresponds to the assumption that only the first-order terms of angle of attack are considered. The conical shock is inclined at an angle η with respect to the circular cone.

This analysis is similar to the analysis of references 2 and 3. No assumption, however, has been introduced for the entropy distribution; only the velocity components have been considered to be in the form of equations (11), and no limiting assumption has been introduced for the derivatives.

In reference 3, in addition to the equations

$$v_r = v_{r_a} + \alpha v_{r_b} \cos \theta \quad (15a)$$

$$v_n = v_{n_b} + \alpha v_{n_b} \cos \theta \quad (15b)$$

the expressions

$$w = \alpha w_b \sin \theta \quad (15c)$$

$$p = p_a + \alpha p_b \cos \theta \quad (16a)$$

$$\rho = \rho_a + \alpha \rho_b \cos \theta \quad (16b)$$

$$S = S_a + \alpha S_b \cos \theta \quad (16c)$$

have been used, and the derivatives of entropy, pressure, and density have been obtained from differentiation of equations (16). In this way a solution has been found which gives values of entropy that are variable along the cone surface and are constant in each meridian plane, while the entropy actually remains constant along the cone surface and changes in the meridian plane. An incorrect entropy distribution has therefore been obtained at the surface of the body.

In order to analyze in more detail the significance of equations (16) and their inconsistency with the approximation considered in references 2 and 3, consider equation (7). In the plane of symmetry $\theta=0$ or $\theta=\pi$, $\frac{\partial S}{\partial \psi}=0$; therefore, $S_a + \alpha S_b$ or $S_a - \alpha S_b$ of equation (16c) must remain constant.

Consider now the plane $\theta=\pi$ and express the entropy S in the form

$$S = S' - S'' \frac{\Delta \theta^2}{2} \quad (17)$$

which satisfies the condition of symmetry. Because of equation (7),

$$\frac{\partial S'}{\partial \psi} = 0 \quad (18)$$

and, from equations (16) and (17),

$$S' = S_a - \alpha S_b \quad (19)$$

and

$$\alpha S_b = -S'' \quad (20)$$

From equations (7) and (17),

$$v_n \sin \psi \left(\frac{\partial S'}{\partial \psi} - \frac{\partial S''}{\partial \psi} \frac{\Delta \theta^2}{2} \right) = w S'' \Delta \theta$$

However, $\frac{\partial S'}{\partial \psi} = 0$; therefore,

$$\frac{\Delta \theta}{2} \frac{\partial S''}{\partial \psi} = - \frac{w S''}{v_n \sin \psi}$$

or, since from equation (15c) $w = -\alpha w_b \Delta \theta$,

$$\frac{\partial S''}{\partial \psi} = - \frac{\alpha w_b S''}{v_n \sin \psi}$$

By use of equation (20), in the neighborhood of the plane $\theta=\pi$,

$$\alpha \frac{\partial S_b}{\partial \psi} = \frac{2 w_b S_b \alpha^2}{v_n \sin \psi} = - \frac{2 \alpha w_b S''}{v_n \sin \psi}$$

In reference 3, the term $\frac{w S''}{v_n \sin \psi}$ has been considered everywhere to be of the order of α^2 and has been neglected; hence, $\frac{\partial S_b}{\partial \psi} = 0$ and $\frac{\partial S_a}{\partial \psi} = 0$. However, neglecting this term is correct only when the ratio w_b/v_n is of an order different from $1/\alpha$ and, therefore, when $|v_n| \gg 0$. Near the surface of the cone, v_n approaches zero and, therefore, the term $\frac{\partial S''}{\partial \psi}$ becomes large and cannot be neglected. The extent of the field around the cone where the term $\frac{\partial S''}{\partial \psi}$ is of the order of α can be easily determined.

Consider a polar coordinate system having its axis coincident with the axis of the cone. At the surface of the body v_n is zero; therefore, in the neighborhood of the body the velocity component v_n can be expressed in the form

$$v_n = \left(\frac{\partial v_n}{\partial \psi} \right)_v \Delta \psi$$

or, by use of equation (10), in the form

$$v_n = - \left(2 v_r + \frac{\partial w}{\sin \psi \partial \theta} \right) (\Delta \psi)_v \quad (21)$$

Therefore, v_n is of the order of α when $(\Delta \psi)_v$ is of the order of α . In this conical layer of thickness $(\Delta \psi)_v$ of the order of α , $\frac{\partial S''}{\partial \psi}$ is also of the order of α or larger. In this layer, which can be called the vortical layer, the term $\frac{\partial S_a}{\partial \psi}$ also is of the order of α because from equations (18) and (19) $\frac{\partial S_a}{\partial \psi}$ can be shown to be of the same order as $\frac{\partial S''}{\partial \psi}$.

In order to investigate the effect of this vortical layer on the velocity and pressure distribution at the surface of the cone, consider equations (2), (4), (6), and (7). If the velocity components in the neighborhood of the meridian plane $\theta=\pi$ are expressed as

$$v_r = v_r' - \frac{\Delta \theta^2}{2} v_r'' \quad (22a)$$

$$v_n = v_n' - \frac{\Delta \theta^2}{2} v_n'' \quad (22b)$$

$$w = w'' \left(\Delta \theta - \frac{\Delta \theta^3}{3!} \right) \quad (22c)$$

the following expressions can be obtained:

$$\frac{\partial S''}{\partial \psi} = \frac{2w''S''}{v_n' \sin \psi} \quad (23)$$

$$\frac{\partial v_r''}{\partial \psi} = v_n'' - \frac{2w''}{v_n'} \left(\frac{v_r''}{\sin \psi} + w'' \right) \quad (24)$$

$$-\frac{\partial w''}{\partial \psi} = \frac{1}{v_n' \sin \psi} \left(v_r' v_r'' + v_n' v_n'' + w'' v_r' \sin \psi + v_n' w'' \cos \psi + \frac{S'' a'^2}{\gamma R} \right) \quad (25)$$

$$\frac{\partial v_n''}{\partial \psi} = \frac{1}{1 - \frac{v_n'^2}{a'^2}} \left[2B \left(\frac{v_n' v_n''}{a'^2} - A \frac{v_n'^2}{a'^2} \right) - v_n'' \cot \psi - v_r'' \left(2 - \frac{v_n'^2}{a'^2} \right) - \frac{w''}{\sin \psi} \left(\frac{2w''^2}{a'^2} - \frac{2v_n' v_n''}{a'^2} + \frac{2v_n' \sin \psi}{a'^2} \frac{\partial w''}{\partial \psi} \right) - \frac{2v_r' w''^2}{a'^2} \right] \quad (26)$$

where

$$A = \frac{-v_r' v_r'' - v_n' v_n'' + w''^2}{a'^2} \frac{\gamma - 1}{2} \quad (27)$$

$$B = -\frac{v_r' + v_n' \cot \psi + \frac{w''}{\sin \psi}}{1 - \frac{v_n'^2}{a'^2}} \quad (28)$$

and

$$\frac{\partial v_{r_a}}{\partial \psi} = v_{r_a} - \frac{a'^2}{v_{r_a}} \frac{1}{\gamma R} \frac{\partial S_a}{\partial \psi} \quad (29)$$

Therefore, all the derivatives of the velocity components of zero and first order are affected by the entropy variation in the meridian plane. The terms $\frac{\partial S_a}{\partial \psi}$ and $\frac{\partial S''}{\partial \psi}$ are of the order of α in a layer of thickness α near the surface of the cone. In this layer they change the value of $\frac{\partial p}{\partial \psi}$ of quantities of the order of α and the pressure at the surface of the cone of quantities of the order θ/α^2 . The only place where the terms $\frac{\partial S_a}{\partial \psi}$ and $\frac{\partial S''}{\partial \psi}$ are of zero order is near the surface of the cone in a layer of thickness α^2 , where v_n tends to the order θ/α^2 (equation (9)). Because the effect of this vortical layer existing at the surface of the cone on the pressure is of the order θ/α^2 , it can be considered in this approximation, which neglects terms of the order of α^2 or higher, that across this layer the pressure distribution remains constant, but an abrupt variation of entropy occurs; therefore, in this approximation the phenomenon can be represented as in references 3 and 4, where the entropy remains constant in every meridian plane until a vortical layer of infinitesimal thickness is reached at the surface of the cone across which a variation of entropy occurs from the value $S_a + \alpha S_b \cos \theta$ to the value $S_a - \alpha S_b$, that exists at the surface of the cone. Across the layer a variation of density and velocity components occurs and can be easily determined.

Let v_{r_e} , w_e , S_e , p_e , ρ_e , and a_e be the quantities at the external surface of the layer (these are the quantities tabulated in

reference 4) and v_{r_c} , w_c , S_c , p_c , and ρ_c be the quantities at the surface of the cone. Because it has been shown that

$$p_e = p_c \quad (30)$$

then

$$v_{r_e}^2 + w_e^2 - v_{r_c}^2 - w_c^2 = -\frac{2}{\gamma - 1} a_e^2 \frac{S_e - S_c}{c_p} \quad (31)$$

where $S_e - S_c$ is the entropy jump across the layer.

Now,

$$v_r = v_{r_a} + \alpha v_{r_b} \cos \theta$$

$$w = \alpha w_b \sin \theta$$

and in the plane $\theta = \pi$

$$v_{r_e} = v_{r_c}$$

$$w_e = w_c = 0$$

$$S_e = S_c$$

or

$$\left. \begin{aligned} (v_{r_a} - \alpha v_{r_b})_e &= (v_{r_a} - \alpha v_{r_b})_c = v_r' \\ (S_a - \alpha S_b)_e &= (S_a - \alpha S_b)_c = S' \end{aligned} \right\} \quad (32)$$

Therefore, if terms of the order of α^2 are neglected, equation (31) becomes

$$v_r'(v_{r_b})_e - v_r'(v_{r_b})_c = -\frac{1}{\gamma - 1} a^2 \frac{S_b}{c_p} \quad (33)$$

or

$$(v_{r_b})_c - (v_{r_b})_e = \frac{a^2}{(\gamma - 1)v_r'} \frac{S_b}{c_p} \quad (34)$$

However, from equation (1a), at the surface of the cone,

$$w = \frac{\partial v_r}{\sin \psi \partial \theta}$$

or

$$w_b = -\frac{v_{r_b}}{\sin \psi_c} \quad (35)$$

therefore, the values of v_{r_b} and w_b can be determined from

equation (34) and from the tables of reference 4 where

$$S_b = c_v \left(\frac{p_b}{p_a} - \gamma \frac{\rho_b}{\rho_a} \right) \quad (36)$$

and

$$\alpha^2 = \frac{\gamma-1}{2} (1 - v_r'^2) \quad (37)$$

The values v_{r_a} , v_{r_b} , and w_b having been determined, the values of v_r and w can be obtained at any part of the cone from equations (15).

THE NUMERICAL DETERMINATION OF THE FLOW FIELD AROUND CONES AT SMALL ANGLES OF ATTACK

The method presented permits the determination of the pressure distribution around the cones with the assumption that the terms of the order of α^2 can be neglected. The pressure at any point can be obtained from the equation

$$\frac{p}{p_1} = \left(\frac{1-V^2}{1-V_1^2} \right)^{\frac{\gamma}{\gamma-1}} e^{-\frac{1}{\gamma-1} \frac{\Delta S}{c_v}} \quad (38)$$

where V is the local velocity corresponding to the pressure p and ΔS is the increase of entropy with respect to the stream conditions where p_1 and V_1 exist. From equations (15), V^2 is found to be

$$V^2 = v_{r_a}^2 + \alpha^2 v_{r_b}^2 \cos^2 \theta + 2\alpha v_{r_a} v_{r_b} \cos \theta + \alpha^2 w_b^2 \sin^2 \theta \quad (39)$$

However, in equation (39) the terms of the order of α^2 having the form $2v_{r_a} v_{r_b} \cos m\theta$ have been neglected (see equations (11)). If all the terms of the order of α^2 are neglected, V^2 becomes

$$V^2 = v_{r_a}^2 + 2\alpha v_{r_a} v_{r_b} \cos \theta \quad (40)$$

Equations (39) and (40) are different in terms of the order of α^2 ; however, for finite angles of attack good agreement is obtained only if equation (39) in which some of the α^2 terms are retained is used in equation (38).

The reason for the better approximation given by equation (39) can be understood if the magnitude of the terms containing α^2 in the expression of V^2 is considered. Along the surface of the cone, αw_b is given by

$$\alpha w_b = -\frac{\alpha v_{r_b}}{\sin \psi_c} \quad (41)$$

For a finite value of α and a small value of ψ_c , $\alpha^2 w_b^2$ is of the same order as αv_{r_b} because $\sin^2 \psi_c$ is also small; therefore, $\alpha^2 w_b^2$ can have an effect on the velocity and pressure distribution of the same order as the term $\alpha v_{r_a} v_{r_b}$ which is the

only term retained in equation (40). Because the term $\alpha^2 w_b^2$ is correct and significant, it can still be retained also when other terms in α^2 are neglected and, therefore, equation (39) is the expression that must be used for finite angle of attack. (For example, for a 10° cone ($\psi_c = 10^\circ$) $\sin^2 \psi_c = \frac{1}{33}$ and $\frac{\alpha}{\sin^2 \psi_c} = 1$ for $\alpha = 1.75^\circ$, which can be considered a small angle.)

In reference 3, equation (16a) has been used in the derivation of the method; however, the use of this equation is not necessary, as is briefly shown in the following paragraph.

Consider a conical circular shock having the semiapex angle σ and inclined at an angle δ with respect to the undisturbed stream. In the neighborhood of the plane $\theta = \pi$ the velocity components can be expressed as in equations (22) and at the shock are given by (from equations (12))

$$v_r' = V_1 \cos \sigma - V_1 \delta \sin \sigma \quad (42)$$

$$v_r'' = -\delta V_1 \sin \sigma \quad (43)$$

$$w'' = V_1 \delta \quad (44)$$

$$v_n' = -\frac{\gamma-1}{\gamma+1} \frac{1-V_1^2 \cos^2 \sigma}{V_1 \sin \sigma} + \frac{\gamma-1}{\gamma+1} \delta \cos \sigma \left(-2V_1 + \frac{1-V_1^2 \cos^2 \sigma}{V_1 \sin^2 \sigma} \right) \quad (45)$$

$$v_n'' = \frac{\gamma-1}{\gamma+1} \delta \cos \sigma \left(-2V_1 + \frac{1-V_1^2 \cos^2 \sigma}{V_1 \sin^2 \sigma} \right) \quad (46)$$

and S' and S'' are given by

$$S' = c_v \log_e \left\{ 1 + \left(\frac{\gamma-1}{2} M_1^2 + 1 \right) [V_1^2 \sin^2 (\sigma + \delta) - v_n'^2] \right\} + (c_p - c_v) \log_e \frac{-v_n'}{V_1 \sin (\sigma + \delta)} \quad (47)$$

$$S'' = 2\delta \frac{V_1^2 \cos \sigma \sin \sigma - v_n' \frac{v_n''}{\delta}}{1 + \frac{\gamma-1}{2} M_1^2 + V_1^2 \sin^2 \sigma - v_n'^2} - (c_p - c_v) \delta \left(\frac{v_n''/\delta}{v_n'} + \frac{\cos \sigma}{\sin \sigma} \right) \quad (48)$$

All the velocity components are referred to the limiting velocity, and V_1 is the undisturbed velocity also referred to the limiting velocity.

In the meridian plane $\theta = \pi$ the entropy S' is constant;

therefore when $w=0$, from equation (1a),

$$\frac{\partial v_r'}{\partial \psi} = v_n' \quad (49)$$

If equation (4) is applied to the meridian plane $\theta=\pi$ and equation (21) is used, the radius of the hodograph diagram at any value of ψ smaller than σ is given by (reference 6)

$$(R)_\psi = - \left[\frac{v_r' + v_n' \cot \psi + \frac{w''}{\sin \psi}}{1 - \frac{v_n'^2}{a'^2}} \right] \quad (50)$$

where

$$\frac{2}{\gamma-1} a'^2 = 1 - v_r'^2 - v_n'^2 \quad (51)$$

Therefore, at the point $\psi-\Delta\psi$ in the meridian plane $\theta=\pi$,

$$(v_r')_{\psi-\Delta\psi} = -(v_n')_\psi \sin \Delta\psi + (v_r' - R)_\psi \cos \Delta\psi + (R)_\psi \quad (52)$$

and

$$(v_n')_{\psi-\Delta\psi} = (v_n')_\psi \cos \Delta\psi + (v_r' - R)_\psi \sin \Delta\psi \quad (53)$$

From equations (50) to (53), the velocity components v_r' and v_n' can be determined if the component w'' is known in the meridian plane $\theta=\pi$. Since $\frac{\partial w''}{\partial \psi}$ is given by equation (25), the value of w'' can be determined for any value of ψ . But v_{ra} and v_{na} are the quantities obtained for zero angle of attack at the same coordinate ψ of a coordinate system in axis with the conical shock, and

$$v_r'' = v_r' - v_{ra}$$

$$v_n'' = v_n' - v_{na}$$

therefore, the entire flow field can be determined until v_n'' becomes 0. The value of ψ for which $v_n''=0$ corresponds to $\psi_c + \alpha - \delta$ and, therefore, gives the value of α .

Considerations similar to those used for cones can be used for the characteristics method presented in reference 6. In this case the pressure at the surface of the body can be obtained from the complete equations, and the vortical layer must be considered in order to obtain the correct distribution of entropy. The application is the same because the entropy does not change along each streamline.

COMPARISON WITH EXPERIMENTAL RESULTS

In order to have an indication of the accuracy that can be expected from the first-order theory, theoretical results have been compared with some experimental results available. The theoretical results have been obtained by using the

values of reference 4 for the conditions outside the vortical layer, and the pressure at the surface of the cone has been determined in the following way:

From tables of reference 4 the value of δ/α has been determined (δ/ϵ of tables). The position ψ in the plane $\theta=\pi$ of the conical body in the shock coordinate system is

$$\psi = \psi_c + \alpha - \delta \quad (54)$$

The value of v_{ra} at $\psi_c + \alpha - \delta$ has been determined from the tables of reference 4 (v_r at ψ is given by $u_s - 2u_s \frac{(\alpha-\delta)^2}{2}$).

The value of v_r'' has been obtained from the tables in shock coordinates

$$[(v_{ra})_c]_\psi = -(x)_\psi - \left(\frac{\partial v_{ra}}{\partial \psi} \right)_\psi \frac{\delta}{\alpha} = - \left[x_{\psi_c} + (v_{na})_\psi \frac{\delta}{\alpha} \right] \quad (55)$$

Then $(v_{ra})_c$, $(v_{rb})_c$, and $(w_b)_c$ in the body coordinate system have been obtained by means of equations (32), (34), and (35).

From equation (36) S_b has been obtained (it has a negative value), and from tables of reference 7 S_a can be determined—for example, from the value of the angle of the shock obtained from reference 7—and

$$\Delta S = S_a - \alpha S_b \quad (56)$$

The pressure has been obtained from equation (38).

In figure 5 a comparison is presented for a cone of $\psi_c = 7.5^\circ$ at $M=1.6$ and four angles of attack. The experimental data are obtained from tests performed in the Langley 4- by 4-foot supersonic tunnel. For comparison the values given by reference 4 and by linear theory are also shown. In figure 6 a comparison is presented for a cone of $\psi_c = 10^\circ$ at $M=6.86$ and two angles of attack. The experimental data have been obtained from tests performed at the Langley 11-inch hypersonic tunnel. The agreement in both cases is good, even at angles of attack where it would be expected that higher-order terms would be important.

CONCLUDING REMARKS

The flow around cones without axial symmetry at supersonic velocity has been analyzed. Singular points which complicate the analysis of the flow field were shown to exist in the flow. The results of the analysis were applied to the determination of the flow around circular cones at an angle of attack. The concept of a vortical layer around the cone at small angles of attack has been introduced, and the correct values of the first-order terms of the velocity components were determined.

FIGURE 5.—Comparison of experimental pressure distribution over the surface of a cone with the theoretical pressure distribution. $\psi_s = 7.5^\circ$; $M = 1.6$. (Experimental data obtained from the Langley 4- by 4-foot supersonic tunnel.)

FIGURE 6.—Comparison of experimental pressure distribution over the surface of a cone with the theoretical pressure distribution. $\psi_c = 10^\circ$; $M = 6.86$. (Experimental values for two different values of r along the cone surface; data obtained from the Langley 11-inch hypersonic tunnel.)

The method determined was applied to cones at finite angle of attack, and it is shown that good agreement with experimental results can be obtained from the first-order theory if the complete equation for the pressure distribution is used. The analysis can be extended to the application of the characteristics method around bodies of revolution at small angles of attack.

REPORT 1046

A GENERAL INTEGRAL FORM OF THE BOUNDARY-LAYER EQUATION FOR INCOMPRESSIBLE FLOW WITH AN APPLICATION TO THE CALCULATION OF THE SEPARATION POINT OF TURBULENT BOUNDARY LAYERS¹

By NEAL TETERVIN and CHIA CHIAO LIN

SUMMARY

A general integral form of the boundary-layer equation is derived from the Prandtl partial-differential boundary-layer equation. The general integral equation, valid for either laminar or turbulent incompressible boundary-layer flow, contains the Von Kármán momentum equation, the kinetic-energy equation, and the Loitsianskii equation as special cases.

In an attempt to obtain a practical method for the calculation of the development of the turbulent boundary layer, use is made of the experimental finding that all the velocity profiles of the turbulent boundary layer form essentially a single-parameter family. The general equation is thereby changed to a simpler one from which an equation for the space rate of change of the shape parameter of the turbulent boundary layer can be obtained.

The resulting equation for the space rate of change of the velocity-profile parameter is restricted by the assumption that the velocity profiles of the turbulent boundary layer can be approximated by power profiles. Two of the resulting equations are used to calculate the distribution of the profile shape parameter over an airfoil for one experimentally determined pressure distribution. Although different assumptions were tried for the shearing stress across the boundary layer, the calculated distribution of the profile shape parameter did not agree exactly with the experimental distribution.

An examination is made of the effect of using the experimentally determined single-parameter family of velocity profiles instead of the power profiles on certain functions that occur in the equation for the space rate of change of the velocity-profile parameter. One calculation of the distribution of the profile shape parameter over an airfoil is also made for the experimentally determined pressure distribution by using the single-parameter family of velocity profiles found from experiment. A comparison of the results with those of a calculation made with the same assumptions except for the use of power profiles shows some difference near the separation point. It is believed, however, that the apparent lack of reliability of the specific equations used to make the calculations is caused mainly by the lack of precise knowledge concerning the surface shear and the distribution of the shearing stress across the turbulent boundary layer. The present analysis emphasizes the need for information concerning the shearing stresses in turbulent boundary layers.

INTRODUCTION

An outstanding problem in aerodynamic theory is to calculate whether the flow will separate from the surface of a specific body and, if so, where the separation will occur. The concept of the boundary layer and the equations that describe the flow in it, introduced by Prandtl (reference 1) and first worked out in some detail by Blasius (reference 2), reduce the problem to solving the Prandtl boundary-layer equation when the flow is laminar. Because of the mathematical difficulty of solving the equation, approximate methods were developed for the calculation of the properties of the laminar boundary layer (reference 3). In some of these methods, for example, the Pohlhausen method (reference 3) and the Wiegardt method (reference 4), a functional form is chosen for the velocity distribution through the boundary layer and is combined with either the Von Kármán momentum equation alone (reference 5) or with both the Von Kármán momentum equation and the kinetic-energy equation (reference 4). The result is the replacement of the Prandtl partial-differential equation by one ordinary differential equation in the Pohlhausen method and by two ordinary differential equations in the Wiegardt method. A solution of the ordinary differential equation or equations provides the boundary-layer velocity profiles along the body. These and other approximate methods that use only the Von Kármán momentum equation, or the momentum and kinetic-energy equations together, do not satisfy exactly the Prandtl boundary-layer equation.

Because the flow in the boundary layer is more often turbulent than laminar in cases encountered in engineering, the problem of calculating the separation point is of even more importance for turbulent than for laminar boundary layers. In spite of the importance of the problem, however, less progress has been made in the development of methods for the calculation of the behavior of turbulent boundary layers than for laminar boundary layers. The lack of progress stems from the absence of an explicit independent equation for the shearing stress that is accurate enough to lead to a description of the flow when used with the Prandtl equation.

The main attempts to obtain methods for the calculation of the behavior of the incompressible turbulent boundary

¹Supersedes NACA TN 2158, "A General Integral Form of the Boundary-Layer Equation for Incompressible Flow with an Application to the Calculation of the Separation Point of Turbulent Boundary Layers" by Neal Tetervin and Chia Chiao Lin, 1950.

layer in the presence of pressure gradients are those of references 6 to 12. The results of these attempts are unsatisfactory either because the assumptions upon which they rest are incorrect or because the equations used to make calculations were not derived from the boundary-layer equations.

The analysis of reference 6 is based on the assumption that the velocity profile is a single-valued function of the ratio of the pressure gradient to the skin friction, an assumption shown to be incorrect by later investigators (for example, see reference 12). In the analyses of references 7, 10, 11, and 12 the momentum equation is used, together with an auxiliary equation, to calculate the distribution of velocity profiles over a surface. In each of these four methods the auxiliary equation is not derived from the boundary-layer equations but is empirical.

In reference 8, the equation that gives the variation of the mixing length across a pipe (reference 3) was used to calculate the velocity profiles. The fact that the mixing-length distribution across the boundary layer is not the same as across pipes is shown in references 13 to 15.

Reference 9 does not provide a method for the calculation of the distribution of turbulent velocity profiles along a surface. It does, however, suggest that separation of the turbulent boundary layer always occurs when the numerical value of the nondimensional pressure gradient reaches an empirical constant.

The purpose of the present investigation is to begin with the boundary-layer equation for incompressible flow and to proceed as closely to a method for the calculation of the behavior of the turbulent boundary layer as the present knowledge of the turbulent boundary layer permits.

At first it might appear that the use of empirical auxiliary equations in methods for the calculation of the behavior of turbulent boundary layers can be avoided by developing a method similar to the Pohlhausen method which requires the solution of only the Von Kármán momentum equation. For turbulent flow, however, in contrast with laminar flow, the conditions on the behavior of the velocity profile at the surface that can be obtained from the boundary-layer equation seem to be of little or no use for the determination of the shape of the velocity profile across the boundary layer. This difference between laminar and turbulent flow makes inapplicable the Pohlhausen process in which a type of function is chosen to represent the velocity profiles, the function for the velocity profiles is combined with the Von Kármán momentum equation, and the resulting ordinary differential equation for the space rate of change of the profile shape parameter is solved.

An auxiliary equation for the calculation of the behavior of the turbulent boundary layer can, however, be obtained from the boundary-layer equation by making use of the

experimentally verifiable fact (references 7, 10, 11, 14, and 15) that all velocity profiles of the turbulent boundary layer form essentially a single-parameter family of curves. In the present analysis the Loitsianskii equation (reference 16) is generalized by multiplying the Prandtl boundary-layer equation not only by an arbitrary power of the velocity in the boundary layer but also by an arbitrary power of the distance from the surface. The resulting equation is then integrated across the boundary layer and provides a general integral form of the boundary-layer equation, valid for either laminar or turbulent flow. This general integral form of the boundary-layer equation reduces to the Loitsianskii equation when the distance from the surface is raised to the zeroth power, to the Von Kármán momentum equation when both the distance from the surface and the velocity are raised to the zeroth power, and to the kinetic-energy equation when the distance from the surface is raised to the zeroth power and the velocity is raised to the first power.

When use is made of the assumption of a single-parameter family of velocity profiles, the general integral form of the boundary-layer equation becomes a general equation for the rate of change along the surface of the velocity-profile shape parameter. This equation for the rate of change of the velocity-profile shape parameter is the desired auxiliary equation.

The assumption of the single-parameter family of velocity profiles changes the problem from one of finding a solution of a partial-differential equation, the Prandtl boundary-layer equation, to one of finding a solution of two simultaneous ordinary differential equations, the equation for the rate of change of the shape parameter and the Von Kármán momentum equation. The differential equation for the rate of change of the shape parameter, however, cannot result in a solution of the problem in the present analysis because a knowledge of the shearing stress is lacking. In the present analysis various assumptions are made for the distribution of shearing stress through the boundary layer, and the distribution of the shape parameter over the surface of an airfoil is then calculated. Because of the arbitrary assumptions for the shear distribution and the use of a flat-plate skin-friction formula, precise agreement between the calculated and experimentally obtained distributions of the shape parameter is not obtained.

The problem of finding the shearing stress in the turbulent boundary layer remains. It is believed, however, that, if suitable approximations are found for the shear and surface friction, the equations presented herein should enable the development of the turbulent boundary layer to be calculated with an accuracy sufficient for engineering purposes.

The present work was begun while Dr. Lin was temporarily at the Langley Laboratory and was continued by correspondence.

j, q, l	coefficients in polynomial for $\int_0^1 \xi^{\frac{H-1}{2}} \frac{\partial g}{\partial \xi} d\xi$
K	ratio of kinetic-energy thickness to momentum thickness $\left(\frac{1}{\theta} \int_0^\delta (1-f^2) f dy \right)$
$K' = \frac{dK}{dH}$	
k	function of H $\left(\frac{-(H-1)K}{K'} \right)$
$L = \frac{1}{\theta^{n+1}} \int_0^\delta f(1-f^{m-1}) y^n dy$	
$M = \frac{1}{\theta^{n+1}} \int_0^\delta y^n (1-f^{m+1}) dy$	
m	exponent of u in derivation of general equation
$N = \frac{1}{\theta^{n+1}} \int_0^\delta y^n (1-f^{m+1}) f dy$	
$N' = \frac{dN}{dH}$	
n	exponent of y in derivation of general equation
P	coefficient of ω in equation for $\theta \frac{dH}{dx}$
p	exponent in equation for power profiles $f = \xi^p$
p_1	static pressure
$Q = \frac{1}{\theta^n} \int_0^\delta y^{n-1} (1-f^{m+1}) dy$	

$R_\theta = \frac{\theta U \rho}{\mu}$	
r_0	radius of body of revolution
S	coefficient of ϕ in equation for $\theta \frac{dH}{dx}$
U	velocity parallel to surface and at outer edge of boundary layer
u	velocity parallel to surface and inside boundary layer, positive in direction of positive x
v	velocity perpendicular to surface and inside boundary layer, positive in direction of positive y
v_0	value of v at $y=0$
x	coordinate parallel to surface, positive in direction from leading to trailing edge
y	coordinate perpendicular to surface, positive outward from surface
δ	smallest value of y for which the difference $U-u$ is negligible
δ^*	displacement thickness $\left(\int_0^\delta (1-f) dy \right)$
$\xi = \frac{y}{\delta}$	
$\eta = \frac{y}{\theta}$	
θ	momentum thickness $\left(\int_0^\delta f(1-f) dy \right)$
$\lambda = \frac{\delta}{\tau_0} \frac{dp_1}{dx}$	
μ	viscosity
$\xi = -\frac{\omega}{\phi}$	
$\xi_0 = \frac{1}{H-1} \left(1 - \frac{2}{K} \int_0^1 f dg \right)$	
ρ	density
τ	shearing stress
τ_0	surface shearing stress
$\phi = \frac{\tau_0}{\rho U^2}$	
$\psi = \frac{v_0}{U}$	
$\omega = \frac{\theta}{U} \frac{dU}{dx}$	

ANALYSIS

DERIVATION OF GENERAL EQUATION

The general equation is derived for the body of revolution because the equation for two-dimensional flow can be obtained from this equation by letting the radius of a transverse section of the body of revolution become infinite.

The boundary-layer equation of motion for the body of revolution, also valid for two-dimensional flow, from reference 3 is

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{dp_1}{dx} + \frac{1}{\rho} \frac{\partial \tau}{\partial y} \quad (1)$$

After multiplying through by u^m , making use of the equation of continuity that is valid in the boundary layer of a body of revolution (reference 3)

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{u}{r_0} \frac{dr_0}{dx} = 0$$

and noting that

$$\rho U \frac{dU}{dx} = -\frac{dp_1}{dx}$$

equation (1) becomes

$$\begin{aligned} \frac{u^{m+1}}{m+1} \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{u}{r_0} \frac{dr_0}{dx} \right) + \frac{u}{m+1} \frac{\partial u^{m+1}}{\partial x} + \frac{v}{m+1} \frac{\partial u^{m+1}}{\partial y} \\ = u^m \left(U \frac{dU}{dx} + \frac{1}{\rho} \frac{\partial \tau}{\partial y} \right) \end{aligned} \quad (2)$$

After equation (2) is written in a form in which each term vanishes at the outer edge of the boundary layer, each term of the equation is multiplied by y^n and integrated from $y=0$ to $y=\delta$. The result (see appendix A for detailed development) is

$$\begin{aligned} (n+1)N \frac{d\theta}{dx} + \theta \left(\frac{dN}{dx} - nI_1 \right) + \frac{\theta}{U} \frac{dU}{dx} [N(m+2) - n(J-M) - \\ L(m+1)] + \frac{\theta}{r_0} \frac{dr_0}{dx} [N - n(J-M)] - nQ \frac{v_0}{U} \\ = -(m+1) \frac{\tau_0}{\rho U^2} \int_0^{\delta/\theta} f^m \eta^n \frac{\partial \tau}{\partial \eta} d\eta \end{aligned} \quad (3)$$

Equation (3) is the general integral form of the boundary-layer equation.

The Von Kármán momentum equation is obtained from equation (3) by letting $m=0$ and $n=0$, the equation for kinetic energy is obtained by letting $m=1$ and $n=0$, and the equation for moment of momentum is obtained by letting $m=0$ and $n=1$.

In the case $m=n=0$,

$$N\theta = \int_0^\delta (1-f)f dy = \theta$$

or

$$N=1$$

Also,

$$L\theta = \int_0^\delta (f-1) dy = -\delta^*$$

or

$$L = -\frac{\delta^*}{\theta} = -H$$

It can be easily verified that all the integrals, except Q , involved in equation (3) have finite integrands as n approaches 0. The limit nQ , however, approaches unity as

n approaches 0; thus

$$\begin{aligned} nQ\theta^n &= n \int_0^\delta y^{n-1} (1-f^{m+1}) dy \\ &= \left[y^n (1-f^{m+1}) \right]_0^\delta - \int_0^\delta y^n \frac{\partial}{\partial y} (1-f^{m+1}) dy \end{aligned}$$

The first term drops out if $\dot{n} \neq 0$. Then, by taking the limit $n \rightarrow 0$, the result is

$$\lim_{n \rightarrow 0} nQ\theta^n = 1$$

Hence, when $m=n=0$, equation (3) becomes

$$\frac{d\theta}{dx} + \frac{\theta}{U} \frac{dU}{dx} (H+2) + \frac{\theta}{r_0} \frac{dr_0}{dx} - \frac{v_0}{U} = \frac{\tau_0}{\rho U^2} \quad (4)$$

Equation (4) is the momentum equation for flow over a body of revolution with flow through the surface. For two-dimensional flow, equation (4) becomes

$$\frac{d\theta}{dx} + \frac{\theta}{U} \frac{dU}{dx} (H+2) - \frac{v_0}{U} = \frac{\tau_0}{\rho U^2} \quad (5)$$

when the value of $\frac{d\theta}{dx}$ from equation (4) is substituted into equation (3), the result is

$$\begin{aligned} \theta \left(\frac{dN}{dx} - nI_1 \right) + \frac{\theta}{U} \frac{dU}{dx} \{ m(N-L) - n[(J-M) + N(H+2)] - \\ L - NH \} - \frac{\theta}{r_0} \frac{dr_0}{dx} n[(J-M) + N] - \frac{v_0}{U} [nQ - N(n+1)] \\ = -\frac{\tau_0}{\rho U^2} \left[(m+1) \int_0^{\delta/\theta} f^m \eta^n \frac{\partial g}{\partial \eta} d\eta + (n+1)N \right] \end{aligned} \quad (6)$$

where

$$g = \frac{\tau}{\tau_0}$$

The assumptions contained in equation (6) are the usual boundary-layer assumptions. Equation (6) is valid for both laminar and turbulent flow.

FORM OF EQUATION (6) FOR SINGLE-PARAMETER FAMILY OF VELOCITY PROFILES

Equation (6) is now to be placed in a form valid when the velocity profiles form a single-parameter family of curves ($f=f(\eta, H)$). For this purpose the term I_1 of equation (6) is modified in the following manner:

By definition,

$$I_1 \dot{\theta}^{n+1} = \int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y \frac{\partial (1-f)}{\partial x} dy \right] dy$$

Because f depends only on η and H ,

$$\frac{\partial (1-f)}{\partial x} = \frac{\partial (1-f)}{\partial \eta} \frac{\partial \eta}{\partial x} + \frac{\partial (1-f)}{\partial H} \frac{dH}{dx}$$

From the definition of η

$$\frac{\partial \eta}{\partial x} = -\frac{\eta}{\theta} \frac{d\theta}{dx}$$

then

$$\int_0^y \frac{\partial(1-f)}{\partial x} dy = -\frac{1}{\theta} \frac{d\theta}{dx} \int_0^y \eta \frac{\partial(1-f)}{\partial \eta} dy + \frac{dH}{dx} \int_0^y \frac{\partial(1-f)}{\partial H} dy$$

or, after an integration by parts of the first term on the right-hand side, the result is

$$\int_0^y \frac{\partial(1-f)}{\partial x} dy = -\frac{1}{\theta} \frac{d\theta}{dx} \left[y(1-f) - \int_0^y (1-f) dy \right] - \frac{dH}{dx} \int_0^y \frac{\partial f}{\partial H} dy$$

The expression for $I_1 \theta^{n+1}$ then becomes

$$I_1 \theta^{n+1} = -\frac{1}{\theta} \frac{d\theta}{dx} \int_0^\delta y^n (1-f^{m+1}) dy + \frac{1}{\theta} \frac{d\theta}{dx} \int_0^\delta y^n f (1-f^{m+1}) dy + \frac{1}{\theta} \frac{d\theta}{dx} \int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y (1-f) dy \right] dy - \frac{dH}{dx} \int_0^\delta y^{n-1} (1-f^{m+1}) \left(\int_0^y \frac{\partial f}{\partial H} dy \right) dy$$

But

$$\int_0^\delta y^n (1-f^{m+1}) dy = M \theta^{n+1}$$

$$\int_0^\delta y^n (1-f^{m+1}) f dy = N \theta^{n+1}$$

and

$$\int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y (1-f) dy \right] dy = J \theta^{n+1}$$

Then with

$$\int_0^\delta y^{n-1} (1-f^{m+1}) \left(\int_0^y \frac{\partial f}{\partial H} dy \right) dy = I \theta^{n+1}$$

the expression for I_1 can be written as

$$I_1 = \frac{1}{\theta} \frac{d\theta}{dx} (-M + N + J) - I \frac{dH}{dx} \quad (7)$$

When the expression for I_1 from equation (7) is substituted into equation (6) and equation (4) for $\frac{d\theta}{dx}$ is used, the following equation is obtained:

$$\begin{aligned} \theta \frac{dH}{dx} \left(\frac{dN}{dH} + nI \right) &= \frac{\theta}{U} \frac{dU}{dx} [-n(H+1)(J-M) + L(m+1) + \\ &\quad N(H-m)] + \frac{\tau_0}{\rho U^2} \left[n(J-M) - N - \right. \\ &\quad \left. (m+1) \int_0^{\delta/\theta} f^m \eta^n \frac{\partial g}{\partial \eta} d\eta \right] + \\ &\quad \frac{v_0}{U} [n(J-M) - N + nQ] \end{aligned} \quad (8)$$

where $\frac{dN}{dx} = \frac{dN}{dH} \frac{dH}{dx}$ has been used. Equation (8) for $\theta \frac{dH}{dx}$ is applicable both to two-dimensional flow and to flow over a body of revolution.

In equation (8) all the integrals, except the one involving the shear ratio g , are functions of H , m , and n only. For

the present no restrictive assumptions regarding the shear are made. The form of the kinetic-energy equation for a single-parameter family of velocity profiles is obtained from equation (8) by placing $m=1$ and $n=0$ and dividing by $N'(H)=K'(H)$. Thus,

$$\theta \frac{dH}{dx} = \frac{K(H-1)}{K'} \frac{\theta}{U} \frac{dU}{dx} - \left(\frac{K+2}{K'} \int_0^{\delta/\theta} f \frac{\partial g}{\partial \eta} d\eta \right) \frac{\tau_0}{\rho U^2} - \left(\frac{K-1}{K'} \right) \frac{v_0}{U} \quad (9)$$

The symbol K represents the ratio of the kinetic-energy thickness $\int_0^\delta (1-f^2) f dy$ to the momentum thickness. Note that in the derivation of equation (9) from equation (8), the assumption of a single-parameter family of curves is not restricted to the case $\frac{v_0}{U}=0$.

RESTRICTION OF GENERAL EQUATION TO POWER PROFILES

The data in figure 1 show that the power profiles defined by $f=\zeta^p$ are a good approximation to the "standard" profiles derived by fairing experimental data (reference 10). Equation (8) can be further developed by using the assumption that $f=\zeta^p$. After some fairly lengthy calculations (see appendix B), equation (8) becomes

$$\begin{aligned} \theta \frac{dH}{dx} &= \frac{-4p(p+1)(2p+1)[p(m+2)+n+1]}{pm+n+1} \frac{\theta}{U} \frac{dU}{dx} + \\ &\quad \frac{2p[p(m+2)+n+1]}{pm+n} \left\{ (2p+1) + \right. \\ &\quad \left. [p(m+2)+n+1] \int_0^1 \zeta^{p(m+n)} \frac{\partial g}{\partial \zeta} d\zeta \right\} \frac{\tau_0}{\rho U^2} + \\ &\quad \frac{2p(p+1)[p(m+2)+n+1]}{p(m+1)+n} \frac{v_0}{U} \end{aligned} \quad (10)$$

As a first approximation the assumption has been made that $f=\zeta^p$ even when $\frac{v_0}{U} \neq 0$.

The occurrence of the arbitrary positive integers m and n in equations (8) and (10) requires an explanation. In order to determine why m and n appear, equation (8) is written in a different form. By making use of the definitions for N , I , J , M , L , and Q and integrating by parts where necessary in order to eliminate terms that contain η^{n-1} , the result is

$$\begin{aligned} \frac{dN}{dH} + nI &= -(m+1) \int_0^{\delta/\theta} \eta^n f^m \left(f \frac{\partial f}{\partial H} - \frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta \right) d\eta \\ &\quad - n(H+1)(J-M) + L(m+1) + N(H-m) \\ &= (m+1) \int_0^{\delta/\theta} \eta^n f^m \left[(H+1) \frac{\partial f}{\partial \eta} \int_0^\eta f d\eta + f^2 - 1 \right] d\eta \\ &\quad n(J-M) - N - (m+1) \int_0^{\delta/\theta} f^m \eta^n \frac{\partial g}{\partial \eta} d\eta \\ &= -(m+1) \int_0^{\delta/\theta} \eta^n f^m \left(\frac{\partial f}{\partial \eta} \int_0^\eta f d\eta + \frac{\partial g}{\partial \eta} \right) d\eta \end{aligned}$$

and

$$n(J-M)-N+nQ=(m+1)\int_0^{\delta/\theta}\eta^n f^m \frac{\partial f}{\partial \eta} \left(1 - \int_0^\eta f d\eta\right) d\eta$$

Equation (8) then becomes

$$\theta \frac{dH}{dx} = \frac{\int_0^{\delta/\theta} \eta^n f^m \left\{ \frac{\tau_0}{\rho U^2} \left(\frac{\partial f}{\partial \eta} \int_0^\eta f d\eta + \frac{\partial g}{\partial \eta} \right) + \frac{\theta}{U} \frac{dU}{dx} \left[1 - f^2 - (H+1) \frac{\partial f}{\partial \eta} \int_0^\eta f d\eta \right] + \frac{v_0}{U} \left[\frac{\partial f}{\partial \eta} \left(\int_0^\eta f d\eta - 1 \right) \right] \right\} d\eta}{\int_0^{\delta/\theta} \eta^n f^m \left(f \frac{\partial f}{\partial H} - \frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta \right) d\eta} \quad (11)$$

By using the assumption of a single-parameter family of curves directly in the partial-differential equation (1), the following ordinary differential equation is obtained:

$$\theta \frac{dH}{dx} = \frac{\frac{\tau_0}{\rho U^2} \left(\frac{\partial f}{\partial \eta} \int_0^\eta f d\eta + \frac{\partial g}{\partial \eta} \right) + \frac{\theta}{U} \frac{dU}{dx} \left[1 - f^2 - (H+1) \frac{\partial f}{\partial \eta} \int_0^\eta f d\eta \right] + \frac{v_0}{U} \left[\frac{\partial f}{\partial \eta} \left(\int_0^\eta f d\eta - 1 \right) \right]}{f \frac{\partial f}{\partial H} - \frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta} \quad (12)$$

The concept of a single-parameter family of velocity profiles is consistent with equation (1) and with particular functions for $\tau_0/\rho U^2$, g , and f when the right-hand side of equation (12) is independent of η . When the right-hand side of equation (12) is independent of η , the right-hand side of equation (11) is independent of m and n . Equations (11) and (12) are then identical.

To obtain an equation for $\theta \frac{dH}{dx}$ that does not contain either m or n or both, the functions $\tau_0/\rho U^2$, g , and f must therefore be such that the right-hand side of equation (12) is independent of η ; the solution of the equation for $\theta \frac{dH}{dx}$ then provides a solution of equation (1). Note that the problem is to find a solution not of equation (1) alone but of equation (1) and the independent relation for the shearing stress in turbulent boundary layers; this relation is at present unknown.

The nature of the approximation made in the present analysis, in order to obtain a specific equation for $\frac{dH}{dx}$, may be clarified by noting that a specific equation for $\frac{dH}{dx}$ is obtained from equation (8) by choosing the functions $\tau_0/\rho U^2$, g , and f and substituting an arbitrary positive integer for m and an arbitrary positive integer for n . The calculated distribution of H over a body for arbitrarily chosen functions for $\tau_0/\rho U^2$, g , and f is then consistent with the momentum equation and one of the integral equations for $\frac{dH}{dx}$. For example, if $m=1$ and $n=0$, both the momentum and the kinetic-energy equations are satisfied but no other ones. If $m=0$ and $n=1$, only the momentum and the moment of momentum equations are satisfied. In the present analysis only the momentum, the kinetic-energy, and the moment of momentum equations—equations which have familiar physical meaning—are used.

As noted previously, equation (11) is independent of m and n if the functions $\tau_0/\rho U^2$, g , and f are such that the right-hand side of equation (12) is independent of η . In this case a solution of equation (1) results and the functions $\tau_0/\rho U^2$, g , and f and the calculated distribution of H satisfy every particular equation obtainable from equation (11), (10), or (8) by assigning positive integers to m and n .

Note that m and n cannot both be made zero in equation (8) because $\frac{dN}{dH} + nI = 0$ for $m=n=0$. If m and n are both

FIGURE 1.—Comparison of experimental and power velocity profiles.

zero, equation (8) becomes $0=0$. It is also noted that equations (8) and (10) are valid both for flow over a body of revolution and for two-dimensional flow.

For $m=1$ and $n=0$, equation (10) leads to the equation for kinetic energy

$$\theta \frac{dH}{dx} = -H(H-1)(3H-1) \frac{\theta}{U} \frac{dU}{dx} + (3H-1) \left(H + \frac{3H-1}{2} \int_0^1 \xi^p \frac{\partial g}{\partial \xi} d\xi \right) \frac{\tau_0}{\rho U^2} + \frac{(H+1)(3H-1)}{4} \frac{v_0}{U} \quad (13)$$

where the relation for power profiles $2p+1=H$ has been introduced. This form of the energy equation can also be obtained from equation (9) by noting that, from the definition of K and the equation for power profiles,

$$K = \frac{2(2p+1)}{3p+1} = \frac{4H}{3H-1}$$

A comparison of the values of K obtained from this formula and obtained from the standard profiles is given in figure 2.

The equation of moment of momentum for power profiles is obtained from equation (10) by letting $m=0$ and $n=1$; it is

$$\theta \frac{dH}{dx} = -\frac{H(H+1)(H^2-1)}{2} \frac{\theta}{U} \frac{dU}{dx} + (H^2-1) \left[H + (H+1) \int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi \right] \frac{\tau_0}{\rho U^2} + (H^2-1) \frac{v_0}{U} \quad (14)$$

In this equation the term involving the shear distribution may be rewritten as follows:

$$\int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi = - \int_0^1 g d\xi$$

It then involves the mean shear inside the boundary layer.

ATTEMPTS TO DERIVE A RELATION GOVERNING THE CHANGE OF THE FORM PARAMETER

In most of the recent analyses of the development of a turbulent boundary layer, an empirical relation governing the change of the form parameter H is usually introduced.

FIGURE 2.—Values of K for experimental and power velocity profiles.

It is clear that equation (10) automatically furnishes such relations if the shear distribution is known. In this section, three attempts are described to establish such a relation. These attempts are based on the following simple assumptions for the shear distribution:

(a) The shear distribution depends only on $\frac{\delta}{\tau_0} \frac{dp_1}{dx}$, which is equal to the Pohlhausen parameter multiplied by a factor (reference 3).

(b) The shear is constant across the boundary layer.

(c) The shear distribution depends only on the form parameter of the velocity distribution.

The first two assumptions are used either with the energy equation in the forms given by equations (9) and (13) or with equation (14) for the moment of momentum. The last assumption is used with equations (13) and (14) jointly.

(a) **Shear distribution depending only on the Pohlhausen parameter.**—The first assumption follows the original idea of the method of Von Kármán and Pohlhausen in using polynomial approximations together with the boundary conditions obtained by successive differentiation of the equations of motion (reference 3). Fediaevsky (reference 8) appears to have been the first to introduce it into the investigation of turbulent boundary layers. When the shear stress through the turbulent boundary layer is assumed to be a polynomial of fifth degree in $\xi = \frac{y}{\delta}$ satisfying the following boundary conditions:

at $y=0$

$$\tau = \tau_0 \quad \frac{\partial \tau}{\partial y} = \frac{dp_1}{dx} \quad \frac{\partial^2 \tau}{\partial y^2} = 0$$

at $y=\delta$

$$\tau = 0 \quad \frac{\partial \tau}{\partial y} = 0 \quad \frac{\partial^2 \tau}{\partial y^2} = 0$$

the following expression is obtained:

$$g = (1-\xi)^3 [1 + (3+\lambda)\xi + 3(2+\lambda)\xi^2] \quad (15)$$

The shear distribution g is a function of ξ and λ , where

$$\lambda = \frac{\delta}{\tau_0} \frac{dp_1}{dx} = -\frac{\theta}{U} \frac{dU}{dx} \frac{\delta}{\theta} \frac{\rho U^2}{\tau_0}$$

The particular boundary conditions at $y=0$ restrict this development to the case $\frac{v_0}{U} = 0$.

From the shear distribution (equation (15)) the calculation may be made of the coefficients P and S . The attempt to calculate P and S by using the standard profiles together with equations (9) and (15) was, however, unsuccessful for two reasons. First, the ratio δ/θ , which must be known, could not be accurately determined from the standard profiles. Second, for reasonable values of δ/θ , the calculated values of P were positive for values of H for which P should be negative.

The calculation of the part of P independent of the shear profile was then made both for the standard profiles and the power profiles by making use of the kinetic-energy equations (equations (9) and (13), respectively); the comparison is shown in figure 3. The closeness of the results suggests

that it is permissible to use power profiles as an approximation for calculating P and S . From equations (13) and (15),

$$P = -H(3H-1) \left[H-1 - \frac{96(3H-1)}{(H+5)(H+7)(H+9)} \right] \quad (16)$$

and

$$S = (3H-1) \left[H - \frac{240(3H-1)}{(H+5)(H+7)(H+9)} \right] \quad (17)$$

The functions P and S , given by equations (16) and (17), respectively, are shown in figure 4.

The fact that the equation

$$\theta \frac{dH}{dx} = P\omega + S\phi$$

where P and S are obtained from equations (16) and (17), respectively, does not predict the behavior of the turbulent boundary layer is shown as follows: Let $\omega=0$; then, for H greater than approximately 1.5, $\frac{dH}{dx}$ should be negative. Because S from equation (17) is positive for $H > 1.2$, it follows that $\frac{dH}{dx}$ is positive. This conclusion is incorrect;

FIGURE 3.—Values of P from energy equation. For power profiles, $P = -H(H-1)(3H-1)$; for experimental profiles, $P = \frac{K(H-1)}{K'}$.

FIGURE 4.—Values of P from equation (16) and values of S from equation (17).

therefore, the function for S (equation (17)) is inconsistent with the known behavior of turbulent boundary layers.

To show that the function for P (equation (16)) is inconsistent with the known behavior of turbulent boundary layers, let $H \approx 1.4$. By making $\frac{dU}{dx}$ positive and large, $\frac{dH}{dx}$ becomes positive and large because P given by equation (16) is positive. For positive values of $\frac{dU}{dx}$, however, it is known that $\frac{dH}{dx}$ should be negative. The function for P (equation (16)) is therefore inconsistent with the known behavior of turbulent boundary layers.

In order to determine whether functions for P and S that do not result in obviously incorrect conclusions can be obtained by making the shear polynomial satisfy a greater number of boundary conditions at the outer edge of the boundary layer, the shear polynomial is generalized by writing

$$g = (1-\zeta)^A \left[1 + A\zeta + \frac{A(A+1)}{2} \zeta^2 \right] + \lambda \zeta (1-\zeta)^A (1+A\zeta) \quad (18)$$

The boundary conditions at the surface that are satisfied by equation (18) are

$$\begin{array}{lll} g=1 & \text{or} & \tau=\tau_0 \\ \frac{\partial g}{\partial \zeta}=\lambda & \text{or} & \frac{\partial \tau}{\partial y}=\frac{dp_1}{dx} \\ \frac{\partial^2 g}{\partial \zeta^2}=0 & \text{or} & \frac{\partial^2 \tau}{\partial y^2}=0 \end{array}$$

At $y=\delta$, the conditions that are satisfied are

$$\begin{array}{l} g=0 \\ \frac{\partial g}{\partial \zeta}=0 \\ \frac{\partial^2 g}{\partial \zeta^2}=0 \\ \dots \dots \\ \frac{\partial^{A-1} g}{\partial \zeta^{A-1}}=0 \end{array}$$

In order to evaluate the integral $\int_0^1 \zeta^p \frac{\partial g}{\partial \zeta} d\zeta$ in equation (13) the term $\frac{\partial g}{\partial \zeta}$ is written as

$$\frac{\partial g}{\partial \zeta} = g_1 + \lambda g_2$$

where

$$g_1 = (1-\zeta)^A [A + A(A+1)\zeta] - A(1-\zeta)^{A-1} \left[1 + A\zeta + \frac{A(A+1)}{2} \zeta^2 \right]$$

and, for $A \geq 1$,

$$g_2 = (1-\zeta)^A (1 + 2A\zeta) - \zeta A(1+A\zeta)(1-\zeta)^{A-1}$$

By using the expression for g_1 , the equation obtained for S is

$$S = 2(3p+1)^2 \left\{ \frac{2p+1}{3p+1} - \frac{A!p}{(A+p)(A+p-1)(A+p-2) \dots (p+1)} \left[\frac{1}{p} + \frac{A}{A+1+p} + \frac{A(A+1)(p+1)}{2(A+2+p)(A+1+p)} \right] \right\} \quad (19)$$

By using the expression for g_2 the equation for P is found to be

$$P = -2(2p+1)(3p+1)^2 \left\{ \frac{2p}{3p+1} - \frac{A!(p+1)}{(A+p)(A+p-1)(A+p-2) \dots (p+1)} \left[\frac{1}{A+1+p} + \frac{A(p+1)}{(A+2+p)(A+1+p)} \right] \right\} \quad (20)$$

To avoid positive values for S obtained from equation (19) for $H < 3$, it is found that A must be 1 in the expression for g_1 . It is also found that, to avoid positive values for P in equation (20) for $H > 0$, A must be ∞ in the expression for g_2 . The values for S and P then become

$$S = \frac{(3H-1)(H-1)(H-3)}{H+5} \quad (21)$$

$$P = -H(H-1)(3H-1) \quad (22)$$

The expression for P (equation (22)) is the same as the coefficient of $\frac{\theta}{U} \frac{dU}{dx}$ in equation (13); letting $A \rightarrow \infty$ makes the coefficient of λ in equation (18) become zero. The shear profile then contributes nothing to the coefficient of $\frac{\theta}{U} \frac{dU}{dx}$ in equation (13).

Equations (21) and (22) for S and P , respectively, were tested by making a computation of H and θ for the pressure distribution given in table I of reference 10. The computation began at $\frac{x}{c} = 0.075$ with the values given in table I of reference 10. The equations used are

$$\theta \frac{dH}{dx} = -H(H-1)(3H-1)\omega + \frac{(3H-1)(H-1)(H-3)}{H+5} \phi$$

and

$$\frac{d\theta}{dx} = -(H+2)\omega + \phi$$

The equation for $\frac{d\theta}{dx}$ is the Von Kármán momentum equation.

The equation for ϕ was obtained from reference 17 and is

$$\phi = \frac{0.006535}{R_\theta^{1/6}}$$

The calculated distribution of H along x was far from the experimental curve.

In an attempt to reduce the sensitivity of the equation for $\theta \frac{dH}{dx}$ to the shear distribution, the moment of momentum equation (equation (14)), in which the shear appears in the coefficient of ϕ only as a mean value, is used. When the generalized expression (equation (18)) is used for the shear distribution g , the result obtained is

$$\theta \frac{dH}{dx} = \left[-\frac{H(H-1)(H+1)^2}{2} + \frac{3H(H+1)^3}{(A+2)(A+3)} \right] \omega + (H^2-1) \left[H - \frac{3(H+1)}{A+3} \right] \phi \quad (23)$$

where $\psi=0$ as required by equation (18). To keep the coefficient of ω negative for all positive values of H , A must equal ∞ in the coefficient of ω . The shear distribution is then independent of the pressure gradient. To make the coefficient of ϕ negative for values of H near 3, A must have the smallest value that it can take; therefore, let $A=1$ in the coefficient of ϕ . Equation (23) then becomes

$$\theta \frac{dH}{dx} = -\frac{H(H^2-1)(H+1)}{2} \omega + \frac{(H^2-1)(H-3)}{4} \phi \quad (24)$$

A calculation for the example in table I of reference 10 with equation (24) resulted in a computed curve for H that was far from the experimental curve.

(b) **Assumption of constant shear across the boundary layer.**—All the computations of H have led to values of H much larger than the experimental values. Therefore, in order to reduce the calculated values of H it is necessary to increase S . In order to increase S , the assumption of constant shear across the boundary layer is made. For constant shear it can be shown that

$$\int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi = -1$$

by letting $g = (1-\xi)^B$ and taking the limit of the integral as $B \rightarrow 0$. Equation (14), after the assumption of constant shear is introduced, becomes

$$\theta \frac{dH}{dx} = -\frac{H(H+1)(H^2-1)}{2} \omega - (H^2-1)\phi + (H^2-1)\psi$$

In order to make $\frac{dH}{dx} = 0$ at $H = 1.286$ for $\frac{dU}{dx} = 0$, the coefficient of ϕ was arbitrarily changed to $H^2 - 1.286^2$. The equation then becomes

$$\theta \frac{dH}{dx} = -\frac{H(H+1)(H^2-1)}{2} \omega - (H^2 - 1.653)\phi + (H^2-1)\psi \quad (25)$$

This equation was used for the computation of H with $\psi=0$, and the results for the example given in table I of reference 10 are shown in figure 5.

The assumption of constant shear across the boundary layer was also combined with the kinetic-energy equation. When the power profiles and the assumption of constant shear are used in equation (13), the kinetic-energy equation becomes

$$\theta \frac{dH}{dx} = -H(H-1)(3H-1)\omega - \frac{(H-1)(3H-1)}{2} \phi + \frac{(H+1)(3H-1)}{4} \psi$$

FIGURE 5.—Comparison of experimental values of H and values calculated by equation (25).
 $P = -\frac{H(H+1)(H^2-1)}{2}$; $S = H^2 - 1.653$; $\psi = 0$.

The function $-H(H-1)(3H-1)$ is shown in figure 3 and the function $-\frac{(H-1)(3H-1)}{2}$, in figure 6. When the standard profiles are substituted for the power profiles and the assumption of constant shear is made, the kinetic-energy equation (equation (9)) becomes

$$\theta \frac{dH}{dx} = \frac{K(H-1)}{K'} \omega - \frac{K-2}{K'} \phi - \frac{K-1}{K'} \psi$$

where the function $\frac{K(H-1)}{K'}$ is shown in figure 3 and the function $-\frac{K-2}{K'}$ is shown in figure 6. The results of these calculations of H (with $\psi = 0$) are shown in figure 7. In this case, the use of power profiles makes the result somewhat different from that obtained by using the standard profiles.

(c) **Determination of S by the simultaneous use of the energy and moment of momentum equations.**—It seems obvious that, if equations (13) and (14) were exact, the coefficients of ω , ϕ , and ψ in equation (13) would be equal to the coefficients of ω , ϕ , and ψ in equation (14). The ratio of the coefficients of ω is

$$\frac{-\frac{H(H+1)(H^2-1)}{2}}{-H(H-1)(3H-1)} = \frac{(H+1)^2}{2(3H-1)}$$

The curve of $\frac{(H+1)^2}{2(3H-1)}$ is given in figure 8 and is seen to be close to unity.

FIGURE 6.—Values of S from kinetic-energy equation with the assumption of constant shear.
 For power profiles, $S = -\frac{(H-1)(3H-1)}{2}$; for experimental profiles, $S = -\frac{K-2}{K'}$.

FIGURE 7.—Comparison of experimental values of H and values of H calculated by kinetic energy equation with constant shear across boundary layer.

The ratio of the coefficients of ψ is

$$\frac{4(H^2-1)}{(H+1)(3H-1)} = \frac{4(H-1)}{3H-1}$$

The curve of $\frac{4(H-1)}{3H-1}$ is also given in figure 8. The values are far from unity for small values of H but become equal to unity for $H=3$.

FIGURE 8.—Ratios of pressure and suction factors in energy and momentum equations.

Equating the coefficients of ϕ results in

$$\begin{aligned} (H^2-1) \left[H + (H+1) \int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi \right] \\ = (3H-1) \left[H + \frac{3H-1}{2} \int_0^1 \xi^{\frac{H-1}{2}} \frac{\partial g}{\partial \xi} d\xi \right] \end{aligned}$$

or

$$\begin{aligned} (H^2-1)(H+1) \int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi - \frac{(3H-1)^2}{2} \int_0^1 \xi^{\frac{H-1}{2}} \frac{\partial g}{\partial \xi} d\xi \\ = H^2(3-H) \end{aligned} \quad (26)$$

Now let

$$\int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi = a + bH + cH^2$$

and

$$\int_0^1 \xi^{\frac{H-1}{2}} \frac{\partial g}{\partial \xi} d\xi = j + qH + lH^2$$

When the shear distribution is assumed to depend only on H , the integrals in equation (26) are functions of H alone. Because equation (26) is then an identity, the coefficients of the various powers of H can be equated to zero. The resulting equations are:

For H^0

$$-a - \frac{j}{2} = 0$$

for H^1

$$-a - b + 3j - \frac{q}{2} = 0$$

for H^2

$$a - b - c - \frac{9}{2}j + 3q - \frac{l}{2} = 3$$

for H^3

$$a + b - c - \frac{9}{2}q + 3l = -1$$

for H^4

$$b + c - \frac{9}{2}l = 0$$

for H^5

$$c = 0$$

The results obtained are:

$$a = \frac{28}{128}$$

$$b = -\frac{180}{128}$$

$$c = 0$$

$$j = -\frac{56}{128}$$

$$q = -\frac{32}{128}$$

$$l = -\frac{40}{128}$$

Therefore,

$$\int_0^1 \xi \frac{\partial g}{\partial \xi} d\xi = \frac{7-45H}{32}$$

and

$$\int_0^1 \xi^{\frac{H-1}{2}} \frac{\partial g}{\partial \xi} d\xi = -\frac{7+4H+5H^2}{16}$$

Equation (14), the momentum equation, becomes

$$\begin{aligned} \theta \frac{dH}{dx} = -\frac{H(H^2-1)(H+1)}{2} \omega - \\ \frac{(H-1)(3H-1)(7+22H+15H^2)}{32} \phi + (H^2-1)\psi \end{aligned} \quad (27)$$

and equation (13), the energy equation, becomes

$$\begin{aligned} \theta \frac{dH}{dx} = -H(H-1)(3H-1) \omega - \\ \frac{(H-1)(3H-1)(7+22H+15H^2)}{32} \phi + \frac{(H+1)(3H-1)}{4} \psi \end{aligned} \quad (28)$$

The variation of H with x for the initial values and the pressure distribution given in table I of reference 10 was computed by using a modified form of equation (28). In order that

$\frac{dH}{dx} = 0$ at values of H in agreement with experiment when $\omega = 0$, the coefficient of ϕ in equation (28) was replaced by

$$\frac{(H-H_0)(3H-H_0)(7+22H+15H^2)}{32}$$

where

$$H_0 = H_0(R_\theta)$$

The variation of H_0 with R_θ was calculated from the equation

$$\log_{10} H_0 = 0.5990 - 0.1980 \log_{10} R_\theta - 0.0189 (\log_{10} R_\theta)^2$$

which was derived to represent a faired curve through the

experimental data (see fig. 9); the data were obtained from reference 13 and from British results that are not generally available. The result of a computation of H for $\psi=0$ and with equation (28) modified as follows

$$\theta \frac{dH}{dx} = -H(H-1)(3H-1)\omega - \frac{(H-H_0)(3H-H_0)(7+22H+15H^2)}{32}\phi + \frac{(H+1)(3H-1)}{4}\psi \quad (29)$$

is given in figure 10.

Assumptions (b) and (c) lead to somewhat better results than assumption (a) although they are still not as satisfactory as those obtained from the purely empirical relations introduced in references 10 and 12. It is clear that this difference is caused partly by the inaccuracy of the simple assumptions about the shear distribution and can be improved by using better descriptions. However, in view of the limited present knowledge of the shear distribution, it does not seem worth while to make more complicated assumptions.

FIGURE 9.—Variation of H_0 with R_θ .

It may be noted that the final equations obtained for the change of the form parameter by the three assumptions are all of the form

$$\theta \frac{dH}{dx} = P(H)\omega + S(H)\phi$$

where $\omega = \frac{\theta}{U} \frac{dU}{dx}$ and $\phi = \frac{\tau_0}{\rho U^2}$. This form is used in reference 12, but a different form is used in reference 10.

INVESTIGATION OF ENERGY EQUATION

Since none of the three assumptions for the shear distribution results in a dependable equation for $\frac{dH}{dx}$, an investigation is made to determine whether a result common to the three assumptions—namely that the coefficient of $\frac{\tau_0}{\rho U^2}$ in the equations for $\frac{dH}{dx}$ is a function of H alone—is very far from true by using experimental data and the kinetic-energy equation without any assumption for the shear.

If no assumptions other than the boundary-layer assumptions are made and if in equation (6) $n=0$ and $m=1$, the result is

$$\theta \frac{dK}{dx} = -\phi \left(K + 2 \int_0^{\delta/\theta} f \frac{\partial g}{\partial \eta} d\eta \right) + \omega(H-1)K + \psi(1-K) \quad (30)$$

If the assumption of a single-parameter family of curves is

FIGURE 10.—Comparison of experimental values of H with values calculated by equation (29).

$$P = -H(H-1)(3H-1); S = -\frac{(H-H_0)(3H-H_0)(7+22H+15H^2)}{32}; \psi=0.$$

made ($f=f(\eta, H)$), then $K=K(H)$, and equation (30) becomes

$$\theta \frac{dH}{dx} = -\phi \frac{K+2 \int_0^{\delta/\theta} f \frac{\partial g}{\partial \eta} d\eta}{K'} + \omega \frac{H-1}{K'} K + \psi \frac{1-K}{K'}$$

or, for $\psi=0$,

$$\theta \frac{dH}{dx} = \phi k(H) (\xi + \xi_0) \quad (31)$$

where

$$k(H) = \frac{-(H-1)K}{K'}$$

$$\xi = -\frac{\omega}{\phi}$$

$$\xi_0 = \frac{1}{H-1} \left(1 - \frac{2}{K} \int_0^1 f dg \right)$$

If the assumption is made that $g=g(\eta, H)$, then $f=f(g, H)$ and $\int_0^1 f dg$ is a function of H only. Therefore, $\xi_0=\xi_0(H)$. Equation (31) then becomes

$$\theta \frac{dH}{dx} = \phi k(H) [\xi + \xi_0(H)] \quad (32)$$

In order to obtain an estimate of the quantity $1 - \frac{2}{K} \int_0^1 f dg$ under the assumption that $f=f(g, H)$, reference 12 is used. Equation (7) of reference 12 may be written as

$$\theta \frac{dH}{dx} = \phi k_1(H) [\xi - 2.065(H-1.4)] \quad (33)$$

where

$$k_1(H) = e^{5(H-1.4)}$$

Note that Garner's equation (equation (33)) has the form the kinetic-energy equation takes when the assumptions that $f=f(\eta, H)$ and that $g=g(\eta, H)$ are used in the kinetic-energy equation. The kinetic-energy equation (equation (31)) can also be placed in the form of equation (32) when the more general assumption that $g = \frac{\omega}{\phi} F_0(\eta, H) + F_1(\eta, H)$ is made for the shear distribution. For the purpose of obtaining an estimate of the value of $1 - \frac{2}{K} \int_0^1 f dg$, the quantity $\xi + \xi_0(H)$ in equation (32) is assumed to be identical with the quantity $\xi - 2.065(H-1.4)$ in equation (33). Then

$$\xi_0(H) = -2.065(H-1.4)$$

and for $H=1.5$, for example,

$$\xi_0(H) = -0.2065$$

therefore,

$$\frac{1}{0.5} \left(1 - \frac{2}{K} \int_0^1 f dg \right) = -0.2065$$

or

$$1 - \frac{2}{K} \int_0^1 f dg = -0.1032$$

Therefore $1 - \frac{2}{K} \int_0^1 f dg$ is the difference between two quantities, each of which is much larger than their difference. It follows that, in order to determine $\xi_0(H)$ for values of H not close to separation with any accuracy, f and g must be known with relatively good accuracy.

It may be noted that the moment of momentum equation is also sensitive to g . This sensitivity can be seen by writing the coefficient of ϕ in equation (14) as

$$(H^2-1) \left[(H+1) \left(1 - \int_0^1 g d\zeta \right) - 1 \right]$$

When it is noted that the integral $\int_0^1 g d\zeta$ is of the order of unity and that H lies between 1.2 and 2.6, the sensitivity of the coefficient of ϕ to g becomes clear.

In an attempt to determine whether ξ_0 is determined mainly by H , all the data that were used in reference 10 were used to compute ξ_0 by making use of equation (32) in the form

$$\xi_0(H) = \frac{\theta \frac{dH}{dx}}{\phi k(H)} - \xi$$

The surface-friction coefficient ϕ was calculated by the formula (from reference 17)

$$\phi = \frac{0.006535}{R_\theta^{1/6}}$$

and $k(H)$ was calculated by the expression obtained from the moment of momentum equation

$$k(H) = \frac{H(H^2-1)(H+1)}{2}$$

The values of ξ_0 plotted against H are given in figure 11. The effort to determine whether ξ_0 is a function mainly of H is inconclusive. At least part of the scatter occurs because $\frac{dH}{dx}$ and $\frac{dU}{dx}$ were obtained from curves faired through experimental points. In addition, the calculation of ξ_0 requires

the subtraction of ξ from $\frac{\theta \frac{dH}{dx}}{\phi k(H)}$, an operation which further decreases the accuracy of the calculated values of ξ_0 .

DISCUSSION

Although equation (6) is valid whenever the boundary-layer assumptions are valid, the equations for $\frac{dH}{dx}$ that result after additional assumptions are made do not lead to

FIGURE 11.—Values of ξ_0 plotted against H .

good agreement with experiment. The first of the additional assumptions made is that all velocity profiles of the turbulent boundary layer belong to a single-parameter family of curves. The experimental data of references 7, 10, 11, 14, and 15 substantiate this assumption.

The second assumption is that the single-parameter family of curves can be approximated by power profiles. The data in figure 1, in which velocity profiles are compared, and also the data in figures 2 and 3, in which K and P are compared, show this assumption to be good, at least for $H < 1.8$.

From the data in figures 1 to 3, it is inferred that power profiles can be substituted for the standard velocity profiles without greatly affecting the calculated distribution of H against x for $H < 1.8$. To test this inference, the kinetic-energy equation was used with the assumption of constant shear across the boundary layer; the result is shown in figure 7. As expected from the data of figures 1 to 3, the effect of the substitution of power profiles for the standard profiles is noticeable only for $H > 1.8$. It thus appears that

the inaccuracy of the equations for $\frac{dH}{dx}$ that were tested is caused mainly by the surface-friction law that was used and by the assumed shear distributions rather than by the use of the power profiles.

The data of references 12 and 15 show skin frictions that increase strongly in the region upstream of the separation point before dropping to zero at the separation point. On the other hand, the skin-friction data presented in reference 14 indicate that the skin friction falls monotonically to zero as the separation point is reached. In the present analysis a skin-friction law obtained from experiments on flat plates is used. It is therefore probable that part of the inaccuracy in the equations used to calculate H is caused by the use of a relation for the skin friction that does not give correct values when there are pressure gradients along the surface.

The assumptions for the shear distribution that were made to obtain a specific equation for $\frac{dH}{dx}$ were

(a) The shear distribution depends only on the ratio of the pressure gradient to the skin friction $\frac{\delta}{\tau_0} \frac{dp_1}{dx}$ or $-\frac{\delta}{\theta} \frac{\omega}{\phi}$

(b) The shear is constant across the boundary layer

(c) The shear distribution depends only on the form parameter of the velocity distribution

Because none of these simple assumptions is derived from a knowledge of the details of the turbulent flow, it is not likely that any of them are valid. When it is recalled that the coefficient of ϕ in both the kinetic-energy and the moment of momentum equations is sensitive to the shear distribution, it is not surprising that a reliable equation for $\frac{dH}{dx}$ was not found.

In order to obtain a reliable equation for $\frac{dH}{dx}$ from equation

(8) it thus seems necessary to calculate the surface shear and the shear distribution across the boundary layer more accurately than in the present analysis. Efforts should therefore be made to understand the mechanics of turbulent shear flow sufficiently well to provide an independent relation for the shearing stress that will predict the behavior of turbulent boundary layers when used with the Prandtl boundary-layer equation (equation (1)).

CONCLUDING REMARKS

A general integral form of the boundary-layer equation is derived from the Prandtl partial-differential boundary-layer equation. The general integral equation, valid for either laminar or turbulent incompressible boundary-layer flow, contains the Von Kármán momentum equation, the kinetic-energy equation, and the Loitsianskii equation as special cases.

In an attempt to obtain a practical method for the calculation of the development of the turbulent boundary layer, use is made of the experimental finding that all the velocity profiles of the turbulent boundary layer form essentially a single-parameter family. The general equation is thereby changed to a simpler one from which an equation for the space rate of change of the shape parameter of the turbulent boundary layer can be obtained.

The resulting equation for the space rate of change of the velocity-profile parameter is restricted by the assumption that the velocity profiles of the turbulent boundary layer can be approximated by power profiles. Two of the resulting equations are used to calculate the distribution of the profile shape parameter over an airfoil for one experimentally determined pressure distribution. Although different assumptions were tried for the shearing stress across the boundary layer, the calculated distribution of the profile shape parameter did not agree exactly with the experimental distribution.

An examination is made of the effect of using the experimentally determined single-parameter family of velocity profiles instead of the power profiles on certain functions that occur in the equation for the space rate of change of the velocity-profile parameter. One calculation of the distribution of the profile shape parameter over an airfoil is also made

for the experimentally determined pressure distribution by using the single-parameter family of velocity profiles found from experiment. A comparison of the results with those of a calculation made with the same assumptions except for the use of power profiles shows some difference near the separation point. It is believed, however, that the apparent lack of reliability of the specific equations used to make the calculations is caused mainly by the lack of precise knowledge concerning the surface shear and the distribution of the shearing stress across the turbulent boundary layer. The present analysis emphasizes the need for information concerning the shearing stresses in turbulent boundary layers.

LANGLEY FIELD, VA., May 22, 1950.

APPENDIX A

DETAILED DEVELOPMENT OF EQUATION (3)

Equation (2) can be written so that terms of the form $u^{m+1} - U^{m+1}$ appear explicitly; therefore, each term will vanish at the outer edge of the boundary layer. The resulting equation is

$$\begin{aligned} & \frac{1}{m+1} \left[\frac{\partial}{\partial x} (u^{m+1} - U^{m+1})u + \frac{\partial}{\partial y} (u^{m+1} - U^{m+1})v \right] + \\ & \frac{1}{m+1} \frac{\partial u U^{m+1}}{\partial x} + \frac{1}{m+1} \frac{\partial v U^{m+1}}{\partial y} + \\ & \frac{1}{m+1} \frac{(u^{m+1} - U^{m+1})u}{r_0} \frac{dr_0}{dx} + \frac{1}{m+1} \frac{u U^{m+1}}{r_0} \frac{dr_0}{dx} \\ & = u^m U \frac{dU}{dx} + \frac{u^m}{\rho} \frac{\partial \tau}{\partial y} \end{aligned} \quad (A1)$$

or, after simplification,

$$\begin{aligned} & -\frac{1}{m+1} \left[\frac{\partial}{\partial x} (U^{m+1} - u^{m+1})u + \frac{\partial}{\partial y} (U^{m+1} - u^{m+1})v \right] - \\ & \frac{1}{m+1} \frac{(U^{m+1} - u^{m+1})u}{r_0} \frac{dr_0}{dx} - (u^m U - u U^m) \frac{dU}{dx} = \frac{u^m}{\rho} \frac{\partial \tau}{\partial y} \end{aligned} \quad (A2)$$

Equation (A2) is now multiplied through by y^n and integrated with respect to y from $y=0$ to $y=\delta$. The resulting equation is

$$\begin{aligned} & -\frac{1}{m+1} \int_0^\delta y^n \frac{\partial}{\partial x} (U^{m+1} - u^{m+1})u \, dy - \\ & \frac{1}{m+1} \int_0^\delta y^n \frac{\partial}{\partial y} (U^{m+1} - u^{m+1})v \, dy - \\ & \frac{1}{m+1} \frac{1}{r_0} \frac{dr_0}{dx} \int_0^\delta y^n (U^{m+1} - u^{m+1})u \, dy - \\ & \frac{dU}{dx} \int_0^\delta y^n (u^m U - u U^m) \, dy = \frac{1}{\rho} \int_0^\delta u^m y^n \frac{\partial \tau}{\partial y} \, dy \end{aligned}$$

or, after simplification and substitution of the formula for the differentiation of a definite integral

$$\int_0^\delta y^n \frac{\partial}{\partial x} (U^{m+1} - u^{m+1})u \, dy = \frac{d}{dx} \int_0^\delta y^n (U^{m+1} - u^{m+1})u \, dy$$

the following equation results:

$$\begin{aligned} & -\frac{1}{m+1} \frac{d}{dx} U^{m+2} \int_0^\delta y^n \left[1 - \left(\frac{u}{U} \right)^{m+1} \right] \frac{u}{U} \, dy - \\ & \frac{1}{m+1} \int_0^\delta y^n \frac{\partial}{\partial y} (U^{m+1} - u^{m+1})v \, dy - \\ & \frac{1}{m+1} \frac{U^{m+2}}{r_0} \frac{dr_0}{dx} \int_0^\delta y^n \left[1 - \left(\frac{u}{U} \right)^{m+1} \right] \frac{u}{U} \, dy - \\ & U^{m+1} \frac{dU}{dx} \int_0^\delta \left[\left(\frac{u}{U} \right)^m - \frac{u}{U} \right] y^n \, dy = \frac{1}{\rho} \int_0^\delta u^m y^n \frac{\partial \tau}{\partial y} \, dy \end{aligned} \quad (A3)$$

By integration by parts,

$$\int_0^\delta y^n \frac{\partial}{\partial y} (U^{m+1} - u^{m+1})v \, dy = -n \int_0^\delta (U^{m+1} - u^{m+1})v y^{n-1} \, dy$$

and equation (A3) becomes

$$\begin{aligned} & -\frac{1}{m+1} \frac{d}{dx} U^{m+2} \int_0^\delta y^n \left[1 - \left(\frac{u}{U} \right)^{m+1} \right] \frac{u}{U} \, dy + \\ & \frac{n}{m+1} \int_0^\delta (U^{m+1} - u^{m+1})v y^{n-1} \, dy - \\ & \frac{1}{m+1} \frac{U^{m+2}}{r_0} \frac{dr_0}{dx} \int_0^\delta y^n \left[1 - \left(\frac{u}{U} \right)^{m+1} \right] \frac{u}{U} \, dy - \\ & U^{m+1} \frac{dU}{dx} \int_0^\delta \left[\left(\frac{u}{U} \right)^m - \frac{u}{U} \right] y^n \, dy = \frac{1}{\rho} \int_0^\delta u^m y^n \frac{\partial \tau}{\partial y} \, dy \end{aligned} \quad (A4)$$

The velocity v can be eliminated from the term

$$\int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy$$

by the following development:

The velocity v may be written as

$$v = \int_0^y \frac{\partial v}{\partial y} dy + v_0$$

or, by use of the equation of continuity,

$$\begin{aligned} v &= - \int_0^y \frac{\partial u}{\partial x} dy - \frac{1}{r_0} \frac{dr_0}{dx} \int_0^y u dy + v_0 \\ &= \int_0^y \frac{\partial(U-u)}{\partial x} dy - y \frac{dU}{dx} + \frac{1}{r_0} \frac{dr_0}{dx} \int_0^y (U-u) dy - \frac{U}{r_0} \frac{dr_0}{dx} y + v_0 \\ &= \int_0^y \left[U \frac{\partial(1-\frac{u}{U})}{\partial x} + \frac{dU}{dx} \left(1-\frac{u}{U}\right) \right] dy - y \frac{dU}{dx} + \\ &\quad \frac{U}{r_0} \frac{dr_0}{dx} \int_0^y \left(1-\frac{u}{U}\right) dy - \frac{U}{r_0} \frac{dr_0}{dx} y + v_0 \\ v &= U \int_0^y \frac{\partial(1-\frac{u}{U})}{\partial x} dy + \frac{dU}{dx} \int_0^y \left(1-\frac{u}{U}\right) dy - y \left(\frac{dU}{dx} + \frac{U}{r_0} \frac{dr_0}{dx}\right) + \\ &\quad \frac{U}{r_0} \frac{dr_0}{dx} \int_0^y \left(1-\frac{u}{U}\right) dy + v_0 \end{aligned}$$

or, after terms are collected and f is substituted for u/U , the result is

$$v = U \int_0^y \frac{\partial(1-f)}{\partial x} dy + \left(\frac{dU}{dx} + \frac{U}{r_0} \frac{dr_0}{dx}\right) \left[\int_0^y (1-f) dy - y \right] + v_0$$

The term $\int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy$ can now be written as

$$\begin{aligned} \int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy &= \int_0^\delta (U^{m+1} - u^{m+1}) y^{n-1} \\ &\quad \left\{ U \int_0^y \frac{\partial(1-f)}{\partial x} dy + \left(\frac{dU}{dx} + \frac{U}{r_0} \frac{dr_0}{dx}\right) \left[\int_0^y (1-f) dy - y \right] + v_0 \right\} dy \\ \text{or} \\ \int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy &= U^{m+2} \int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y \frac{\partial(1-f)}{\partial x} dy \right] dy + \left(\frac{dU}{dx} + \right. \\ &\quad \left. \frac{U}{r_0} \frac{dr_0}{dx} \right) U^{m+1} \int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y (1-f) dy - y \right] dy + \\ &\quad v_0 U^{m+1} \int_0^\delta y^{n-1} (1-f^{m+1}) dy \end{aligned}$$

Now let

$$\int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y \frac{\partial(1-f)}{\partial x} dy \right] dy = I_1 \theta^{n+1}$$

$$\int_0^\delta y^{n-1} (1-f^{m+1}) \left[\int_0^y (1-f) dy \right] dy = J \theta^{n+1}$$

$$\int_0^\delta y^n (1-f^{m+1}) dy = M \theta^{n+1}$$

and

$$\int_0^\delta y^{n-1} (1-f^{m+1}) dy = Q \theta^n$$

The term $\int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy$ now becomes

$$\begin{aligned} \int_0^\delta (U^{m+1} - u^{m+1}) v y^{n-1} dy &= U^{m+2} I_1 \theta^{n+1} + \\ &\quad \left(\frac{dU}{dx} + \frac{U}{r_0} \frac{dr_0}{dx}\right) U^{m+1} (J - M) \theta^{n+1} + v_0 U^{m+1} Q \theta^n \end{aligned}$$

Now let

$$\int_0^\delta y^n (1-f^{m+1}) f dy = N \theta^{n+1}$$

and

$$\int_0^\delta (f - f^m) y^n dy = L \theta^{n+1}$$

Equation (A4) can then be written as

$$\begin{aligned} & - \frac{1}{m+1} \frac{d}{dx} (U^{m+2} N \theta^{n+1}) + \frac{n}{m+1} U^{m+2} I_1 \theta^{n+1} + \\ & \frac{n}{m+1} \left(\frac{dU}{dx} + \frac{U}{r_0} \frac{dr_0}{dx}\right) U^{m+1} (J - M) \theta^{n+1} + \frac{n}{m+1} v_0 U^{m+1} Q \theta^n - \\ & \frac{1}{m+1} \frac{U^{m+2}}{r_0} \frac{dr_0}{dx} N \theta^{n+1} + U^{m+1} \frac{dU}{dx} L \theta^{n+1} = \frac{U^m}{\rho} \int_0^\delta f^m y^n \frac{\partial \tau}{\partial y} dy \end{aligned} \quad (A5)$$

After $\frac{d}{dx} U^{m+2} N \theta^{n+1}$ is expanded and terms are collected, equation (A5) becomes

$$\begin{aligned} & (n+1) N \frac{d\theta}{dx} + \theta \left(\frac{dN}{dx} - n I_1\right) + \\ & \frac{\theta}{U} \frac{dU}{dx} [N(m+2) - n(J-M) - L(m+1)] + \\ & \frac{\theta}{r_0} \frac{dr_0}{dx} [N - n(J-M)] - n Q \frac{v_0}{U} = -(m+1) \frac{\tau_0}{\rho U^2} \int_0^{\delta/\theta} f^m \eta^n \frac{\partial \tau}{\partial \eta} d\eta \end{aligned}$$

where

$$\eta = \frac{y}{\theta}$$

APPENDIX B

SIMPLIFICATION OF TERMS IN EQUATION (8) FOR POWER PROFILES

CALCULATION OF $\frac{dN}{dH} + nI$

The definition of $N\theta^{n+1}$ is

$$N\theta^{n+1} = \int_0^\delta (1-f^{m+1}) f y^n dy$$

therefore,

$$N = \int_0^{\delta/\theta} (1-f^{m+1}) f \eta^n d\eta$$

and

$$\frac{dN}{dH} = \int_0^{\delta/\theta} \left[(1-f^{m+1}) \frac{\partial f}{\partial H} - f(m+1) f^m \frac{\partial f}{\partial H} \right] \eta^n d\eta$$

or

$$\frac{dN}{dH} = \int_0^{\delta/\theta} \frac{\partial f}{\partial H} [1 - (m+2)f^{m+1}] \eta^n d\eta$$

The definition of $I\theta^{n+1}$ is

$$I\theta^{n+1} = \int_0^\delta (1-f^{m+1}) \left(\int_0^y \frac{\partial f}{\partial H} dy \right) y^{n-1} dy$$

therefore,

$$I = \int_0^{\delta/\theta} (1-f^{m+1}) \left(\int_0^\eta \frac{\partial f}{\partial H} d\eta \right) \eta^{n-1} d\eta$$

Then

$$\begin{aligned} \frac{dN}{dH} + nI &= \int_0^{\delta/\theta} \frac{\partial f}{\partial H} [1 - (m+2)f^{m+1}] \eta^n d\eta + \\ &+ n \int_0^{\delta/\theta} (1-f^{m+1}) \left(\int_0^\eta \frac{\partial f}{\partial H} d\eta \right) \eta^{n-1} d\eta \end{aligned} \quad (B1)$$

By integration by parts,

$$\begin{aligned} &n \int_0^{\delta/\theta} (1-f^{m+1}) \left(\int_0^\eta \frac{\partial f}{\partial H} d\eta \right) \eta^{n-1} d\eta = \\ &- \int_0^{\delta/\theta} \left[(1-f^{m+1}) \frac{\partial f}{\partial H} - (m+1) f^m \frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta \right] \eta^n d\eta \end{aligned} \quad (B2)$$

When equation (B2) is substituted into equation (B1), the following equation is obtained:

$$\frac{dN}{dH} + nI = (m+1) \int_0^{\delta/\theta} \eta^n f^m \left(\frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta - f \frac{\partial f}{\partial H} \right) d\eta$$

Use is now made of the power-law assumption

$$f = \zeta^p = \eta^p \left(\frac{\theta}{\delta} \right)^p$$

Then

$$\frac{\partial f}{\partial H} = \frac{1-2p^2}{2(p+1)(2p+1)} \zeta^p + \frac{\zeta^p \log \zeta}{2}$$

and

$$\begin{aligned} &\frac{\partial f}{\partial \eta} \int_0^\eta \frac{\partial f}{\partial H} d\eta - f \frac{\partial f}{\partial H} \\ &= p \left\{ \frac{1-2p^2}{2(p+1)^2(2p+1)} \zeta^{2p} + \frac{1}{2} \left[\frac{\zeta^{2p} \log \zeta}{p+1} - \frac{\zeta^{2p}}{(p+1)^2} \right] \right\} - \\ &\quad \left[\frac{1-2p^2}{2(p+1)(2p+1)} \zeta^{2p} + \frac{\zeta^{2p} \log \zeta}{2} \right] \end{aligned}$$

After a lengthy manipulation, $\frac{dN}{dH} + nI$ is found to be

$$\frac{dN}{dH} + nI = -\frac{m+1}{2} \frac{(p+1)^n (2p+1)^n (pm+n)}{p^{n+1} [p(m+2)+n+1]^2}$$

where use has been made of the following equation:

$$\frac{\delta}{\theta} = \frac{(p+1)(2p+1)}{p}$$

CALCULATION OF N

The definition of $N\theta^{n+1}$ is

$$N\theta^{n+1} = \int_0^\delta (1-f^{m+1}) f y^n dy$$

When $f = \zeta^p$ is used, the equation for N is

$$N = \left(\frac{\delta}{\theta} \right)^{n+1} \frac{p(m+1)}{[p(m+2)+n+1](p+n+1)}$$

or

$$N = \frac{(m+1)(p+1)^{n+1}(2p+1)^{n+1}}{p^n [p(m+2)+n+1](p+n+1)}$$

CALCULATION OF J

From the definition of $J\theta^{n+1}$,

$$J\theta^{n+1} = \int_0^\delta (1-f^{m+1}) \left[\int_0^y (1-f) dy \right] y^{n-1} dy$$

When $f = \zeta^p$, the equation for J is

$$J = \left(\frac{\delta}{\theta} \right)^{n+1} \int_0^1 [1 - \zeta^{p(m+1)}] \left(\zeta - \frac{\zeta^{p+1}}{p+1} \right) \zeta^{n-1} d\zeta$$

or, after a lengthy manipulation,

$$\begin{aligned} J &= \frac{(p+1)^n (2p+1)^{n+1}}{p^{n-1}} (m+1) \\ &\quad \left\{ \frac{(p+1+n)[pm+n+2(p+1)] + p(m+1)+1+n}{(n+1)(p+1+n)[p(m+1)+n+1][p(m+1)+p+1+n]} \right\} \end{aligned}$$

CALCULATION OF M

From the definition of $M\theta^{n+1}$

$$M\theta^{n+1} = \int_0^{\delta} (1 - f^{m+1}) y^n dy$$

When $f = \zeta^p$, the equation for M is

$$M = (m+1) \frac{(p+1)^{n+1} (2p+1)^{n+1}}{p^n (n+1) [p(m+1) + n+1]}$$

CALCULATION OF L

From the definition of $L\theta^{n+1}$

$$L\theta^{n+1} = \int_0^{\delta} (1 - f^{m-1}) f y^n dy$$

When $f = \zeta^p$, the equation for L is

$$L = (m-1) \frac{(p+1)^{n+1} (2p+1)^{n+1}}{p^n (p+n+1) (pm+n+1)}$$

CALCULATION OF $\frac{N(H-m) - n(J-M)(H+1) + (m+1)L}{\frac{dN}{dH} + nI}$

From the expressions for J and M , the expression for $J-M$ is

$$J-M = \frac{(p+1)^n (2p+1)^{n+1}}{p^{n-1}} (m+1) \frac{(p+1+n) [pm+n+2(p+1)] + [p(m+1)+1+n]}{(n+1)(p+1+n) [p(m+1)+n+1] [p(m+1)+p+1+n]} - (m+1) \frac{(p+1)^{n+1} (2p+1)^{n+1}}{p^n (n+1) [p(m+1)+n+1]}$$

After a lengthy simplification, the result is

$$J-M = \frac{-(m+1)(p+1)^n (2p+1)^{n+1}}{p^n (p+1+n) [p(m+1)+p+1+n]}$$

or

$$-n(J-M)(H+1) = \frac{2n(m+1)(p+1)^{n+1} (2p+1)^{n+1}}{p^n (p+1+n) [p(m+1)+p+1+n]}$$

where $H=2p+1$ was used. The expression obtained for $N(H-m) + (m+1)L$ is

$$N(H-m) + (m+1)L = \frac{(m+1)(p+1)^{n+1} (2p+1)^{n+1} 2p(pm+m+n)}{p^n (p+n+1) [p(m+2)+n+1] (pm+n+1)}$$

and the expression obtained for

$$N(H-m) - n(J-M)(H+1) + (m+1)L$$

is

$$\begin{aligned} & N(H-m) - n(J-M)(H+1) + (m+1)L \\ &= \frac{2(m+1)(p+1)^{n+1} (2p+1)^{n+1} [n(pm+n+1) + p(pm+m+n)]}{p^n (p+1+n) [p(m+2)+n+1] (pm+n+1)} \end{aligned}$$

By substitution and simplification

$$\begin{aligned} & \frac{N(H-m) - n(J-M)(H+1) + (m+1)L}{\frac{dN}{dH} + nI} \\ &= \frac{-4p(p+1)(2p+1)[p(m+2)+n+1]}{pm+n+1} \end{aligned}$$

It can also be shown that

$$\begin{aligned} & \frac{-N + n(J-M) - (m+1) \int_0^{\delta/\theta} \eta^n f^m \frac{\partial g}{\partial \eta} d\eta}{\frac{dN}{dH} + nI} \\ &= \frac{2p}{pm+n} [p(m+2)+n+1] \left\{ 2p+1 + [p(m+2)+n+1] \int_0^1 \zeta^{p m+n} \frac{\partial g}{\partial \zeta} d\zeta \right\} \end{aligned}$$

EVALUATION OF $-N + n(J-M) + nQ$

From the results for N and $J-M$

$$-N + n(J-M) = \frac{-(m+1)(p+1)^n (2p+1)^{n+1}}{p^n [p(m+2)+n+1]}$$

For Q , the development is

$$Q\theta^n = \int_0^{\delta} (1 - f^{m+1}) y^{n-1} dy$$

and with $f = \zeta^p$, the following expression is obtained for $n \neq 0$:

$$Q = \frac{m+1}{n} \frac{(p+1)^n (2p+1)^n}{p^{n-1} [p(m+1)+n]}$$

Then, by substitution and simplification, for $n \neq 0$,

$$-N + n(J-M) + nQ = \frac{-(m+1)(p+1)^{n+1} (2p+1)^n (pm+n)}{p^n [p(m+2)+n+1] [p(m+1)+n]} \quad (B3)$$

If use is made of the previously derived result that $nQ=1$ for $n=0$, the following equation is obtained for $n=0$:

$$-N + n(J-M) + nQ = \frac{-m(p+1)}{p(m+2)+1} \quad (B4)$$

If n is placed equal to zero in equation (B3), equation (B4) results; therefore, equation (B3) is valid for $n=0$ as well as $n \neq 0$.

Then, for all values of n ,

$$\frac{-N + n(J-M) + nQ}{\frac{dN}{dH} + nI} = \frac{2(p+1)p[p(m+2)+n+1]}{p(m+1)+n}$$

REPORT 1047

THE STABILITY OF THE COMPRESSION COVER OF BOX BEAMS STIFFENED BY POSTS¹

By PAUL SEIDE and PAUL F. BARRETT

SUMMARY

An investigation is made of the buckling of the compression cover of post-stiffened box beams, subjected to end moments. Charts are presented for the determination of the minimum post axial stiffnesses and the corresponding compressive buckling loads required for the compression cover to buckle with nodes through the posts. Application of the charts to design and analysis and the limitations of their use are discussed.

If the flexural stiffness of the tension cover is equal to or less than that of the compression cover, buckle patterns with longitudinal nodes through the posts are not obtainable, no matter how stiff the posts are made or how closely they are spaced.

The weight of the required posts is found to be very low compared with the weight of the compression cover in an illustrative example, the ratio of the two being about 2½ percent.

INTRODUCTION

Post-type construction has recently gained some support in the aircraft industry. This construction has been incorporated in at least one operational aircraft and is being considered for others. The basic elements are relatively thick tension and compression surfaces connected in the interior by posts or rods. These posts serve to raise the buckling load of the surfaces by restricting the buckle patterns that may form. In reference 1 and in the present report, a compression surface supported by a rectangular array of rigid or effectively rigid posts is found to buckle as if continuously supported along either transverse or longitudinal lines through the posts.

If post-type construction is to reach an advanced stage of development, much research is needed. The large number of parameters involved, even in the simplest idealization of the problem, however, makes a complete investigation difficult. The scope of the present investigation has therefore been very much limited.

The problem as conceived in the present report is as follows: Two long, flat, rectangular plates of identical length and width, simply supported along their edges and of unequal thickness and material properties, are connected in the interior by identical axially elastic posts in rectangular array. The connection between the posts and plates is assumed to be one of simple support (of the ball-and-socket type, for instance) so that no resistance is offered to rotation of the plates. One plate is subjected to a longitudinal compressive load and the other, to an equal longitudinal tensile load. Both the longitudinal and transverse spacing

of the posts are uniform; the two spacings, however, may differ. (See fig. 1.) The minimum axial stiffness of the posts required for the compression surface to buckle with nodes through the posts and the corresponding buckling loads are to be determined.

The structure thus outlined is an idealization of a long post-stiffened box beam subjected to end bending moments. The numerical results of a theoretical analysis of this problem are presented herein in both tabular and graphical form (tables I to III and figs. 2 to 4). The analysis itself, presented in the appendix, is of a more general nature and may be used to investigate other problems in the design of plate structures stiffened by posts.

SYMBOLS

b	box-beam width
t	plate thickness
E	Young's modulus of elasticity of plate material
μ	Poisson's ratio of plate material
D	plate flexural stiffness per unit width $\left(\frac{Et^3}{12(1-\mu^2)}\right)$
D_T/D_C	ratio of flexural stiffnesses of tension and compression surfaces
R	plate flexural-stiffness ratio (D_T/D_C)
N_x	plate load per unit width, positive in compression surface for compression and in tension surface for tension
k	plate-load coefficient (buckling-load coefficient for compression plate) ($N_x b^2/\pi^2 D$)
N_{cr}	critical compressive load per unit width in compression surface for equal tensile load in tension surface
$N_{cr} b^2/\pi^2 D_C$	compressive-buckling-load parameter
M	number of longitudinal bays
N	number of transverse bays
L	longitudinal distance between posts
L/b	ratio of longitudinal distance between posts and box-beam width
β	aspect ratio of plate between adjacent lines of post (L/b)
F	axial stiffness of posts, force per unit deflection
$Fb^2/\pi^2 D_C$	post axial-stiffness parameter
S	post axial-stiffness parameter ($Fb^2/\pi^2 D_C$)
X, Y, Z	coordinate axes (see fig. 1)
x, y, z	distance along coordinate axes
w	plate deflection in Z -direction

¹ Supersedes NACA TN 2153, "The Stability of the Compression Cover of Box Beams Stiffened by Posts" by Paul Seide and Paul F. Barrett, 1950.

a_{mn}	general coefficient in Fourier series for w
i, j, m, n, r, s	integers
c	integer defining location of post in x -direction ($1 \leq c \leq (M-1)$)
d	integer defining location of post in y -direction ($1 \leq d \leq (N-1)$)
q	integer defining number of buckles in x -direction ($1 \leq q \leq (M-1)$)
p	integer defining number of buckles in y -direction ($1 \leq p \leq (N-1)$)

U	potential energy
V	strain energy
W	work done by external loads

Subscripts:

C	compression plate
T	tension plate
P	posts

The subscript cr when applied to L/b or β refers to the transition from buckling with longitudinal nodes through the posts to buckling with transverse nodes through the posts.

FIGURE 1.—Idealization of box beam stiffened by posts.

(a) Minimum post axial stiffness required or compression cover to buckle with nodes through the posts.

FIGURE 2.—One row of posts.

(b) Buckling loads for box beams with effectively rigid posts.

FIGURE 2.—Continued.

RESULTS AND DISCUSSION

The numerical results of the present investigation consist of values of the minimum post stiffnesses and the corresponding compressive buckling loads required for the compression surface of long post-stiffened box beams subjected to end bending moments to buckle with nodes through the posts. Because such buckle patterns do not transmit load to the posts, the posts are not compressed and are effectively rigid. Post axial stiffnesses greater than those presented herein will not serve to increase the buckling load of the structure. Combinations of the post axial-stiffness parameter and the compressive-buckling-load parameter, for different values of the ratio of the longitudinal distance between posts to the box-beam width and the ratio of the flexural stiffnesses of the tension and compression surfaces, are given in tables I to III and are presented graphically in figures 2 to 4 for one, two, and three rows of posts.

The most significant qualitative result to be read from the figures (especially figs. 2(c), 3(c), and 4(c)) is that buckling of the compression surface with longitudinal nodes through the posts is never obtainable for box beams in use in aircraft construction (for which the stiffness of the tension surface is at most equal to that of the compression surface),

even if the posts are infinitely stiff. Reference 1 shows that, if the tension surface and the posts are rigid, buckling of the compression surface occurs with longitudinal nodes through the posts when the ratio of the distance between the posts and the box-beam width is less than a certain value $\left(\frac{L}{b} < \left(\frac{L}{b}\right)_{cr}\right)$

and occurs with transverse nodes through the posts when this value is exceeded. These results are found to be valid when the flexural stiffness of the tension surface is as little as about 3.5 times that of the compression surface (the exact value of D_T/D_C depends on the number of rows of posts) and when the post axial stiffnesses are those given in figures 2 (a), 3 (a), and 4 (a). However, if the flexural-stiffness ratio is less than this value of about 3.5, neither longitudinal nor transverse nodes through the posts can be obtained for some values of L/b , even if the post axial stiffness is made infinite. The spread of these values of L/b is indicated by figures 2(c), 3(c), and 4(c); the buckling loads in this region when the posts are rigid are shown by the dashed-line curves of figures 2(b), 3(b), and 4(b). As the flexural-stiffness ratio decreases, the region in which the compression cover buckles with longitudinal nodes through the posts also decreases until, when the ratio is about 1.5 or less, the longitudinal-node buckle pattern is not obtainable.

(c) Buckling phenomena attainable for box beams with effectively rigid posts.

FIGURE 2.—Concluded.

LIMITATIONS ON USE OF CURVES IN ANALYSIS

The use of the curves of figures 2 to 4 for analysis is subject to many limitations. Inasmuch as the investigations of the present report are limited in scope, the buckling loads of plates having post stiffnesses less than the stiffness required for nodes to pass through the posts cannot be found in most cases. Certain conclusions, however, may be drawn from the present results to aid in the determination of whether a given load will be carried by a given plate-post system: namely,

(1) If, for given values of the ratio of the flexural stiffnesses of the tension and compression surfaces and the ratio of longitudinal distance between posts and box-beam width, the required buckling-load coefficient lies above the appropriate curve of figures 2(b), 3(b), or 4(b), the load cannot be carried because these curves indicate the maximum buckling loads of long plate-post structures.

(2) If the buckling-load coefficient lies on or below the solid or dash-dotted part of the appropriate curve and the post axial-stiffness parameter is greater than or equal to the value required for nodes to pass through the posts, as given by figures 2(a), 3(a), or 4(a), the load can be carried.

(3) If the buckling-load coefficient lies on the appropriate solid or dash-dotted line curves, and the post axial-stiffness parameter is less than the required values, the load cannot be carried. Further investigation is required if the buckling-load coefficient lies below these curves.

(4) If the buckling-load coefficient falls on the dashed part of the appropriate curve, the load can definitely not be carried because an infinite post stiffness would be needed. Further investigation is necessary if the buckling-load coefficient is below these curves.

Several simplifying assumptions that also may affect the applicability of the present results to the design and analysis of actual post-stiffened box beams have been made in the statement of the problem. The statement that the plates are flat and subjected to axial loading implicitly neglects the effects of bending of the plates and the resultant loads on the posts, due to the end moments. Possible buckling of the posts has not been considered but may be dealt with by making the moment of inertia of the post as large as possible. If hollow or built-up sections are used for this purpose, the thickness of the walls should be made large enough to prevent local buckling.

(a) Minimum post axial stiffness required for compression cover to buckle with nodes through the posts.

FIGURE 3.—Two rows of posts.

(b) Buckling loads for box beams with effectively rigid posts.

FIGURE 3.—Continued.

Because of the large number of computations involved, no investigations have been made to determine the adequacy of the present results in their application to plates of finite longitudinal length. It seems reasonable, however, in view of the results of references 2 to 4, to conclude that a finite plate having three posts or more in the longitudinal direction may be considered long, insofar as buckling with transverse nodes through the posts is concerned.

ILLUSTRATIVE DESIGN

As an illustration of the application of the various charts to a design problem, the posts are designed for a plate structure for which the following data are given:

Unit load, N_{cr} , pounds per inch.....	15,000
Compression-plate thickness, t_c , equals tension-plate thickness, t_T , inches.....	0.375
Plate width, b , inches.....	28
Vertical distance between plates, h , inches.....	5.5
Modulus of elasticity of plate material, E , psi.....	10.5×10^6
Poisson's ratio of plate material, μ	0.3

It is desired that the buckle pattern be such that nodal lines pass through the posts: This specification is equivalent to that of designing the ribs of skin-stringer construction so that buckling takes place between ribs.

The required compressive-buckling-load coefficient of the structure is given by $N_{cr}b^2/\pi^2D_c$ where

$$D_c = \frac{E_c t_c^3}{12(1-\mu_c^2)} \\ = \frac{10.5 \times 10^6 \times (0.375)^3}{12(1-0.3^2)} \\ = 50,700 \text{ pound-inches}$$

Then,

$$\frac{N_{cr}b^2}{\pi^2D_c} = \frac{15000 \times 28^2}{50700\pi^2} \\ = 23.5$$

Inasmuch as the thickness and material properties of the tension plate are identical with those of the compression plate, the values of D_T/D_c for the problem is unity.

The maximum buckling-load coefficient obtainable with any number of rows of posts is given by $\frac{N_{cr}b^2}{\pi^2D_c} = 4N^2$, the buckling-load coefficient of a long plate of width b/N . From figure 2(b) it can be seen that the required buckling-load coefficient may not be obtained with one row of posts. The coefficient could be obtained by using two rows of posts but the required buckle pattern of nodes passing through the

(c) Buckling phenomena attainable for box beams with effectively rigid posts.

FIGURE 3.—Concluded.

posts could not be obtained. At least three rows of posts must be used.

If three rows are used, the curves of figure 4(b) indicate that, for D_T/D_C equal to 1.00, a buckle pattern with transverse nodes through the posts is obtainable. With $N_{cr}b^2/\pi^2D_C$ equal to 23.5, the corresponding value of L/b is equal to 0.215. Hence, the maximum permissible longitudinal post spacing L is given by

$$\begin{aligned} L &= b \frac{L}{b} \\ &= 28 \times 0.215 \\ &= 6.0 \text{ inches} \end{aligned}$$

The minimum required post stiffness may now be obtained from figure 4 (a).

With L/b equal to 0.215 and D_T/D_C equal to 1.00, the corresponding value of Fb^2/π^2D_C is equal to 300. The post stiffness is then

$$\begin{aligned} F &= \frac{\pi^2 D_C}{b^2} \frac{Fb^2}{\pi^2 D_C} \\ &= \frac{50700\pi^2}{(28)^2} 300 \\ &= 191,000 \text{ pounds per inch} \end{aligned}$$

If the posts were of aluminum, the required area would be

$$\begin{aligned} A &= \frac{h}{E} F \\ &= \frac{5.5 \times 191000}{10.5 \times 10^6} \\ &= 0.100 \text{ square inch} \end{aligned}$$

The diameter of a circular rod would be

$$\begin{aligned} d &= \sqrt{\frac{4}{\pi} \times 0.100} \\ &= 0.36 \text{ inch} \end{aligned}$$

The ratio of the weights of posts and compression cover is 0.026. This ratio is appreciably lower than that of the weights of ribs and compression surface in conventional skin-stringer construction, given in reference 5 as about 0.5 for minimum weight design, and represents a great saving in stiffening material. The question of whether such low weight ratios are obtainable for actual box beams in which factors other than buckling of the compression cover must be considered in design cannot be completely answered until many designs utilizing post stiffening have been made.

(a) Minimum post axial stiffness required for compression cover to buckle with nodes through the posts.

FIGURE 4.—Three rows of posts.

(b) Buckling loads for box beams with effectively rigid posts.

FIGURE 4.—Continued.

CONCLUDING REMARKS

The minimum post axial stiffness and the corresponding buckling loads required for the compression cover of a box beam stiffened by posts and subjected to end moments to buckle with nodes through the posts have been determined. Where buckling with nodes through the posts is not obtainable, even with rigid posts, the buckling loads of box beams with rigid posts are given.

If the flexural stiffness of the tension cover is equal to or less than that of the compression cover, buckle patterns with longitudinal nodes are not obtainable, no matter how

stiff the posts are made or how closely they are spaced.

For the particular example worked in the present report the weight of the required posts is very low compared with the weight of the compression cover, the ratio of the two being about 2½ percent. A complete evaluation of post stiffening is not possible, however, until many more designs and tests have been made.

APPENDIX

DETAILS OF ANALYSIS AND COMPUTATIONS

DERIVATION OF CRITERIA FOR STABILITY OF PLATE STRUCTURES STIFFENED BY POSTS

The following problem is more general than the one outlined in the introduction:

Two flat rectangular plates of equal finite length and width, simply supported along their edges and of unequal thickness and material properties, are connected in the interior by identical axially elastic rods in rectangular array. The connection between the posts and plates is one of simple support, of the ball-and-socket type, for instance, so that no resistance is offered to rotation of the plate. The plates are subjected to unequal axial loads. Both the longitudinal and transverse spacing of the rods are uniform; the two spacings, however, may differ. (See fig. 1.) The combination of loads that will cause the structure to buckle is to be found.

The Rayleigh-Ritz energy method used to analyze this problem consists of the following procedure. Fourier series to represent the deflected shape of the plates are first assumed. The energy of the various components of the structure and the work done by the external loads are then expressed in terms of the unknown Fourier coefficients, and the potential-energy expression of the structure is written. When the potential-energy expression is minimized with respect to each of the coefficients, a set of simultaneous equations is obtained which is manipulated in the manner of references 2 and 6 to yield finally the stability criteria for the structure.

The deflected shapes of the two buckled plates may be expressed generally by the double Fourier series

$$w_c = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} a_{mn_c} \sin \frac{m\pi x}{ML} \sin \frac{n\pi y}{b} \quad (1)$$

$$w_T = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} a_{mn_T} \sin \frac{m\pi x}{ML} \sin \frac{n\pi y}{b} \quad (2)$$

These expressions satisfy the condition of simple support on all four edges of each plate.

The energy stored in the buckled plates is then

$$\begin{aligned} V_C + V_T &= \frac{D_C}{2} \int_0^{ML} \int_0^b \left(\frac{\partial^2 w_C}{\partial x^2} + \frac{\partial^2 w_C}{\partial y^2} \right)^2 dx dy + \\ &\quad \frac{D_T}{2} \int_0^{ML} \int_0^b \left(\frac{\partial^2 w_T}{\partial x^2} + \frac{\partial^2 w_T}{\partial y^2} \right)^2 dx dy \\ &= \frac{\pi^4 b}{8(ML)^3} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \left[m^2 + \left(\frac{ML}{b} \right)^2 n^2 \right]^2 (D_C a_{mn_c}^2 + D_T a_{mn_T}^2) \end{aligned} \quad (3)$$

and that stored in the deformed posts is

$$\begin{aligned} V_P &= \sum_{c=1}^{M-1} \sum_{d=1}^{N-1} \frac{F}{2} (w_C - w_T)^2 \\ &= \frac{F}{2} \sum_{c=1}^{M-1} \sum_{d=1}^{N-1} \left[\sum_{m=1}^{\infty} \sum_{n=1}^{\infty} (a_{mn_c} - a_{mn_T}) \sin \frac{m\pi c}{M} \sin \frac{n\pi d}{N} \right]^2 \end{aligned} \quad (4)$$

The work done by the loads in moving with the ends of the plates is

$$\begin{aligned} W_C + W_T &= \frac{N_{x_c}}{2} \int_0^{ML} \int_0^b \left(\frac{\partial w_C}{\partial x} \right)^2 dx dy - \\ &\quad \frac{N_{x_T}}{2} \int_0^{ML} \int_0^b \left(\frac{\partial w_T}{\partial x} \right)^2 dx dy \\ &= \frac{\pi^2 b}{8ML} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} m^2 (N_{x_c} a_{mn_c}^2 - N_{x_T} a_{mn_T}^2) \end{aligned} \quad (5)$$

The potential energy is

$$\begin{aligned} U &= V_C + V_T + V_P - W_C - W_T \\ &= \frac{\pi^4 b}{8(ML)^3} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \left[m^2 + \left(\frac{ML}{b} \right)^2 n^2 \right]^2 (D_C a_{mn_c}^2 + D_T a_{mn_T}^2) + \\ &\quad \frac{F}{2} \sum_{c=1}^{M-1} \sum_{d=1}^{N-1} \left[\sum_{m=1}^{\infty} \sum_{n=1}^{\infty} (a_{mn_c} - a_{mn_T}) \sin \frac{m\pi c}{M} \sin \frac{n\pi d}{N} \right]^2 - \\ &\quad \frac{\pi^2 b}{8ML} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} m^2 (N_{x_c} a_{mn_c}^2 - N_{x_T} a_{mn_T}^2) \end{aligned} \quad (6)$$

The buckling load is determined by the condition that the potential energy be a minimum; that is,

$$\frac{\partial U}{\partial a_{ij_c}} = \frac{\partial U}{\partial a_{ij_T}} = 0 \quad \begin{aligned} (i=1, 2, \dots, \infty) \\ (j=1, 2, \dots, \infty) \end{aligned}$$

or

$$\begin{aligned} [(i^2 + j^2 M^2 \beta^2)^2 - k_c i^2 M^2 \beta^2] a_{ij_c} + \frac{4M^3 \beta^3 S}{\pi^2} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} (a_{mn_c} - \\ a_{mn_T}) \left(\sum_{c=1}^{M-1} \sin \frac{m\pi c}{M} \sin \frac{i\pi c}{M} \right) \left(\sum_{d=1}^{N-1} \sin \frac{n\pi d}{N} \sin \frac{j\pi d}{N} \right) = 0 \end{aligned} \quad (7)$$

and

$$\begin{aligned} [(i^2 + j^2 M^2 \beta^2)^2 + k_T i^2 M^2 \beta^2] a_{ij_T} - \frac{4M^3 \beta^3 S}{\pi^2 R} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} (a_{mn_c} - \\ a_{mn_T}) \left(\sum_{c=1}^{M-1} \sin \frac{m\pi c}{M} \sin \frac{i\pi c}{M} \right) \left(\sum_{d=1}^{N-1} \sin \frac{n\pi d}{N} \sin \frac{j\pi d}{N} \right) = 0 \end{aligned} \quad (8)$$

(i=1, 2, ... ∞)
(j=1, 2, ... ∞)

Equations (7) and (8) may be combined to yield

$$\begin{aligned} (a_{ij_c} - a_{ij_T}) + \frac{4M^3 \beta^3 S}{\pi^2} \left[\frac{1}{(i^2 + j^2 M^2 \beta^2)^2 - k_c i^2 M^2 \beta^2} + \right. \\ \left. \frac{1/R}{(i^2 + j^2 M^2 \beta^2)^2 + k_T i^2 M^2 \beta^2} \right] \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} (a_{mn_c} - \\ a_{mn_T}) \left(\sum_{c=1}^{M-1} \sin \frac{m\pi c}{M} \sin \frac{i\pi c}{M} \right) \left(\sum_{d=1}^{N-1} \sin \frac{n\pi d}{N} \sin \frac{j\pi d}{N} \right) = 0 \end{aligned} \quad (9)$$

(i=1, 2, ... ∞)
(j=1, 2, ... ∞)

unless $a_{i,c} = a_{i,T}$, in which case

$$k_c = -k_T$$

$$= \left(\frac{i}{M\beta} + j^2 \frac{M\beta}{i} \right)^2 \quad \begin{matrix} (i=1, 2, \dots, \infty) \\ (j=1, 2, \dots, \infty) \end{matrix} \quad (10)$$

which indicates that both plates are subjected to their respective Euler buckling loads.

The remaining details of the analysis are similar to those of references 2 and 6 and are therefore omitted. In summary, the series

$$\left(\sum_{c=1}^{M-1} \sin \frac{m\pi c}{M} \sin \frac{i\pi c}{M} \right) \left(\sum_{d=1}^{N-1} \sin \frac{n\pi d}{N} \sin \frac{j\pi d}{N} \right)$$

may be evaluated by means of the table on page 8 of reference 2. Equations (9) are then seen to separate into independent sets, each of which may be manipulated to yield a stability criterion. The resulting criteria are

$$\frac{1}{S} - \frac{\beta^3 N}{\pi^2} \sum_{r=-\infty}^{\infty} \sum_{s=-\infty}^{\infty} \frac{1}{k_c \beta^2 \left(2s + \frac{q}{M} \right)^2 - \left[\left(2s + \frac{q}{M} \right)^2 + (2rN + p)^2 \beta^2 \right]^2} +$$

$$\frac{\beta^3 N}{\pi^2 R} \sum_{r=-\infty}^{\infty} \sum_{s=-\infty}^{\infty} \frac{1}{k_T \beta^2 \left(2s + \frac{q}{M} \right)^2 + \left[\left(2s + \frac{q}{M} \right)^2 + (2rN + p)^2 \beta^2 \right]^2} = 0 \quad (11)$$

$$\begin{matrix} (q=1, 2, \dots, M-1) \\ (p=1, 2, \dots, N-1) \end{matrix}$$

$$k_c = -k_T$$

$$= \left(\frac{s}{\beta} + r^2 \frac{M^2 \beta}{s} \right)^2 \quad \begin{matrix} (r=1, 3, 5, \dots, \infty) \\ (s=1, 3, 5, \dots, \infty) \end{matrix} \quad (12)$$

and

$$k_c = -k_T$$

$$= \left(\frac{s}{\beta} + r^2 \frac{M^2 \beta}{s} \right)^2 \quad \begin{matrix} (r=2, 4, 6, \dots, \infty) \\ (s=2, 4, 6, \dots, \infty) \end{matrix} \quad (13)$$

Equations (10) to (13) constitute the complete set of stability criteria for the problem.

COMPUTATION DETAILS

The computations may be divided into three main groups:

(a) The determination of the minimum post stiffness required for the compression cover plates to buckle with longitudinal or transverse nodes through the posts.

(b) In those regions where the required stiffness does not exist, the determination of the buckling load attainable with infinitely stiff posts.

(c) The determination of the boundaries of the various regions.

Equation (11), which was used to make the calculations, involves nine quantities, eight of which must be known in order that the ninth may be determined. These nine quantities are the post axial-stiffness parameter ($Fb^2/\pi^2 D_C$ or S), the ratio of the distance between posts and the box-beam width (L/b or β), the two axial-load parameters ($N_{x_c} b^2/\pi^2 D_C$ or k_c and $N_{x_T} b^2/\pi^2 D_T$ or k_T), the ratio of the flexural stiffnesses

of the tension and compression cover (D_T/D_C or R), the number of bays in the longitudinal and transverse directions (M and N), and the integers which indicate the number of buckles in the longitudinal and transverse directions (q and p). Values of these quantities are determined by the details of the problem to be solved. In all the computations for the present report, the box beam has been taken to be infinitely long.

Buckling with transverse nodes through the posts.—If the compression cover buckles with transverse nodes through the posts, the buckling load coefficient is

$$k_c = \left(\frac{1}{\beta} + \beta \right)^2$$

which is the compressive-buckling-load coefficient of a simply supported plate of length L and width b . The load coefficient in the tension cover was chosen for the present report as

$$k_T = \frac{k_c}{R}$$

in which case

$$N_{x_c} = N_{x_T} = N_{cr}$$

The minimum required post axial-stiffness parameter is completely determined by equation (11) for specified values of the cover flexural-stiffness ratio, the length-width ratio, and the number of rows of posts, if the number of buckles in the longitudinal and transverse directions are also known.

The ratio q/M is indicative of the number of buckles in a longitudinal bay of the buckled plate: It seemed reasonable, in view of the results of references 2 to 4, to conclude that q/M should be taken as unity, since it may be assumed that the transition from buckling with deformation of the posts to buckling with transverse nodes through the posts is continuous for structures with an infinite number of longitudinal bays and not abrupt as would be the case if the number of longitudinal bays were finite. One buckle occurs in the transverse direction and, therefore, p was taken equal to unity.

Buckling with longitudinal nodes through the posts.—When the ratio of the longitudinal spacing between posts to the box-beam width becomes small, the buckle pattern abruptly changes from one with transverse nodes through the posts to one with longitudinal nodes through the posts. The value of the width ratio at which this phenomenon occurs was found by equating the buckling loads for the two types of buckling because the two are equal at the point of transition. The compressive-buckling-load coefficient for a long simply supported plate of width b/N is given by

$$k_c = 4N^2$$

The critical length-width ratio was, therefore, found from the relationship

$$4N^2 = \left(\frac{1}{\beta} + \beta \right)^2$$

or

$$\beta_{cr} = N \left(1 - \sqrt{1 - \frac{1}{N^2}} \right)$$

The minimum post axial-stiffness parameter required for buckling to occur with longitudinal nodes through the posts can be found from equation (11) provided that the ratio q/M and the number of transverse buckles are known. The calculations of reference 7 for compressive buckling of plates with longitudinal stiffeners indicate that the change from buckling with deflection of the stiffeners to buckling with nodes at the stiffeners is abrupt and that only one transverse buckle should be assumed for the determination of minimum required flexural stiffness. It seemed logical that this condition should be assumed to hold also for plates stiffened by posts and, accordingly, p was taken equal to unity. The value of q/M was determined by graphically minimizing the post axial-stiffness parameter with respect to q/M ; that is, various values of q/M were chosen, the corresponding values of S were obtained from equation (11), and the correct value of S was determined by drawing a curve through the computed values and picking off the minimum.

Boundary between regions.—A third type of buckling is found to appear for relatively low values of the cover flexural-stiffness ratio. For instance, when R was equal to 2.00 the minimum post axial stiffness required for either longitudinal or transverse node buckle patterns was found to be unobtainable for a certain range of values of the length-width ratio. Further investigation showed that the post axial stiffness required for a longitudinal node buckle pattern became infinite at a certain value of the length-width ratio β less than β_{cr} and that the post axial stiffness required for a transverse node buckle pattern became infinite at some value of β greater than β_{cr} . Between these two values, only buckle patterns with deformation of the posts are obtainable. (If the posts are rigid, they displace axially but are not compressed.)

The maximum value of the cover flexural-stiffness ratio R at which this phenomenon is found to occur was determined by setting the post axial-stiffness parameter equal to infinity, the length-width ratio equal to β_{cr} , the load coefficients k_c and Rk_r equal to $\left(\frac{1}{\beta_{cr}} + \beta_{cr} \right)^2$, the ratio q/M and the number of transverse buckles equal to unity, and by solving equation (11) graphically. This procedure determines the value of R for which the spread of the range of β , in which

the third type of buckle pattern occurs, vanishes and thus determines the maximum value of R for which the phenomenon occurs.

The boundaries between the regions in which the various buckle patterns occur were found by placing the post axial stiffness equal to infinity and using a procedure similar to that of the previous sections to determine the length-width ratio β for various values of R .

When the cover flexural-stiffness ratio is approximately 1.5, the value of β marking the transition from buckling with longitudinal nodes through the posts and buckling with the displacement of the rigid posts is found to become equal to zero, and this fact thus indicates that the longitudinal node buckle pattern is unobtainable for values of R less than 1.5. Because the stability criterion becomes indeterminate when β is equal to zero, more accurate values of the cover flexural-stiffness ratio for which the phenomenon occurs were found by placing β equal to the low value of 0.01 and finding R graphically from equation (11).

Buckling loads attainable with rigid posts.—The buckling loads for various values of R and β in the region where the compression cover buckles with axial displacement of the rigid posts were found by graphically minimizing the loads determined from equation (11) with respect to q/M , with the post axial-stiffness parameter equal to infinity, and with one buckle in the transverse direction.

REPORT 1048

A STUDY OF EFFECTS OF VISCOSITY ON FLOW OVER SLENDER INCLINED BODIES OF REVOLUTION¹

By H. JULIAN ALLEN AND EDWARD W. PERKINS

SUMMARY

The observed flow field about slender inclined bodies of revolution is compared with the calculated characteristics based upon potential theory. The comparison is instructive in indicating the manner in which the effects of viscosity are manifest.

Based on this and other studies, a method is developed to allow for viscous effects on the force and moment characteristics of bodies. The calculated force and moment characteristics of two bodies of high fineness ratio are shown to be in good agreement, for most engineering purposes, with experiment.

INTRODUCTION

The problem of the longitudinal distribution of cross force on inclined bodies of revolution in inviscid, incompressible flow, which was primarily of interest to airship designers in the past, was treated simply and effectively by Max Munk (reference 1). Munk showed that the cross force per unit length on any body of revolution having high fineness ratio can be obtained by considering the flow in planes perpendicular to the axis of revolution to be approximately two-dimensional. By treating the problem in this manner, Munk showed that

$$f = q_0 \frac{dS}{dx} \sin 2\alpha \quad (1)$$

where

f cross force per unit length
 q_0 stream dynamic pressure
 dS/dx rate of change in body cross-sectional area with longitudinal distance along the body
 α angle of inclination

Tsien (reference 2) investigated the cross force on slender bodies of revolution at moderate supersonic speeds—a problem of more interest at the present to missile and supersonic aircraft designers—and showed that, to the order of the first power of the angle of inclination, the reduced Munk formula

$$f = 2q_0 \frac{dS}{dx} \alpha \quad (2)$$

was still applicable. This is not surprising when it is realized that the cross component of the flow field corresponds to a cross velocity

$$V_{v_0} = V_0 \sin \alpha$$

where V_0 is the stream velocity. Thus the cross component of velocity, and hence, the cross Mach number will, for small angles of inclination, have a small subsonic value so that the cross flow will be essentially incompressible in character.

Using equation (1) for the cross-force distribution, then, the total forces and moments experienced by a body in an inviscid fluid stream can be calculated. Comparison of the calculated and experimental characteristics of bodies has shown that the lift experienced exceeds the calculated lift in absolute value by an amount which is greater the greater the angle of attack; the center of pressure is farther aft than the calculations indicate, the discrepancy increasing with angle of attack; while the absolute magnitude of the moment about the center of volume is less than that calculated. It has long been known that these observed discrepancies are due primarily to the failure to consider the effects of viscosity in the flow.

Experience has demonstrated, notably in the development of airfoils, that the behavior of the boundary layer on a body is intimately associated with the nature of the pressure distribution that would exist on the body in inviscid flow. In particular, boundary-layer separation is associated with the gradient of pressure recovery on a body. The severity of the effect of such separation can be correlated, in part, with the magnitude of the total required pressure recovery indicated by inviscid theory. It is therefore to be expected that it will be of value to compare the actual pressure distribution on inclined bodies of revolution with that calculated on the assumption that the fluid is inviscid. For the purpose of this study, a simple method is developed for determining, for an inviscid fluid, the incremental pressure distribution resulting from inclined flow on a slender body of revolution.² The experimental incremental pressure distributions about an airship hull are compared with the corresponding distributions calculated by this method. The comparisons are instructive in indicating the manner in which the viscosity of the fluid influences the flow. In the light of this and other studies, a method for allowing for viscous effects on the force and moment characteristics of slender bodies is developed and the results compared with experiment.

² The problem of determining the pressure distribution on inclined bodies has been treated by other authors, but for several reasons these methods are not satisfactory for the present purposes. For example, Kaplan (reference 3) treated, in a thorough manner, the flow about slender inclined bodies, but the solution, which is expressed in Legendre polynomials, is unfortunately tedious to evaluate. On the other hand, Laitone (reference 4), by linearizing the equations of motion, obtained a solution for the pressure distribution on slender inclined bodies of revolution, but, as will be seen later, the solution is inadequate in the general case due to the linearization.

¹ Supersedes NACA TN 2044, "Pressure Distribution and Some Effects of Viscosity on Slender Inclined Bodies of Revolution" by H. Julian Allen, 1950.

SYMBOLS

A	reference area for body force and pitching-moment coefficient evaluation	S_b	body base area (at $x=L$)
A_p	plan-form area ($2 \int_0^L R dx$)	t	time
c_{d_c}	circular-cylinder section drag coefficient based on cylinder diameter	V_0	free-stream velocity
$c_{d_{\alpha=90^\circ}}$	local cross-flow drag coefficient at any x station based on body diameter	V_x	local axial velocity at body surface at any station x
C	constant of integration	V_{x_0}	axial component of the stream velocity ($V_0 \cos \alpha$)
$C_{d_{\alpha=90^\circ}}$	cross-flow drag coefficient ($\frac{\int_0^L 2c_{d_{\alpha=90^\circ}} R dx}{A_p}$)	V_{y_0}	cross-flow component of the stream velocity ($V_0 \sin \alpha$)
C_{D_F}	body foredrag coefficient ($\frac{\text{foredrag}}{q_0 A}$)	x	axial distance from bow of body to any body station
$C_{D_F(\alpha=0)}$	body foredrag coefficient at zero angle of inclination	x_m	axial distance from bow of body to pitching-moment center
ΔC_{D_F}	incremental foredrag coefficient due to inclination	$x_{\alpha=90^\circ}$	axial distance from bow of body to center of viscous cross force
C_L	body lift coefficient ($\frac{\text{lift}}{q_0 A}$)	X	reference length for moment coefficient evaluation
C_M	body pitching-moment coefficient about station x_m ($\frac{\text{pitching moment}}{q_0 A X}$)	y	ordinate in plane of inclination normal to axis of revolution
D'	mean body diameter ($\frac{A_p}{L}$)	z	ordinate normal to plane of inclination and to axis of revolution
f	local cross force (normal to body axis) at any station x on body	α	angle of body-axis inclination relative to free-stream-flow direction
L	body length	β	$\tan^{-1} \frac{dR}{dx}$
M_0	free-stream Mach number	ν	fluid kinematic viscosity
M_c	cross-flow Mach number ($M_0 \sin \alpha$)	θ	polar angle about axis of revolution measured from approach direction of the cross-flow velocity
p	local surface pressure	ρ	fluid mass density
p_0	free-stream static pressure	ϕ	velocity potential
$p_{\alpha=0}$	local surface pressure at zero angle of inclination		
P	local surface-pressure coefficient ($\frac{p-p_0}{q_0}$)		
$P_{\alpha=0}$	local surface-pressure coefficient at zero angle of inclination ($\frac{p_{\alpha=0}-p_0}{q_0}$)		
ΔP	incremental surface-pressure coefficient due to angle of inclination ($\frac{P-P_{\alpha=0}}{q_0}$)		
q_0	free-stream dynamic pressure		
Q	body volume		
r	polar radius about axis of revolution		
R	local body radius at any station x		
R_0	free-stream Reynolds number based on maximum body diameter		
R_c	cross-flow Reynolds number ($R_0 \sin \alpha$)		
R_c'	cross-flow Reynolds number based on diameter D'		
S	body cross-sectional area at station x		

PRESSURE DISTRIBUTION ON SLENDER INCLINED BODIES OF REVOLUTION

POTENTIAL FLOW THEORY

Consider the flow over the body of revolution shown in figure 1 which is inclined at an angle α to the stream of velocity V_0 . If the body is slender, the axial component velocity V_x at the body surface will not differ appreciably from the axial component V_{x_0} of the stream velocity. With this condition, it is clear that the cross flow may be treated

FIGURE 1.—Body of revolution in inclined flow field.

approximately by considering it to be two-dimensional in a plane which is parallel to the yz plane and is moving axially with the constant velocity V_{x_0} . In other words, the problem may be treated by determining the two-dimensional flow about a circular cylinder which is first growing (over the forebody) and then collapsing (over the afterbody) with time.

The velocity potential for the cross flow at any x station is given in polar coordinates as

$$\phi = -V_{x_0} \left(r + \frac{R^2}{r} \right) \cos \theta \quad (3)$$

which in this moving reference plane is a function of time.

Bernoulli's equation for an incompressible flow which changes with time is

$$\frac{p}{\rho} = -\frac{\partial \phi}{\partial t} - \frac{1}{2} \left[\left(\frac{\partial \phi}{\partial r} \right)^2 + \left(\frac{\partial \phi}{r \partial \theta} \right)^2 \right] + C \quad (4)$$

Now from equation (3)

$$\frac{\partial \phi}{\partial t} = -2 V_{x_0} \left(\frac{R}{r} \right) \frac{dR}{dt} \cos \theta \quad (5)$$

but

$$\frac{dR}{dt} = \frac{dx}{dt} \frac{dR}{dx} = V_{x_0} \tan \beta \quad (6)$$

so that equation (5) becomes

$$\frac{\partial \phi}{\partial t} = -2 V_{x_0} V_{x_0} \tan \beta \left(\frac{R}{r} \right) \cos \theta \quad (7)$$

Also, by differentiation of equation (3),

$$\left. \begin{aligned} \frac{\partial \phi}{\partial r} &= -V_{x_0} \cos \theta \left(1 - \frac{R^2}{r^2} \right) \\ \frac{\partial \phi}{r \partial \theta} &= V_{x_0} \sin \theta \left(1 + \frac{R^2}{r^2} \right) \end{aligned} \right\} \quad (8)$$

so that equation (4) for the pressure at any point in the flow field becomes

$$\begin{aligned} \frac{p}{\rho} &= 2 V_{x_0} V_{x_0} \tan \beta \left(\frac{R}{r} \right) \cos \theta - \frac{V_{x_0}^2}{2} \left\{ \cos^2 \theta \left[1 - \left(\frac{R}{r} \right)^2 \right]^2 + \right. \\ &\quad \left. \sin^2 \theta \left[1 + \left(\frac{R}{r} \right)^2 \right]^2 \right\} + C \end{aligned} \quad (9)$$

For

$$r \rightarrow \infty, p \rightarrow p_0$$

so

$$C = \frac{p_0}{\rho} + \frac{V_{x_0}^2}{2}$$

and hence equation (9) for the pressure at the surface of the body becomes for $r=R$

$$\frac{p-p_0}{\rho} = 2 V_{x_0} V_{x_0} \tan \beta \cos \theta + \frac{V_{x_0}^2}{2} (1 - 4 \sin^2 \theta) \quad (10)$$

and writing

$$V_{x_0} = V_0 \sin \alpha$$

$$V_{x_0} = V_0 \cos \alpha$$

the surface pressure in coefficient form becomes

$$P = \frac{p-p_0}{q_0} = 2 \tan \beta \cos \theta \sin 2\alpha + (1 - 4 \sin^2 \theta) \sin^2 \alpha \quad (11)$$

For bodies of moderate fineness ratio at zero angle of inclination, the surface pressure at any station, designated $p_{\alpha=0}$, will differ slightly from the static pressure p_0 but, if the fineness ratio is not too low, the pressure, $p_{\alpha=0}$, in any yz plane will be approximately constant for several body radii from the surface. Under the assumption that the pressure at the surface at zero inclination applies uniformly in the portion of the yz plane for which the major effects of the cross-flow distribution are felt, the change in pressure from p_0 to $p_{\alpha=0}$ will be additive to, but will not otherwise influence, the cross-flow pressure distribution. Hence for any station on a body of high fineness ratio for which at zero inclination the pressure is $p_{\alpha=0}$, the pressure coefficient distribution at this same station under inclined flow conditions will be; from equation (11),

$$P = P_{\alpha=0} + (2 \tan \beta \cos \theta) \sin 2\alpha + (1 - 4 \sin^2 \theta) \sin^2 \alpha \quad (12)$$

For very slender bodies at small angles of inclination

$$\tan \beta \cong \beta$$

$$\sin 2\alpha \cong 2\alpha$$

$$\sin^2 \alpha \cong \alpha^2$$

so that equation (12) becomes³

$$P = P_{\alpha=0} + (4 \cos \theta) \beta \alpha + (1 - 4 \sin^2 \theta) \alpha^2 \quad (13)$$

The cross force per unit length of the body is then found as

$$f = \int_0^{2\pi} p R \cos \theta d\theta = 2 q_0 \int_0^{\pi} P R \cos \theta d\theta + 2 \int_0^{\pi} p_0 R \cos \theta d\theta$$

³ Equation (13), for the case in which β is constant, reduces to that derived by Busemann (reference 5) for the flow over an inclined cone. Laitone's linearized solution (reference 4) for the pressure distribution over bodies at supersonic speeds agrees with equation (13) except that the α^2 term, of course, is absent. This linearized solution is inadequate in general since, for the cases of usual interest, the values of α are of the same order of magnitude as β , thus the α^2 term is as important as the α term.

and clearly

$$2 \int_0^\pi p_0 R \cos \theta d\theta = 0$$

Substituting $\dot{P}$ from equation (12) gives

$$f = 2Rq_0 P_{\alpha=0} \int_0^\pi \cos \theta d\theta + 4Rq_0 \tan \beta \sin 2\alpha \int_0^\pi \cos^2 \theta d\theta + 2Rq_0 \sin^2 \alpha \int_0^\pi (1 - 4 \sin^2 \theta) \cos \theta d\theta$$

The first and third integrals are zero, while the second integral yields

$$f = 2\pi Rq_0 \tan \beta \sin 2\alpha$$

and since

$$2\pi R \tan \beta = 2\pi R \frac{dR}{dx} = \frac{dS}{dx}$$

then

$$f = q_0 \frac{dS}{dx} \sin 2\alpha$$

which is equation (1) derived by Munk for the cross force on slender airship hulls and, in the form,

$$f = 2q_0 \frac{dS}{dx} \alpha$$

that derived by Tsien for the cross force, to the order of the first power of the angle of inclination, for slender bodies at moderate supersonic speeds. This development shows that these equations for the cross force are also correct to the second power of α for inviscid flow.

COMPARISONS WITH EXPERIMENT AND DISCUSSION OF THE EFFECTS OF VISCOSITY

In reference 6, a thorough investigation at low speeds was made of the pressure distribution over a hull model of the rigid airship "Akron." Incremental pressure distributions due to inclination calculated by equation (12) for four stations along the hull at three angles of attack are compared with the experimental values in figures 2(a) to 2(d). In each of the figures is shown a sketch of the airship which indicates the station at which the incremental pressure distributions apply. This comparison represents a severe test of the theoretical method of this report since the method was developed on the assumption that the fineness ratio of the body is very large, while for the case considered the fineness ratio is only 5.9.

At the more forward stations (figs. 2(a) and 2(b)), the agreement is seen to be essentially good⁴ but some discrep-

⁴ At stations extremely close to the bow the method must be inaccurate as evident from the work of Upson and Klikoff (reference 7).

ancy, particularly at values of θ near 180° , is evident which increases with increasing distance from the bow. Downstream of the maximum diameter section (figs. 2(c) and 2(d)) the discrepancy increases very rapidly.

The disagreement that exists at the afterbody stations results from effects of viscosity not considered in the theory, as will be seen from the following: R. T. Jones, in reference 8, showed that, for laminar flow on an infinitely long yawed cylinder of arbitrary cross section, the behavior of the component flow of a viscous fluid in planes normal to the cylinder axis was independent of the component flow parallel to the axis.⁵ For an inclined circular cylinder, then, viewed along the cylinder axis the viscous flow about the cylinder would appear identical to the flow about a circular cylinder section in a stream moving at the velocity $V_0 \sin \alpha$. Hence separation of the flow would occur in the yz plane as a result of the adverse pressure gradients that exist across the cylinder. Jones demonstrated that this behavior explained the cross forces on inclined right circular cylinders that were experimentally observed in reference 10. That such separation effects also occur on the inclined hull model of the "Akron" is also evident from the pressure distributions in figures 2(c) and 2(d).

While the treatment of reference 8 explains qualitatively the observed behavior of the flow field about the hull model considered, it cannot be used quantitatively for a low fineness ratio body such as the "Akron" for at least two reasons.

First, the influence of the term

$$2 \tan \beta \cos \theta \sin 2\alpha$$

of equation (12) is to distort the typical circular-cylinder pressure distribution, given by the term

$$(1 - 4 \sin^2 \theta) \sin^2 \alpha$$

so as to move the calculated position of minimum pressure away from the $\theta = 90^\circ$ point and to change the magnitude of the pressure to be recovered on the lee side of the body. Over the forward stations of the body, where $\tan \beta$ is positive, the position of minimum pressure lies between 90° and 180° and the theoretical pressure recovery is small and even zero at the most forward stations. For the rearward station where $\tan \beta$ is negative, the minimum pressure lies between 0° and 90° , and the theoretical pressure recovery is large and increases proceeding toward the stern. For the hull of the "Akron" model, the theoretical line of minimum pressure along the hull is shown in figure 3 for the angles of attack of 6° , 12° , and 18° .⁶ Since separation can only occur in an adverse

⁵ The recent work of A. P. Young and T. B. Booth (reference 9) indicated that this may be true for the turbulent flow case as well.

⁶ It is of interest to note in this figure that even for small angles of inclination the line of minimum pressure becomes oriented close to the direction of the axis of revolution, while at zero inclination it must, of course, be normal to this axis.

FIGURE 2—Calculated and experimental pressure distribution on a model hull of the U. S. S. Akron.

FIGURE 3.—Calculated lines of minimum pressures for a model hull of U. S. S. Akron at three angles of attack.

gradient, it is clear that the line of separation will roughly parallel the line of minimum pressures. Hence, the flow about forward stations will be, or will more nearly be, that calculated for a nonviscous fluid. Over the rearward stations the flow separation should tend to be even more pronounced than would occur on a right circular cylinder. That such is the case is shown by the flow studies on the ellipsoid of revolution of reference 11. In those studies, the flow on the model surface was investigated by lampblack and kerosene traces. The traces showed the line of separation followed the trend indicated above. From the foregoing, it is evident that the potential flow solution for the pressures on inclined bodies can only be expected to hold over the forebody, and that over the afterbody the pressure distribution, particularly on the lee side, will be importantly influenced by the fluid viscosity.

Second, it is evident that there exists a certain analogy between the cross flow at various stations along the body and the development with time of the flow about a cylinder starting from rest. This may be seen by considering the development of the cross flow with respect to a coordinate system that is in a plane perpendicular to the axis of the inclined body. Let the plane move downstream with a velocity V_0 and let the coordinate system move within the plane such that the axis of revolution of the body is always coincident with the x axis of the coordinate system. The cross velocity is then $V_0 \sin \alpha$. At any instant during the travel of the plane from the nose to the base of the body, the trace of the body in the plane will be a circle and the cross-flow pattern within the plane may be compared with the flow pattern about a circular cylinder. Neglecting, for the moment, the effect of the taper over the nose portions of the body, it might be anticipated that over successive downstream sections, the development of the cross flow with distance along the body as seen in this moving plane would appear similar to that which would be observed with the passage of time for a circular cylinder impulsively set in motion from rest with the velocity $V_0 \sin \alpha$. Thus the flow in the cross plane for the more forward sections should contain a pair of symmetrically disposed vortices on the lee side (cf. reference 12). These vortices should increase in strength as the plane moves rearward and eventually, if the body is long enough, should discharge to form a Kármán vortex street as viewed in the moving cross plane. Viewed in

this moving plane the vortices would appear to be shed and slip rearward in the wake, but viewed with respect to the stationary body the shed vortices would appear fixed. This process of the growth and eventual discharge of the lee-side vortices should occur over a shorter length of body the higher the angle of attack since the movement of the cylindrical trace in the cross plane at any given station is greater the greater the angle of attack. For a low fineness ratio body, however, the development of the lee-side vortices would be expected to have progressed no farther than the "symmetrical pair" case even at the highest angles of attack of interest. This is corroborated by the flow surveys of Harrington (reference 11).

For bodies of high fineness ratio, such as those used for supersonic missiles, it was clearly of interest to determine experimentally the nature of the anticipated growth and discharge of lee-side vortices. In the course of an investigation of a series of bodies with ogival noses and cylindrical afterbodies conducted in the Ames Laboratory 1- by 3-foot supersonic wind tunnels, it was determined that the growth and discharge of lee-side vortices did occur for such bodies at angle of attack as was evidenced in two ways. The schlieren picture for one of the bodies (fig. 4 (a)) showed a line on the lee side at the more forward stations which drifted away from the body surface and eventually branched into a series of lines trailing in the stream direction. The "line" at the more forward stations was indicated to be the cores of the symmetrical vortex pair, which in this side view would appear coincident. The branches were indicated to be the cores of the alternately shed vortices. In order to make the vortices visible in a more convincing manner, use was made of a technique which we have termed the "vapor screen" method. With this technique, the cross flow is made visible in the following manner (see fig. 5): A small amount of water vapor, which condenses in the wind-tunnel test section to produce a fine fog, is introduced into the tunnel air stream. A narrow plane of bright light, produced by a high-pressure mercury-vapor lamp, is made to shine through the glass window in a plane essentially perpendicular to the axis of the tunnel. In the absence of the model this plane appears as a uniformly lighted screen of fog particles. When the model is put in place at any arbitrary angle of attack, the result of any disturbances in the flow produced by the model which affects the amount of light scattered by the water particles in this lighted plane can be seen and photographed.

In figures 4 (b) and 4 (c) are shown photographs of the vapor screens corresponding to the indicated stations for the body of figure 4 (a). The photographs are three-quarter front views from a vantage point similar to that of the sketch of figure 5. In these photographs vortices made themselves evident as black dots on the vapor screens due to the absence of scattered light, which is believed to result from the action of the vortices in spinning the fine droplets of fog out of the fast turning vortex cores. Other details of the flow, particu-

FIGURE 4.—Schlieren and vapor-screen photographs showing vortex configuration for an inclined body of revolution ($\alpha \approx 25^\circ$) at supersonic speed ($M \approx 2$).

larly shock waves, are evident as a change in light intensity. Figure 4 (c) shows the symmetrical vortex pair to exist as previously indicated at the more forward stations, while figure 4 (b) demonstrates that the vortices are shed at stations far removed from the bow. Other observations at different angles of attack demonstrated that the shedding of vortices began, as indicated previously, at the more forward stations the higher the angle of attack. It is of interest to point out that in these wind-tunnel tests the order of discharge of the vortices was aperiodically reversed. Thus, in any cross-flow plane, the discharged vortex closest to the body would at one instant be on one side of the body and at the next instant, or perhaps several seconds later, on the other. No regularity in this change in the distribution of the vortex street has been found.

METHOD FOR ESTIMATING FORCE AND MOMENT CHARACTERISTICS OF SLENDER INCLINED BODIES IN VISCOUS FLOW

For bodies of high fineness ratio at high angles of attack when the cross force is important, it is clear that the third term of equation (13) must predominate since β is small, so that the pressure distribution increment due to angle of attack will closely approximate the pressure distribution for a circular-cylinder section at a velocity equal to the cross component of velocity for the body. Moreover, except for the sections near the bow, development of the cross-flow boundary layer will have been sufficient to promote the flow that is characteristic of the steady-state flow for a circular-cylinder section at the Mach and Reynolds numbers corresponding to the cross velocity over the body.

FIGURE 5.—Schematic diagram of vapor-screen apparatus showing vortices from a lifting body of revolution.

For the limiting case of a slender body, the appropriate value of the cross-wise drag coefficient is, of course, the value of the drag for an infinite cylinder. As will be shown later, experiments indicate that for actual bodies of finite length a somewhat smaller value should be used. Since the actual cross-wise drag coefficient of a body of finite length is always somewhat less than the coefficient for an infinite body, this reduced value suggests itself. Thus it might be expected that the viscous cross-force distribution on such a body could be calculated on the assumption that each circular element along the body experiences a cross force equal to the drag force the section would experience with the axis of revolution normal to a stream moving at the velocity $V_0 \sin \alpha$. This viscous contribution is given by

$$2Rc_{d\alpha=90^\circ} q_0 \sin^2 \alpha dx$$

where R is the body radius at x and $c_{d\alpha=90^\circ}$ is the local drag

coefficient at x for $\alpha=90^\circ$ corresponding to the Reynolds number

$$R_c = R_0 \sin \alpha$$

and the Mach number

$$M_c = M_0 \sin \alpha$$

As a first approximation to the total cross force we may add the potential cross force to the viscous contribution. The total cross force at x would then be ⁷

$$f = q_0 \frac{dS}{dx} \sin 2\alpha \cos \frac{\alpha}{2} + 2Rc_{d\alpha=90^\circ} q_0 \sin^2 \alpha$$

With this simple allowance for viscous effects the lift coefficient,⁸ the foredrag coefficient, and the pitching-moment

⁷ From the work of Ward (reference 13), it may be shown that the potential cross force is directed midway between the normal to the axis of revolution and the normal to the wind direction.

⁸ In the expression for C_L the contribution of the axial drag force $-C_{D_P}(\alpha=0) \cos^2 \alpha \sin \alpha$ is inconsequential small and has been ignored.

coefficient about an arbitrary moment center x_m from the nose are given by

$$\left. \begin{aligned} C_L &= \frac{S_b}{A} \sin 2\alpha \cos \frac{\alpha}{2} + C_{d_{\alpha=90^\circ}} \frac{A_p}{A} \sin^2 \alpha \cos \alpha \\ C_{D_F} &= C_{D_{F_{\alpha=0}}} \cos^3 \alpha + \frac{S_b}{A} \sin 2\alpha \sin \frac{\alpha}{2} + C_{d_{\alpha=90^\circ}} \frac{A_p}{A} \sin^3 \alpha \\ C_M &= \left[\frac{Q - S_b(L - x_m)}{AX} \right] \sin 2\alpha \cos \frac{\alpha}{2} + \\ &\quad C_{d_{\alpha=90^\circ}} \frac{A_p}{A} \left(\frac{x_m - x_{\alpha=90^\circ}}{X} \right) \sin^2 \alpha \end{aligned} \right\} \quad (14)$$

where

$$C_{d_{\alpha=90^\circ}} = \frac{\int_0^L c_{d_{\alpha=90^\circ}} 2R dx}{A_p}$$

and

$$x_{\alpha=90^\circ} = \frac{\int_0^L c_{d_{\alpha=90^\circ}} 2R x dx}{A_p C_{d_{\alpha=90^\circ}}}$$

where

- A_p plan-form area
- S_b base area
- Q body volume
- L body length
- A reference area for coefficient evaluation
- X reference length for pitching-moment-coefficient evaluation

Because of the approximate nature of the theory, it is not considered justified to retain the complex forms of these equations. Accordingly, it is assumed that, for the functions of the angle of attack, cosines may be replaced by unity and sines by the angles in radians to give⁹

$$\left. \begin{aligned} C_L &= 2 \left(\frac{S_b}{A} \right) \alpha + C_{d_{\alpha=90^\circ}} \left(\frac{A_p}{A} \right) \alpha^2 \\ \Delta C_{D_F} &= C_{D_F} - C_{D_{F_{\alpha=0}}} = \frac{S_b}{A} \alpha^2 + C_{d_{\alpha=90^\circ}} \left(\frac{A_p}{A} \right) \alpha^3 \\ C_M &= 2 \left[\frac{Q - S_b(L - x_m)}{AX} \right] \alpha + C_{d_{\alpha=90^\circ}} \left(\frac{A_p}{A} \right) \left(\frac{x_m - x_{\alpha=90^\circ}}{X} \right) \alpha^2 \end{aligned} \right\} \quad (15)$$

To assess the adequacy of these equations for predicting the force and moment characteristics of high fineness ratio bodies, two bodies of revolution were tested in the 1- by 3-foot supersonic wind tunnel at a Mach number of 1.98 from angles of attack of zero to more than 20° and in the 1- by 3½-foot high-speed wind tunnel from Mach numbers of 0.3 to 0.7 at 90° angle of attack to determine the cross-flow drag coefficient $C_{d_{\alpha=90^\circ}}$ and the center of application $x_{\alpha=90^\circ}$ of this force.¹⁰ The bodies investigated (see fig. 6)

FIGURE 6.—Bodies of revolution.

each had a 33½-caliber ogival nose and constant diameter afterbody of such length as to make the fineness ratios 21.1 for body I and 13.1 for body II. Shown in figures 7 and 8 are the lift coefficient, foredrag-increment coefficient, pitching-moment coefficient about the bow, and center of pressure as a function of angle of attack for the two bodies as determined from the tests in the 1- by 3-foot wind tunnels. Also shown are the calculated characteristics (indicated by the solid-line curves) using the experimental values of $C_{d_{\alpha=90^\circ}}$ and $x_{\alpha=90^\circ}$ (see figs. 9 and 10) obtained from the 90° angle-of-attack tests in the 1- by 3½-foot wind tunnel as well as calculated characteristics obtained from potential theory (indicated by the dotted-line curves). The reference area A for coefficient evaluation for these data is the base area and the reference length X for moment-coefficient evaluation is the base diameter.

It is seen that for the higher fineness ratio body (body I), the calculated characteristics which include the allowance for viscous effects are in good agreement with experiment and that the potential theory is clearly inadequate at all but very small angles of attack. For the lower fineness ratio body (body II), the calculated allowances for viscous effects depart further from experiment than they do for body I, as would be expected, although again they are in much better agreement with experiment than are the calculated characteristics based only on potential theory.

While the comparisons made demonstrate that the indicated allowance for viscous effects is adequate for very high-fineness-ratio bodies, the calculated characteristics were, themselves, based on experimentally determined values of $C_{d_{\alpha=90^\circ}}$ and $x_{\alpha=90^\circ}$. For the method to be useful in design, of course, some means for calculating these parameters must exist. In many cases, there are available sufficient experimental drag data on cylinders to provide the required information. In the appendix one approximate method is given for determining the values of $C_{d_{\alpha=90^\circ}}$ and $x_{\alpha=90^\circ}$ for the bodies I and II previously considered.

The variations of the coefficients of lift, foredrag increment, and pitching moment and of the center-of-pressure position with angle of attack for the two bodies as estimated using the calculated cross-flow drag characteristics given in the appendix are shown in figures 7 and 8 (as the dashed-line curves). The estimated characteristics are seen to be in even better agreement with experiment than are the calculated variations using the experimental cross-flow drag characteristics.

⁹ In the expression for ΔC_{D_F} , the term $-C_{D_{F_{\alpha=0}}} \alpha^2$, which should properly appear on the right side of this equation, has been omitted since, for practical cases, its contribution is small.

¹⁰ Although the cross Reynolds numbers for the 1- by 3½-foot wind-tunnel test were almost twice that for the 1- by 3-foot wind-tunnel tests, the results are considered comparable since in the range of Reynolds numbers investigated the drag characteristics of circular cylinders are insensitive to change in Reynolds numbers.

APPENDIX

ESTIMATION OF CROSS-FLOW DRAG COEFFICIENT

A procedure which suggests itself for estimating the magnitude of the cross-flow drag coefficient $C_{d_{\alpha=90^\circ}}$ as a function of angle of attack for the two ogival-nosed bodies treated in the text is to consider them to have the same characteristics as circular cylinders of constant diameter.

$$D' = \frac{A_p}{L}$$

The cross-flow drag coefficient of this fictitious cylinder of finite length can then be approximated by first determining the drag coefficient, c_{d_c} , of a circular-cylinder section of diameter D' at the cross-flow Mach number

$$M_c = M_0 \sin \alpha$$

and cross-flow Reynolds number

$$Re_c' = \frac{V_0 D'}{\nu} \sin \alpha$$

and then correcting this drag coefficient for the effect of the finite fineness ratio, L/D' .

From references 14 and 15, it is found that for the values of D' corresponding to the two bodies considered the circular-cylinder section drag coefficients, c_{d_c} , are the same for both bodies and dependent only on the Mach number. The values at various cross Mach numbers are given in figure 9.

From reference 16, it is found that for a finite-length circular cylinder in the range of Reynolds numbers for which the cross-drag coefficient, as for the present cases, is 1.2 at low Mach numbers, the ratio of the drag of the circular cylinder of finite length to that for the circular cylinder of infinite length is 0.755 for body I and 0.692 for body II. Assuming that this ratio is independent of Mach number, the estimated values of $C_{d_{\alpha=90^\circ}}$ for the two bodies are as given in figure 9 wherein they may be compared with the experimental values obtained from the 1- by 3½-foot wind-tunnel tests.

The value of $x_{\alpha=90^\circ}$ is logically assumed to be the distance from the bow to the centroid of plan-form area. This

assumed position which is independent of Mach number is compared with the experimentally determined values from the 1- by 3½-foot wind-tunnel tests for the two bodies in figure 10.

REPORT 1049

EXPERIMENTAL INVESTIGATION OF THE EFFECT OF VERTICAL-TAIL SIZE AND LENGTH AND OF FUSELAGE SHAPE AND LENGTH ON THE STATIC LATERAL STABILITY CHARACTERISTICS OF A MODEL WITH 45° SWEEPBACK WING AND TAIL SURFACES¹

By M. J. QUEIJO and WALTER D. WOLHART

SUMMARY

An investigation was made to determine the effects of vertical-tail size and length and of fuselage shape and length on the static lateral stability characteristics of a model with wing and vertical tails having the quarter-chord lines swept back 45°. The results indicate that the directional instability of the various isolated fuselages was about two-thirds as large as that predicted by classical theory. A reduction in area of vertical tails (geometric aspect ratio kept constant) attached to a given fuselage resulted in an increase in the effective aspect ratio of the vertical tail for the range of tail sizes considered. Simple analytical considerations indicate, however, that for tail sizes below the range investigated the opposite effect would be expected.

For the fuselage-tail combinations investigated, the tail effectiveness, usually decreased with increasing angle of attack, with the greatest rate of decrease occurring at angles of attack greater than about 16°.

The wing-fuselage interference for the midwing arrangements investigated was only slightly affected by the shape of the fuselage and tended to increase slightly the directional stability of the combination. The interference effects of the wing tended to decrease the vertical-tail effectiveness, particularly at high angles of attack. The large effects observed were attributed to a partially stalled condition of the wing.

INTRODUCTION

Recent advances in the understanding of the principles of high-speed flight have led to significant changes in the design of the principal components of airplanes. Two of the more important changes have been the incorporation of large amounts of sweep of the wing and tail surfaces and the elevation of the horizontal tail to a higher position. Much information is available on the influence of the wing, fuselage, and tail geometry on the static stability characteristics of the more conventional airplane designs (for example, references 1 and 2); however, little information is available on the influence of the various airplane components on the characteristics of airplanes having wings and tail surfaces with large amounts of sweep. In order to provide such

information, a series of investigations is being conducted in the Langley stability tunnel with a model having various interchangeable parts. The effects of changes in the size and location of the horizontal tail on the low-speed static lateral stability characteristics have been reported in reference 3. The effects on the static-lateral-stability derivatives of variations of vertical-tail size and length and of fuselage shape and length are presented herein. The data also have been used to determine interference effects between the wing and fuselage and the interference effects of the wing-fuselage combination on the vertical-tail effectiveness.

SYMBOLS AND COEFFICIENTS

The data presented herein are in the form of standard NACA coefficients of forces and moments which are referred to the stability axes, with the origin at the projection on the plane of symmetry of the quarter-chord point of the mean aerodynamic chord or at the midpoint of the fuselage. The positive directions of the forces, moments, and angular displacements are shown in figure 1. The coefficients and symbols are defined as follows:

- A aspect ratio (b^2/S)
 b span, measured perpendicular to fuselage center line, feet

F	fuselage; used with subscripts 1 to 5 to denote the various fuselages (see fig. 3)
S	slat
e	effective
s	side area

APPARATUS AND TESTS

All parts of the models used in this investigation were constructed of mahogany. Sketches of the parts of the models are presented as figures 2, 3, and 4. The various vertical tails and fuselages will be referred to henceforth by the symbol and number assigned to them in figures 2 and 3. All vertical tails had 45° sweepback of the quarter-chord line, taper ratio of 0.6, and NACA 65A008 profiles (table I) in planes parallel to the fuselage center line. The ratios of tail area to wing area were chosen to cover a range representative of that used for current high-speed airplane configurations. The tails were mounted on the fuselages so that the tail length was always a constant percent of the fuselage length $\left(\frac{l_v}{l} = 0.42\right)$. The tail length was varied by changing the fuselage length. The three fuselages (fineness ratios of

FIGURE 2.—Dimensions of vertical tails tested. $\lambda=0.6$; $\Lambda=45^\circ$; profile, NACA 65A008. All dimensions are in inches.

0, 6.67 and 10.0) of circular-arc profile used in the investigation are shown in figure 3. Two additional fuselages having the same fineness ratio as fuselage 2 (fineness ratio of 6.67) were used to determine the effects of fuselage nose and trailing-edge modifications. All fuselages had circular cross sections and all had the same maximum thickness. The coordinates of the fuselages are given in table II.

The wing had an aspect ratio of 4.0, taper ratio of 0.6, sweepback of 45° of the quarter-chord line, and NACA 65A008 profiles parallel to the plane of symmetry. The wing was mounted on the fuselage so that the quarter-chord point of the mean aerodynamic chord coincided with the fuselage mounting point (fig. 4). A summary of the geometric characteristics of the various model components is given in table III. A full-span slat, fitted to the wing for some tests with fuselage F_2 , had a chord which was 8 percent of the wing chord. (See fig. 4.) The slat was made by bending a strip of $\frac{1}{16}$ -inch-thick aluminum sheet to fit the

contour of the wing leading edge. Photographs of two of the model configurations are presented as figure 5.

Most of the tests of this investigation were conducted in the 6-foot-diameter rolling-flow test section of the Langley stability tunnel. Tests of configurations with fuselages F_4 and F_5 were conducted in the 6- by 6-foot curved-flow test section of the Langley stability tunnel. All tests were made at a dynamic pressure of 24.9 pounds per square foot, which corresponds to a Mach number of 0.13 and a Reynolds number of 0.71×10^6 based on the wing mean aerodynamic chord. The angle of attack of the model was varied from about -4° to approximately 32° for yaw angles of 0° and $\pm 5^\circ$.

CORRECTIONS

The angle of attack, longitudinal-force coefficient, and rolling-moment coefficient have been corrected for jet-boundary effects. No corrections have been applied for the effects of blocking, turbulence, or support-strut interference.

FIGURE 3.—Dimensions of fuselages; profile ordinates in table II. All dimensions are in inches.

At relatively large angles of attack (above about 20°) the vertical tail generally was in the wake of the support strut; hence, data dependent principally on the vertical-tail contribution probably are unreliable at angles of attack above about 20° . This unreliability is particularly true for data obtained with fuselage F_3 , and therefore these data are not presented.

METHODS OF ANALYSIS

The results of the present investigation are analyzed in terms of the individual contributions of the various parts and the more important interference effects. In accordance with conventional procedures (for example, see reference 2), the static-lateral-stability derivatives of a complete airplane

FIGURE 4.—Dimensions and location of wing and vertical tails. All dimensions are in feet.

can be expressed as

$$C_{Y\psi} = (C_{Y\psi})_F + (C_{Y\psi})_W + (C_{Y\psi})_V + \Delta_1 C_{Y\psi} + \Delta_2 C_{Y\psi} \quad (1)$$

$$C_{n\psi} = (C_{n\psi})_F + (C_{n\psi})_W + (C_{n\psi})_V + \Delta_1 C_{n\psi} + \Delta_2 C_{n\psi} \quad (2)$$

$$C_{l\psi} = (C_{l\psi})_F + (C_{l\psi})_W + (C_{l\psi})_V + \Delta_1 C_{l\psi} + \Delta_2 C_{l\psi} \quad (3)$$

The subscripts F and W refer to the derivatives of the isolated fuselage and of the isolated wing, respectively. In the general case, the subscript V refers to the contribution of the vertical tail when mounted on the fuselage and when in the presence of the horizontal tail. The present tests were made without a horizontal tail, since the effects of various horizontal-tail sizes and locations were investigated in reference 3. In the present report, therefore, the derivatives with the subscript V include both the effectiveness of the isolated vertical tail and the interference of the fuselage.

The vertical-tail contribution can be expressed analytically as follows:

$$(C_{Y\psi})_V = (C_{L\alpha})_V \frac{S_V}{S_W} \eta_Y \quad (4)$$

$$(C_{n\psi})_V = -(C_{L\alpha})_V \frac{l_V}{b_W} \frac{S_V}{S_W} \eta_N \quad (5)$$

(a) Configuration $W+F_1+V_2$.

FIGURE 5.—View of model in the Langley stability tunnel.

(b) Configuration $W_S+F_2+V_2$.

FIGURE 5.—Concluded.

$$(C_{l_\psi})_v = \left(\frac{z_v}{b_w} \cos \alpha - \frac{l_v}{b_w} \sin \alpha \right) \frac{S_v}{S_w} (C_{L_\alpha})_v \quad (6)$$

where $(C_{L_\alpha})_v$ is the effective vertical-tail lift-curve slope when the model is at zero angle of attack, and η_Y and η_N are correction factors which account for the variation in tail effectiveness with angle of attack. (A similar correction to C_{l_ψ} is neglected because it generally has been found to be very nearly 1.0.) Equations (4) to (6) are similar to equations given in reference 4, except that in the reference the factors η_Y and η_N are neglected. The results of the present tests are used for evaluating the factors η_Y and η_N and the effective aspect ratio A_{e_v} , corresponding to the vertical-tail lift-curve slope $(C_{L_\alpha})_v$.

Perhaps the most consistent approach to the problem of evaluating tail effectiveness would involve determination of A_{e_v} corresponding to $(C_{L_\alpha})_v$ as determined from equation (4). In order to make use of such values of A_{e_v} in the calculation of $(C_{n_\psi})_v$ and $(C_{l_\psi})_v$, effective, rather than geometric, values

of the tail length l_v and of the tail height z_v also would have to be known. From practical considerations, it has seemed most convenient to assume that the location of the vertical-tail center of pressure is given accurately by the geometric lengths l_v and z_v . Since the directional-stability parameter $(C_{n_\psi})_v$ is considered to be the most important of the three static-lateral-stability parameters, values of A_{e_v} , corresponding to $(C_{L_\alpha})_v$ as determined from equation (5), are obtained in the present analysis. The reliability of values of A_{e_v} so determined, when used to calculate $(C_{Y_\psi})_v$ and $(C_{l_\psi})_v$, is checked against the experimental results.

Since, at zero angle of attack, the factor η_N is 1.0, equation (5) can be rewritten as

$$(C_{L_\alpha})_v = -\frac{b_w S_w}{l_v S_v} (C_{n_\psi})_v$$

Values of A_{e_v} , corresponding to $(C_{L_\alpha})_v$, may be obtained from theory such as that of reference 5. A correction to A_{e_v} for the effect of the horizontal tail can be obtained from reference 3.

The increments prefixed by Δ_1 and Δ_2 express, respectively, the interference of the wing-fuselage combination and the interference of the wing-fuselage on the vertical-tail effectiveness; for example,

$$\Delta_1 C_{Y_\psi} = (C_{Y_\psi})_{W+F} - [(C_{Y_\psi})_W + (C_{Y_\psi})_F]$$

and

$$\Delta_2 C_{Y_\psi} = [(C_{Y_\psi})_{W+F+V} - (C_{Y_\psi})_{W+F}] - [(C_{Y_\psi})_{F+V} - (C_{Y_\psi})_F]$$

The interference increments usually are assumed to apply to airplanes having configurations which are somewhat similar to that of the model used in evaluating the increments. Of the various factors which affect the magnitudes of the interference increments, the height of the wing, relative to the center line of the fuselage, previously has been found to be one of the most important (reference 2). Since, for the present investigation, the wing was located on the center line of the fuselages, the results are considered applicable only to midwing or near-midwing arrangements.

RESULTS AND DISCUSSION

PRESENTATION OF RESULTS

The basic data obtained in this investigation are presented in figures 6 to 14. The longitudinal characteristics of the wing alone and of the wing with slat are given in figure 6. The static-lateral-stability parameters of the various configurations investigated are given in figures 7 to 14. A summary of the configurations investigated and of the figures that give data for these configurations is given in table IV. Most of the remaining figures (figs. 15 to 30) were made up from the data of figures 7 to 14 and present the data in a form more suitable for analysis.

WING CHARACTERISTICS

The longitudinal aerodynamic characteristics of the wing alone (fig. 6) have been given in reference 3; hence, they are reviewed only briefly in this report. The plain wing stalled at about 24° angle of attack ($C_L=1.0$) and showed an aerodynamic-center position of $0.25\bar{c}_w$. The theory of reference 5 predicts an aerodynamic-center position of $0.26\bar{c}_w$. Addition of the $0.08c_w$ slat delayed the stall to about 26° angle of attack ($C_L=1.1$) but had no appreciable effect on the position of the aerodynamic center at low angles of attack. The slat caused an appreciable reduction in drag at angles of attack greater than about 8° .

Many of the aerodynamic parameters of a complete airplane are dependent to some extent on the character of the flow over the wing; hence, some consideration must be given to the angle-of-attack range over which flow does not separate from the wing. As pointed out in reference 6, an indication of the limit of this range can be obtained by locating the initial break in the plot of $C_D - \frac{C_L^2}{\pi A_w}$ against angle of attack.

A plot of this increment for the plain wing and for the wing with slat is given in figure 15. The figure shows breaks in the curves at about 7.7° and at about 16° for the wing alone and for the wing with slat, respectively. Corresponding breaks in the curves of the aerodynamic characteristics of combinations involving the wing and the wing with slat are to be expected at about these same angles of attack.

Investigations involving Reynolds number as a variable have shown that for smooth wings increases in Reynolds number tended to extend the angle-of-attack range before which initial breaks occurred in plots of aerodynamic parameters against angle of attack. For this reason, results obtained for configurations with slats might be expected to be somewhat similar to data for the plain wing at a higher Reynolds number than the test Reynolds number.

FUSELAGE CHARACTERISTICS

The important characteristics of the various fuselages are summarized in figure 16. In general, the parameters considered $(C_{Y_\psi})_F$ and $(C_{n_\psi})_F$ varied only slightly with angle of attack, and therefore the analysis has been limited to characteristics at $\alpha=0^\circ$.

In order that the results obtained may be applied conveniently to arbitrary airplane configurations, coefficients in terms of fuselage dimensions rather than wing dimensions are needed. This manner of expressing the coefficient is accomplished by plotting the quantities $(C_{Y_\psi})_F \frac{S_w}{S_s}$ and $(C_{n_\psi})_F \frac{S_w b_w}{V_F}$ against fuselage fineness ratio. The quantities plotted, therefore, are effectively a lateral-force coefficient based on fuselage side area S_s and a yawing-moment coefficient based on fuselage volume V_F .

Comparisons are made with the theory presented in reference 7. Although the theory, which is based on potential-flow considerations, predicts no side force, the experimental results show a positive side force which increases as the fineness ratio is decreased. The variations in fuselage shape considered, for a constant fineness ratio, have a negligible effect on the value of a lateral-force coefficient based on fuselage side area.

FIGURE 16.—Summary of fuselage contributions to C_{r_ψ} and C_{n_ψ} . $\alpha=0^\circ$.

FIGURE 15.—Effect of wing leading-edge slat on the variation of $C_D - \frac{C_L^2}{\pi A_w}$ of the wing with angle of attack.

The experimental results obtained for the directional-stability parameter $(C_{N\psi})_F$ of the biconvex fuselages show about the same trend with variation in fineness ratio as that predicted by theory, although, quantitatively, the magnitude is only about two-thirds of that predicted by theory. For a constant fineness ratio, the variations in fuselage shape considered produced a rather large change in the magnitude of the directional-stability parameter based on fuselage volume. An increase in volume near the fuselage nose increased this parameter; whereas an increase in volume over the rear half of the fuselage decreased this parameter.

VERTICAL-TAIL EFFECTIVENESS

Effective aspect ratio.—As explained in the section entitled "Methods of Analysis," the effective aspect ratio of the vertical tail is obtained by calculating the tail lift-curve slope from experimental values of $(C_{N\psi})_V$ and then obtaining the corresponding aspect ratio from a theory of plain wings. The theory of reference 5 has been used herein, although it is realized that a swept vertical tail represents an unsymmetrical configuration to which the theory is not strictly applicable. The relationship, given by reference 5, between lift-curve slope and aspect ratio for wings having a sweep angle of 45° and a taper ratio of 0.6 is reproduced in figure 17. The results of the effective-aspect-ratio determinations are presented in figure 18 in the form of the ratio A_{eV}/A_V plotted against b_V/D_F for $\alpha=0^\circ$. The quantity b_V/D_F is the ratio of vertical-tail span to the fuselage diameter at the longitudinal location of the vertical-tail aerodynamic center and is regarded as a significant parameter for determining the influence of the fuselage on the vertical-tail effectiveness. An average curve is drawn through the data obtained with the tails of aspect ratio 1.0, and another curve, through the two points obtained with the tails of aspect ratio 2.0. The fairing of the average curve at low values of b_V/D_F has been

FIGURE 17.—Variation of lift-curve slope with aspect ratio for 45° sweptback wings with taper ratio 0.6.

guided by the shape of the calculated curve which represents reasonable maximum values of A_{eV}/A_V for given values of b_V/D_F . The calculated curve was determined by an equation derived on the assumption that the fuselage acts as an infinite end plate on the portion of the vertical tail protruding outside the fuselage. The equation of the curve is

$$\frac{A_{eV}}{A_V} = \frac{2\left(2\frac{b_V}{D_F} - 1\right)}{2\frac{b_V}{D_F} - \frac{1 - \lambda_V}{1 + \lambda_V}} \quad (7)$$

A reduction in area (geometric aspect ratio kept constant) of vertical tails attached to a given fuselage resulted in an increase in the effective aspect ratios of the vertical tails for the range of tail size investigated. The calculated curve indicates that for smaller tails the opposite would be true.

The experimental data show that the ratio A_{eV}/A_V approaches the value 1.0 as b_V/D_F becomes large. This variation is to be expected since an increase in b_V/D_F represents a decrease in the size of the end plate relative to the vertical tail. For very large values of b_V/D_F , the effective and geometric aspect ratios should be approximately equal. The values of A_{eV}/A_V given in figure 18 depend to some extent on the curve of $C_{L\alpha}$ against A from which the values of A_{eV} were obtained. The values of A_{eV} might have been slightly different had some variation of $C_{L\alpha}$ with A other than that of reference 5 been used. The data show some scatter at low values of b_V/D_F ; this scatter indicates that factors other than b_V/D_F enter into the determination of A_{eV}/A_V . The vertical-tail contribution to $C_{Y\psi}$ and $C_{N\psi}$ at $\alpha=0^\circ$ is shown in figure 19. Also shown in the figure are calculated curves of the parameters as determined by equations (4) and (5) and the use of average values of A_{eV} to determine $(C_{L\alpha})_V$. Ratios of A_{eV}/A_V of 1.25 and 1.45 were used for vertical tails having geometric aspect ratios of 1.0 and 2.0, respectively. The fact that reasonably good

FIGURE 18.—Effective aspect ratio of vertical tails as influenced by the fuselage. $\alpha=0^\circ$.

agreement between the calculated curves and the experimental values of C_{n_ψ} was obtained is of only incidental interest, since the experimental results shown were originally used to determine appropriate values of the ratio A_{eV}/A_V . The scatter of the experimental points is indicative, however, of the accuracy that might be expected by use of average values of A_{eV}/A_V for arbitrary arrangements. The agreement between the calculated and experimental values of $(C_{Y_\psi})_V$ also is reasonably good. Therefore, the values of A_{eV}/A_V calculated from increments of $(C_{n_\psi})_V$ appear to be usable for predicting $(C_{Y_\psi})_V$ with reasonable accuracy at least for the arrangements investigated.

FIGURE 19.—Effect of tail area and tail length on vertical-tail contribution to C_{Y_ψ} and C_{n_ψ} , $\alpha = 0^\circ$.

The vertical-tail contribution to the derivative C_{l_ψ} can be separated into two parts as given by the two terms of the following equation:

$$(C_{l_\psi})_V = \frac{z_V}{b_W} \frac{S_V}{S_W} (C_{L_a})_V \cos \alpha - \frac{l_V}{b_W} \frac{S_V}{S_W} (C_{L_a})_V \sin \alpha$$

For small angles of attack the equation can be written as

$$(C_{L_a})_V = \frac{z_V}{b_W} \frac{S_V}{S_W} (C_{L_a})_V - \frac{l_V}{b_W} \frac{S_V}{S_W} (C_{L_a})_V \frac{\alpha}{57.3}$$

The first part of the equation is the increment of $(C_{l_\psi})_V$ at $\alpha = 0^\circ$, and the second part shows that the variation of $(C_{l_\psi})_V$ with α is given by

$$\frac{\partial (C_{l_\psi})_V}{\partial \alpha} = - \frac{l_V}{b_W} \frac{S_V}{S_W} \frac{(C_{L_a})_V}{57.3}$$

In analyzing the contribution of the vertical tail to C_{l_ψ} , consideration has been given to the increment of $(C_{l_\psi})_V$ at zero angle of attack and the rate of change of $(C_{l_\psi})_V$ with angle of attack. The experimental and calculated results for both of these effects are shown in figure 20 to be in fairly good agreement.

Angle-of-attack correction.—In the preceding section, the effective aspect ratio of the vertical tail mounted on the fuselage was determined at zero angle of attack. The effects of variations in angle of attack are now evaluated in terms of the correction factors to the vertical-tail contribution to C_{Y_ψ} and C_{n_ψ} , η_Y and η_N , respectively.

The variation of the factor η_Y with angle of attack is shown in figure 21 for three values of the ratio l_V/b_W . In each case an average curve is drawn through the data. The ratios l_V/b_W and S_V/S_W seem to cause no appreciable change in the variation of η_Y with α for values of α less than 6° .

FIGURE 20.—Effect of tail area and length on the vertical-tail contribution to C_{l_ψ} , $\alpha = 0^\circ$.

At higher angles of attack, however, both l_v/b_w and S_v/S_w appear to affect the variation of η_Y with α , but not enough data were available to establish a definite relation between the various parameters. The effects of fuselage shape and vertical-tail aspect ratio on the variation of η_Y with α are shown in figure 22. Also given in the figure is the average curve from figure 21(b). It is seen that the curve fits the data reasonably well and that the variations in fuselage shape considered have very little effect on the variation of η_Y with α . Changes in vertical-tail aspect ratio appear to have some effect on the variation of η_Y with α ; nevertheless, the general trend shown by the average curve is still fairly accurate.

In general, it appears that the vertical-tail contribution to $C_{Y\psi}$ may be reduced as much as twenty percent as the angle of attack is increased from 0° to 15° and that this reduction usually increases rapidly at higher angles of attack.

The variation of the factor η_N with α is shown in figure 23 for several values of l_v/b_w and S_v/S_w . Average curves are drawn through each set of data. At low angles of attack the area ratio S_v/S_w appears to have a negligible effect on the variation of η_N with α ; however, it does have a large effect at angles of attack greater than about 8° and the effects increase with an increase of the l_v/b_w ratio. Fuselage shape and vertical-tail aspect ratio appear to have some effect on the variation of η_N with α (fig. 24), but the effects are not clearly defined by the data. In general, the average curve of figure 23 (b) fits the data of figure 24 reasonably well.

Except for the smallest vertical tail (V_1), the tail contributions to $C_{n\psi}$ tend to show a smaller decrease with angle of attack than had previously been noted for the tail contribution to $C_{Y\psi}$.

INTERFERENCE EFFECTS

Wing-fuselage interference.—The lateral-stability data of this investigation were used to determine wing-fuselage interference increments by the procedure explained under "Methods of Analysis." The increments are presented in figure 25 as functions of the angle of attack. Both $\Delta_1 C_{Y\psi}$ and $\Delta_1 C_{l\psi}$ show large variations with angle of attack and are of large magnitude at high angles of attack. The increment $\Delta_1 C_{n\psi}$ is rather small for all fuselage shapes investigated and tends to increase slightly the directional stability of the wing-fuselage combination over most of the angle-of-attack range.

FIGURE 21.—Effect of tail area and length on the angle-of-attack correction to the vertical-tail contribution to $C_{Y\psi}$. Circular-arc fuselages.

FIGURE 22.—Effect of fuselage shape and vertical-tail aspect ratio on the angle-of-attack correction to the vertical-tail contribution to $C_{Y\psi}$.

The average value of $\Delta_1 C_{n_\psi}$ is about -0.0002 up to 16° angle of attack.

Wing-fuselage interference on vertical-tail effectiveness.—Increments of $\Delta_2 C_{Y_\psi}$, $\Delta_2 C_{n_\psi}$, and $\Delta_2 C_{l_\psi}$ are shown in figures 26, 27, and 28, respectively, for various combinations of the circular-arc fuselages and the vertical tails of aspect ratio 1.0. The data are divided into groups of constant l_v/b_w ratio. An average curve was drawn through each set of data. In general, the data show little scatter about the faired curves. The addition of the wing almost invariably reduced the tail contribution to the directional stability for the arrangements investigated (fig. 27). The effect was negligible at very small angles of attack, but at 20° angle of attack a value of $\Delta_2 C_{n_\psi}$ of about 0.0020 was obtained with the largest fuselage (F_3 .) The large interference effects noted at high angles of attack probably result from the partially stalled condition of the wing at these attitudes. If stalling could be avoided, the

FIGURE 23.—Effect of tail area and length on the angle-of-attack correction to the vertical-tail contribution to C_{n_ψ} . Circular-arc fuselages.

interference effects undoubtedly would be considerably smaller.

The effects of fuselage shape on the increments of C_{Y_ψ} , C_{n_ψ} , and C_{l_ψ} caused by wing-fuselage interference on the vertical-tail effectiveness are indicated in figure 29. Also given in the figure are the average curves of the $\frac{l_v}{b_w} = 0.464$ data of figures 26 (b), 27 (b), and 28 (b). The figure indicates that variations in fuselage shapes considered have little effect on the interference increments and that the average curves fit the data quite well.

A comparison is given in figure 30 between the interference increments $\Delta_1 C_{n_\psi}$ and $\Delta_2 C_{n_\psi}$ for a model configuration with and without the wing slat. The model configuration was made up of the wing, fuselage F_2 , and vertical tail V_2 . The increment $\Delta_1 C_{n_\psi}$ for both configurations varied erratically with angle of attack and indicated no definite trends. The increment $\Delta_2 C_{n_\psi}$ for the model with the slat was larger (more positive) than for the wing without the slat up to about 20° , after which the opposite was true.

It should be pointed out again that the interference increments presented herein can be expected to apply fairly accurately only to midwing or near-midwing configurations since the height of the wing relative to the fuselage center line has been found to be an important factor in determining interference increments (reference 2).

CONCLUSIONS

The results of an investigation to determine the effects of vertical-tail size and length and of fuselage shape and length

FIGURE 24.—Effect of fuselage shape and vertical-tail aspect ratio on the angle-of-attack correction to the vertical-tail contribution to C_{n_ψ} .

FIGURE 25.—Variation of increments of $C_{Y\psi}$, $C_{n\psi}$, and $C_{l\psi}$ caused by wing-fuselage interference with angle of attack.

on the lateral static stability characteristics of a model with a 45° sweptback wing indicate the following conclusions:

1. The directional instability of the various isolated fuselages was about two-thirds as large as that predicted by classical theory.

2. A reduction in area (geometric aspect ratio kept constant) of vertical tails attached to a given fuselage resulted in an increase in the effective aspect ratio of the vertical tails for the range of tail sizes considered. Simple analytical considerations indicate, however, that for tail sizes below the range investigated the opposite effect would be expected.

3. For the fuselage-tail combinations investigated, the tail effectiveness usually decreased with increasing angle of

FIGURE 26.—Effect of the tail area and length on the increment of $C_{Y\psi}$ caused by wing-fuselage interference on vertical-tail effectiveness. Circular-arc fuselages.

attack, with the greatest rate of decrease occurring at angles of attack greater than about 16° .

4. The wing-fuselage interference for the midwing arrangements investigated was only slightly affected by the shape of the fuselage and the interference tended to increase slightly the directional stability of the combinations.

5. The interference effects of the wing tended to decrease the vertical-tail effectiveness, particularly at high angles of attack. The large effects observed were attributed to a partially stalled condition of the wing.

FORMULAS FOR THE SUPERSONIC LOADING, LIFT, AND DRAG OF FLAT SWEEPED-BACK WINGS WITH LEADING EDGES BEHIND THE MACH LINES

By DORIS COHEN

SUMMARY

The method of superposition of linearized conical flows has been applied to the calculation of the aerodynamic properties, in supersonic flight, of thin flat, swept-back wings at an angle of attack. The wings are assumed to have rectilinear plan forms, with tips parallel to the stream, and to taper in the conventional sense. The investigation covers the moderately supersonic speed range where the Mach lines from the leading-edge apex lie ahead of the wing. The trailing edge may lie ahead of or behind the Mach lines from its apex. The case in which the Mach cone from one tip intersects the other tip is not treated.

Formulas are obtained for the load distribution, the total lift, and the drag due to lift. For the cases in which the trailing edge is outside the Mach cone from its apex (supersonic trailing edge), the formulas are complete. For the wing with both leading and trailing edges behind their respective Mach lines, a degree of approximation is necessary. It has been found possible to give practical formulas which permit the total lift and drag to be calculated to within 2 or 3 percent of the accurate linearized-theory value. The local lift can be determined accurately over most of the wing; but the trailing-edge-tip region is treated only approximately.

Charts of some of the functions derived are included to facilitate computing, and several examples are worked out in outline.

INTRODUCTION

It is customary, in supersonic wing theory, to describe any straight segment of the boundary of a wing plan form as supersonic or subsonic accordingly as the segment lies outside or is contained within its foremost Mach cone; that is, as the component of the flight velocity normal to the edge is greater than or less than the speed of sound. These two circumstances result in fundamentally different types of flow over the surface. It is apparent that the real reference is not to a property of the wing plan form, but to a combination of plan-form geometry and the velocity of the wing relative to the speed of sound. Thus (see fig. 1) every swept-back wing, on entering the supersonic regime, has subsonic leading and, in most cases, subsonic trailing edges. At a higher Mach number, the same plan form may have subsonic leading edges and supersonic trailing edges. Finally, if the Mach number is increased sufficiently, both leading and trailing edges will become supersonic.

Interference effects also depend on the flight Mach number, since the extent of the various disturbance fields is determined by the angle between the Mach lines. Thus, no single concise formula or method of treatment has as yet been developed to predict, even approximately, the aerodynamic characteristics of an arbitrary wing plan form through the supersonic speed range.

The present report is concerned with the loading, lift, and drag, according to linearized theory, of thin, flat, swept-back wings with rectilinear boundaries and conventional taper. Various methods are available for the calculation of these properties when the leading edge is supersonic. Of these, the method of reference 1 is perhaps the most convenient. Formulas obtained by this method for the loading and lift-curve slope of wings with supersonic leading and trailing edges are presented in reference 2. In the following, therefore, the emphasis will be on the solution of the problems arising from the interaction of the flow fields in the presence of subsonic leading edges (figs. 1 (b), (c),

FIGURE 1.—A typical tapered swept-back wing at six supersonic Mach numbers, showing the Mach lines from the leading- and trailing-edge apices and from the tips.

and (d)). The case (fig. 1 (a)) in which the Mach number and aspect ratio are so low that interaction takes place between the tip flow fields will not be treated. An approximate solution to this problem may be found in reference 3.

When a wing with a subsonic leading edge is to be studied, considerable simplification of the problem may be achieved by making use of the solutions, available in reference 4

is the ratio of the slope of the ray t_a of that field to the slope of the Mach lines.

If the ratio of the slope of the leading edge to the slope of the Mach lines is

$$m = \beta \cot \Lambda \tag{3}$$

where Λ is the angle of sweepback, then at the leading edge $a=m$, and a ray from the leading-edge tip is designated by t_m . If s is the wing semispan, the leading-edge tip has the coordinates $\frac{\beta s}{m}$, s and any point x, y has the conical coordinate

$$t_m = \beta \frac{y-s}{x-\frac{\beta s}{m}} \tag{4}$$

in the field with apex at $\frac{\beta s}{m}$, s .

Other symbols referring to angular locations will be defined in the same way as needed. A summary of the symbols will be found in appendix A.

BOUNDARY CONDITIONS FOR CANCELLATION OF LIFT

The general problem of deriving the flow over a wing of finite dimensions from the known flow over an infinite wing is the problem of determining the induction effects due to the edges. These effects may be thought of as associated with the cancellation of the lifting pressure at the boundaries of the finite wing. In the linearized lifting-surface theory, they may be evaluated by the superposition of flow fields with negative lifting pressure over the portion of the infinite wing outside the boundaries of the finite plan form, provided the other boundary conditions are not disturbed. In the case of a flat wing at an angle of attack, the latter provision means that the canceling field must (1) induce no downwash within the boundaries of the finite wing and (2) introduce no new lifting pressure outside those boundaries.

In accordance with thin-airfoil theory, the boundary conditions will be satisfied in the horizontal plane rather than on the surface of the wing. Also, by thin-airfoil theory, the conditions on the lifting pressure are converted to conditions on the velocity field through the relation

$$\frac{\Delta p}{q} = 4 \left(\frac{u}{V} \right)_{z=+0} \tag{5}$$

In the simplest case, the lift to be canceled will be distributed uniformly over a semi-infinite region bounded by two straight lines. The boundary conditions of the problem may then be said to be conical with respect to the intersection of the two lines, which become "rays" of the canceling conical field. The boundary conditions on the canceling velocity field in this case may be summarized as follows:

- (1) The streamwise velocity u must approach values equal in magnitude and opposite in direction on the upper and lower surfaces of the horizontal plane.
- (2) In the horizontal plane, u must be constant over the infinite sector in which lift is to be canceled.
- (3) The vertical velocity w must be zero in the portion of the $z=0$ plane occupied by the projection of the finite wing.

(4) From equation (5), u must equal zero in the portion of the horizontal plane not covered by conditions (2) or (3).

(5) In supersonic flow there exists the additional condition that all the velocities must go to zero on the Mach cone from the apex of the field.

CANCELLATION OF NONUNIFORM LIFT

The foregoing are the general conditions for a uniformly loaded canceling flow field. Under the proper conditions, a nonuniform distribution of lift may be canceled by the superposition of a number of such fields. This procedure is best explained by a concrete example.

Consider the problem of a swept-back wing flying at a high Mach number such that, as in figure 1 (c), the Mach lines from the leading-edge apex intersect the tips of the wing. The method of deriving the swept-back wing from an infinite triangular wing in that case is indicated in figure 3. It may be noted at the start that, according to linear theory, the lift behind the supersonic trailing edge may be canceled in any way without affecting the velocities on the wing. Thus it remains only to consider the effect of canceling the lift outboard of the tips.

FIGURE 3.—Method of cancellation of lift beyond the tip when the leading-edge Mach line intersects the side edge of the wing.

An infinite triangular wing with supersonic leading edges has a load distribution which is constant over the portions of the wing between the leading edge and the Mach lines from the leading-edge apex (see fig. 4). This constant load may be canceled outboard of each of the tips of the swept-back wing by a single negatively loaded triangle of infinite extent, one side coinciding with the side edge of the wing and a second side coinciding with the extension of the leading edge. However, the area to be removed (region BAC, fig. 3) includes also a region over which the pressure varies, and is conical with respect to A, no one conical solution can satisfy the requirements of the problem. The problem is brought within the limitations of the conical solutions by

FIGURE 4.—Lift distribution on a triangular wing with supersonic leading edges.

considering the lift to be made up of an infinite number of constantly loaded, overlapping sectors of infinite extent. (See fig. 3.) These sectors are bounded on one side by the wing tip; the second side is the extension of a ray from apex 0 of the wing. Between the leading edge ($a=m$) and the leading-edge Mach line ($a=1$), no division of the field is necessary since the lift density is constant in that region.

If a sector with apex at A and angle $\tan^{-1} \frac{m}{\beta}$ is used to cancel this uniform lift, then the remaining superposed fields must be used where $a < 1$ (see fig. 4) to restore the difference between that lift and the loading on the triangular wing.

If u_1 is the streamwise component of the perturbation velocity corresponding to the constant loading ahead of the leading-edge Mach lines, and $u_\Delta(a)$ is the same velocity in the region between the Mach lines, then the magnitude of the u component of the velocity in the initial canceling sector will be $-u_1$, and on the remaining sectors (see fig. 3) minus the increment in $u_1 - u_\Delta$ corresponding to an increment in a , or $\frac{du_\Delta}{da} da$. (Note that this last quantity is positive, as required). To determine the total effect of canceling the loading outboard of the tip, the velocities induced by the latter infinitesimally loaded elements are integrated and added to the negative effect of the initial constant-load sector.

II—LOADING ON WING WITH SUBSONIC LEADING EDGE

LOAD DISTRIBUTION OVER TRIANGULAR WING

In the notation of this paper, the velocity distribution over a flat lifting triangle with leading edge behind the Mach lines may be written

$$u_\Delta = \frac{m u_0}{\sqrt{m^2 - a^2}} \quad (6)$$

where

$$u_0 = \frac{m V \alpha}{\beta E'(m)} \quad (7)$$

is the (constant) velocity along the center line $a=0$. In the expression for u_0 , $E'(m)$ is the complete elliptic integral of the second kind, of modulus $\sqrt{1-m^2}$. The load distribution is obtained from the velocity distribution by equation (5).

SWEPT-BACK WING WITH SUPERSONIC TRAILING EDGE (TIP CORRECTION)²

If the problem is now to find the loading on a swept-back wing with subsonic leading edges, but supersonic trailing edges, only the tip effects will modify the triangular-wing distribution. The calculation of the tip effect on a wing with subsonic leading edge ($m < 1$) is somewhat complicated by the fact that the pressure becomes infinite at the leading edge, but otherwise follows the procedure outlined in the preceding section.

It will first be necessary to present the expression for the previously described conical field with uniformly loaded sector to be used as the element in canceling the lift outboard of the tip.

ELEMENTARY SOLUTION FOR A STREAMWISE TIP

If s is the semispan of the wing, the apex of any element a (see the section on Notation) is at

$$x_a = \frac{\beta s}{a}, \quad y_a = s \quad (8)$$

and, from equation (2),

$$t_a = \beta \frac{y-s}{x - \frac{\beta s}{a}} \quad (9)$$

Then, if u_a is the constant perturbation-velocity component to be canceled over the region between the tip and the extension of the ray a , the previously listed boundary conditions for each of the required canceling fields may be written as follows (see fig. 5):

- (1) and (2) When $0 \leq t_a \leq a$, $u = \pm u_a$ (constant for the field)
- (3) When $t_a < 0$, $w = 0$
- (4) When $t_a > a$, $u = 0$
- (5) When $|t_a| \geq 1$, $u = v = w = 0$.

The solution of the supersonic flow equation satisfying the above boundary conditions has been derived in reference 4.³ In the xy plane, the streamwise component of the velocity is

$$u = \pm r.p. \frac{u_a}{\pi} \cos^{-1} \frac{a + t_a + 2at_a}{t_a - a} \quad (10)$$

The signs refer to the upper and lower surfaces, respectively.

In figure 5, the essential features of the solution are shown. At the top is a detail view of the wing side edge and shows the boundary conditions. In the center is a typical plot of the argument of the inverse cosine in equation (10), against t_a . Where this quantity is less than -1 (i. e., $0 \leq t_a \leq a$), the real part of the inverse cosine is π . Where the argument is greater than $+1$ ($t_a > a$ and $t_a < -1$), the

² Approximate formulas, valid when m is close to 1, have been presented for this case in reference 10.

³ The corresponding solutions for raked-in or raked-out tips may also be found in reference 4, or deduced from later sections in the present report.

FIGURE 5.—Elementary solution for canceling lift at the tip.

real part of the inverse cosine is zero. On the wing ($-1 \leq t_a < 0$), the argument goes from $+1$ to -1 and the inverse cosine is real. Thus in canceling, or subtracting, the velocity u_a between $t_a=0$ and $t_a=a$, the increment in velocity

$$u(x, y, a) = -\frac{u_a}{\pi} \cos^{-1} \frac{a + t_a + 2at_a}{t_a - a} \quad (11)$$

is induced on the wing upper surface.

TIP-INDUCED CORRECTION TO THE LOADING

Following the procedure outlined in Part I, we proceed to determine the effect of canceling the lift outboard of the wing tip. Since the value of u_a for the initial canceling field $-u_a(m)$ and the value for the first incremental field $\frac{du_a}{da} da$ are both infinite when the leading edge is subsonic, it is first necessary to write the induced velocity at a point x, y as

$$(\Delta u)_{tp} = \lim_{a \rightarrow \infty} \left[\frac{-u_{\Delta}(a)}{\pi} \cos^{-1} \frac{a+t_a+2at_a}{t_a-a} + \frac{1}{\pi} \int_{a_0}^a \frac{du_{\Delta}}{da} \cos^{-1} \frac{a+t_a+2at_a}{t_a-a} da \right] \quad (12)$$

where the limit a_0 is the value of a corresponding to the rearmost sector including the point x, y in its Mach cone. The value of a_0 is found by setting t_a (equation (9)) equal to -1 . Thus, for the tip correction,

$$a_0 = \frac{\beta s}{x + \beta(y - s)} \quad (13)$$

This parameter will be additionally useful as the value of a at which the velocity correction given by equation (11) goes to zero and its derivative has a singularity.

Before performing the integration of equation (12), t_a must be replaced by its expression in terms of x , y , and a . Then integration of the second term by parts results in a term which, at the upper limit, exactly cancels the first term, and at the other limit is zero, leaving, after substitution for u_A ,

$$(\Delta u)_{\text{tp}} = \frac{-m(x + \beta y)u_0}{\pi \sqrt{s}} \int_{a_0}^m \frac{\sqrt{a_0(s-y)} da}{(ax - \beta y) \sqrt{(m^2 - a^2)(1+a)(a-a_0)}} \quad (14)$$

This integral is finite and can be evaluated in terms of elliptic integrals as follows:

$$(\Delta u)_{itp=u_0} \left[\sqrt{\frac{m\beta(s-y)}{2(x+\beta y)}} K_0 - \frac{mx}{\sqrt{m^2 x^2 - \beta^2 y^2}} \Lambda_0(k, \psi) \right] \quad (15)$$

where

$$\Lambda_0 = K_0 E(\psi, k') - (K_0 - E_0) F(\psi, k') \quad (16)$$

and K_0 and E_0 are $2/\pi$ times the complete elliptic integrals K and E of modulus

$$k = \sqrt{\frac{(m - a_0)(1 - m)}{2m(a_0 + 1)}}$$

In equation (16), $F(\psi, k')$ and $E(\psi, k')$ are the incomplete integrals with the complementary modulus $k' = \sqrt{1 - k^2}$ and argument

$$\psi = \sin^{-1} \sqrt{\frac{a_0(mx + \beta y)}{\beta s(a_0 + m)}}$$

The functions K_0 , E_0 and Λ_0 are tabulated in reference 11⁴ or may be computed from the tables of reference 12. A plot of Λ_0 is given in figure 6.

Value at the side edge.—At the tip, y is equal to s and the first term in equation (15) vanishes. In the second term, ψ becomes $\pi/2$ and $E(\psi, k')$ and $F(\psi, k')$ reduce to the complete integrals $E' = E(k')$ and $K' = K(k')$, respectively. Then, since, by Legendre's relation,

$$K'E - K'K + KE' = \pi/2$$

Λ_0 reduces to 1. The induced velocity correction is seen to be exactly equal to $-u_\Delta$, bringing the lift to zero at the wing tip.

Drop in lift across tip Mach line.—An interesting effect shows itself at the other limit of the tip region, that is, at the Mach line from the tip of the leading edge. Along this line only the influence of the leading-edge pressure is felt, so that

* The quantity K_0 is called F_0 in reference 11.

FIGURE 6.—The elliptic function $\Delta_0(\psi, k) = K_0 E(\psi, k) - (K_0 - E_0) F(\psi, k)$.

$\alpha_0 = m$. Then $k=0$, $k'=1$, $K=\pi/2$, $E(\psi, k')$ reduces to

$$\sin \psi = \sqrt{\frac{mx + \beta y}{2\beta s}}, \text{ and finally}$$

$$(\Delta u)_{tip} (t_m = -1) \equiv \Delta u^* = \frac{-u_0 \beta s}{\sqrt{2(x + \beta y)(mx - \beta s)}} \quad (17a)$$

or, since along the tip Mach line $\beta(s - y) = x - \frac{\beta s}{m}$,

$$\Delta u^* = \frac{-u_0 \sqrt{m\beta s}}{\sqrt{2(1+m)(mx - \beta s)}} \quad (17b)$$

This result indicates a finite drop in pressure across the Mach line from the tip, an effect which is associated with the cancellation of infinite pressure at the leading edge and consequently does not appear as long as the leading edge is ahead of the Mach lines. The ratio of the drop in lift across the tip Mach line to the uncorrected lift can be written

$$\frac{\Delta u^*}{u_a} = -\sqrt{\frac{(1+a)(m+a)}{2m(1+m)}} \quad (18)$$

This ratio is plotted against a/m in figure 7 and shows the percentage loss of lift at the tip to be very large. In fact, for any but the lowest-aspect-ratio wings, the lift remaining in that region is almost negligible. This effect, which should be of considerable practical interest, was first indicated in the results of reference 13 for the limiting case of $m=0$.

FIGURE 7.—Percent drop in lift across Mach line from tip.

SWEPT-BACK WING WITH SUBSONIC TRAILING EDGE

The tip-effect correction just derived applies equally to wings with supersonic or subsonic trailing edges. The effect of a subsonic trailing edge is calculated separately, and is primarily due to canceling the triangular-wing loading in the wake region. If, however, the triangular-wing loading

has been modified by the introduction of side edges, then this modification must also be taken into account when canceling the lift behind the trailing edge. In the conical-flow method, the various component flow fields must be canceled individually. The sections immediately following will discuss the cancellation of the triangular-wing loading; cancellation of the tip-induced components of velocity will be considered under the heading "Secondary Corrections."

PRIMARY TRAILING-EDGE CORRECTIONS

Procedure for canceling lift in the wake region.—The basic procedure is again to consider the load to be canceled to be built up by the superposition of uniformly loaded sectors, bounded on one side (see fig. 8) by the rays a , and on the other by the trailing edge of the wing. It is convenient at this point to introduce the parameter

$$m_t = \beta \times \cot (\text{angle of sweep of trailing edge})$$

FIGURE 8.—Oblique constant-lift element (shaded) for cancellation of lift at subsonic trailing edge, and induced velocity distribution.

The boundary conditions to be satisfied by the u component of the elementary canceling velocity field are indicated for the right span in figure 8; each field must have constant velocity u_a when $a \leq t_a \leq m_t$ and zero streamwise velocity over the wake region, $-1 \leq t_a < a$. The concomitant vertical velocity must be zero on the wing surface. However, when a is small, the region $-1 \leq t_a < a$ will include a portion of the left-hand wing panel. Since in this region the u component of velocity has already been specified, the vertical velocity

will not, in general, be zero. Nor is it possible to modify the field to satisfy the boundary condition on the far wing, since the area involved is not conical with respect to the apex of the field.

The error involved in the foregoing procedure is minimized by the use of a symmetrical flow field to cancel the initial load u_0 at $a=0$, where a single conical field can be made to satisfy the boundary conditions exactly on both wing panels. This flow field (see fig. 9) would have its origin at the apex $c_0, 0$ of the trailing edge, and the constant-load region would extend over the entire wake region. Between the trailing edge of the wing and the Mach lines from $c_0, 0$ the induced downwash would be zero in the plane of the wing, while the pressure would vary as required to satisfy the fundamental flow equations.

In figure 9, a typical curve of u_Δ is shown, from which it can be seen that the load to be canceled is very nearly constant over a considerable fraction of the wake region. Cancellation of the velocity u_0 by the symmetrical field will consequently leave only a small variation in u to be canceled by the oblique fields described earlier in the section. The resulting violation of the flat-plate condition may be expected to be small,⁵ and will take place only over a small region near the tip of the trailing edge.

FIGURE 9.—Symmetrical field for cancellation of u_0 at subsonic trailing edge.

⁵ Calculations made to check this statement have shown the induced downwash angles to be less than 0.5 percent of the angle of attack, even in the most unfavorable circumstances.

Symmetrical solution.—For the symmetrical solution we define the conical variable

$$t_0 = \frac{\beta y}{x - c_0} \quad (19)$$

which is zero along the center line of the wing and equals $\pm m_t$ at either trailing edge. Then the boundary conditions to be satisfied in the xy plane may be summarized as follows:

$$\begin{aligned} -m_t \leq t_0 \leq +m_t, \quad u &= \pm u_0 \\ m_t < |t_0| \leq 1 \quad w &= 0 \end{aligned}$$

The required solution is given in reference 14. The u component in the xy plane is

$$r. p. \frac{\pm u_0}{K'(m_t)} F(\phi, \sqrt{1 - m_t^2})$$

where $K'(m_t)$ is the complete elliptic integral of the first kind of modulus $\sqrt{1 - m_t^2}$ and $F(\phi, \sqrt{1 - m_t^2})$ is the corresponding incomplete integral of argument

$$\phi = \sin^{-1} \sqrt{\frac{1 - t_0^2}{1 - m_t^2}}$$

The form of the induced velocity on the wing (see fig. 9) is very similar to the inverse cosine curves of the tip solutions.

On the wing, ϕ is real and the symbols $r. p.$ may be omitted. The velocity induced on the upper surface by cancellation of u_0 behind the trailing edge is therefore

$$(\Delta u)_0 = -\frac{u_0}{K'(m_t)} F(\phi, \sqrt{1 - m_t^2}) \quad (20)$$

Oblique solutions for the wake region.—The symbol t_a will be used as before to indicate a ray of the flow field with apex at x_a, y_a , the point of intersection of the ray a with the wing boundary—in this case the trailing edge. Along the trailing edge,

$$y_a = \frac{m_t}{\beta} (x_a - c_0)$$

Since $a = \beta (y_a/x_a)$, we may solve for x_a and y_a as functions of a and the constants m_t and c_0 :

$$x_a = \frac{m_t c_0}{m_t - a} \quad (21)$$

$$\beta y_a = \frac{m_t c_0 a}{m_t - a} \quad (22)$$

Then

$$t_a = \frac{\beta y (m_t - a) - m_t c_0 a}{x (m_t - a) - m_t c_0} \quad (23)$$

The boundary conditions to be satisfied by the elementary solution are (for $a > 0$)

$$a \leq t_a \leq m_t \quad u = \pm u_a$$

$$m_t < t_a \leq +1 \quad w = 0$$

$$-1 \leq t_a < a \quad u = 0$$

The solution satisfying these conditions may be obtained from the tip solutions by an oblique transformation. (See reference 4.) In the xy plane, the resulting expression for the u component is

$$r \cdot p \pm \frac{u_a}{\pi} \cos^{-1} \frac{(1-a)(t_a-m_t)-(m_t-a)(1-t_a)}{(1-m_t)(t_a-a)}$$

Then the velocity induced at any point x, y on the upper surface of the wing by the cancellation of the infinitesimal increment of perturbation velocity u_a over the sector bounded by the ray a and the trailing edge is

$$\frac{d\Delta u}{da} da = (\Delta u)_a = \frac{-u_a}{\pi} \cos^{-1} \frac{(1-a)(t_a-m_t)-(m_t-a)(1-t_a)}{(1-m_t)(t_a-a)} \quad (24)$$

Correction of loading near the trailing edge.—To determine the lift at any point x, y near the trailing edge of the wing, it is first necessary to determine the most rearward canceling sector a_0 that will influence that point. Setting t_a (equation (23)) equal to 1, we solve for

$$a_0 = m_t \frac{x - \beta y - c_0}{x - \beta y - m_t c_0} \quad (25)$$

Then the total correction to the triangular-wing velocity u_Δ obtained as a result of canceling that velocity behind the trailing edge is

$$(\Delta u)_{T.E.}(x, y) = (\Delta u)_0 + \int_0^{a_0} \frac{d\Delta u}{da} da \quad (26a)$$

The integral in the foregoing expression has been evaluated in terms of an incomplete elliptic integral of the third kind, which may be computed with the aid of the tables of references 11 and 15. Because it will be necessary to define several new functions it was thought better to present the results in an appendix (appendix B). For practical use, graphical or numerical integration may be preferred, in which case a convenient form is obtained by rewriting u_a as $(du_\Delta/da) da$, or du_Δ , in equation (24). Thus equation (26a) becomes

$$(\Delta u)_{T.E.}(x, y) = (\Delta u)_0 -$$

$$\frac{1}{\pi} \int_{u_0}^{u_\Delta(a_0)} \cos^{-1} \frac{(1-a)(t_a-m_t)-(m_t-a)(1-t_a)}{(1-m_t)(t_a-a)} du_\Delta \quad (26b)$$

where t_a and u_Δ must be evaluated for selected values of a between zero and a_0 . The integrand, of course, goes to zero at $u_\Delta(a_0)$. At points along the leading edge (in cases in which the leading edge extends into the zone of influence of the trailing edge), the integral takes on a somewhat simpler form, with the result that the entire trailing-edge correction at such points can be written

$$(\Delta u)_{T.E.}\left(x, \frac{mx}{\beta}\right) = -u_0 \left\{ \frac{F(\phi, \sqrt{1-m_t^2})}{K(\sqrt{1-m_t^2})} - \frac{1}{\pi} \cos^{-1} \frac{(t_0-m_t)-m_t(1-t_0)}{(1-m_t)t_0} + \frac{1}{\pi} \sqrt{\frac{2(t_0-m_t)}{(1-m_t)(1-m_t)t_0}} \left[F(\psi, k) - \frac{1-a_0}{m-a_0} E(\psi, k) \right] \right\} \quad (26c)$$

where the first term inside the braces is $\frac{(\Delta u)_0}{u_0}$ and, in the last term,

$$\psi = \sin^{-1} \sqrt{\frac{2a_0}{m+a_0}}$$

and

$$k = \sqrt{\frac{(1-m)(m+a_0)}{2m(1-a_0)}}$$

SECONDARY CORRECTIONS

The term "secondary corrections" is used here to designate the effect of canceling the lift introduced outside the boundaries of the wing in the process of canceling the original triangular-wing loading beyond the tips and behind the trailing edge. As previously mentioned, cancellation of lift at the tip introduces new (negative) components of lift to be canceled at the trailing edge. The original cancellation of lift behind the trailing edge, on the other hand, will introduce negative incremental pressures outboard of the tip and, under certain circumstances (see figs. 1 (a) and (b)), ahead of the leading edge. The distribution of lift to be canceled in each case is no longer part of a single conical field, but is composed of an infinite number of superposed conical fields originating at various points along the trailing edge or tip. In order to cancel these pressures accurately, it would be necessary to set up, for each of the original canceling elements, an infinity of positively loaded elements at the opposite boundary. Thus, each secondary correction would require a double integration for each point, and would obviously be quite tedious. The procedure is described in detail in references 7 and 8. The more recent work of Mirels (reference 5) offers an alternative method which, while no less tedious at the computational state, is somewhat easier to set up for computing. Nevertheless, the exact calculation of the secondary corrections, and of the succeeding corrections arising as the secondary corrections are in turn canceled at the opposite edges, appears feasible only with the aid of high-speed computing machinery.

These corrections may be thought of as a converging series, since in each case (except in the neighborhood of the leading edge) the induced effect is smaller than the canceled lift. Over most of the wing, the secondary correction is of the same order of magnitude as the tolerable error. Formulas for obtaining a major part of the secondary corrections can be given rather simply and should suffice to give results of practical accuracy in problems (fig. 1(c)) not involving leading-edge corrections. Problems of the type shown in figure 1(b) will be discussed in a later section.

Secondary corrections at the trailing edge.—The pressure differences induced by the tip are in the main due to cancellation of the infinite pressure at the leading edge. It should therefore be permissible, for the secondary corrections, to approximate the tip-correction field by a single conical field from the leading-edge tip. The lift associated with this field may then be canceled behind the wing (see fig. 10) by a single infinity of superposed fields, as was the original triangular-wing loading. If the values of $(\Delta u)_{tt}$ calculated for points x_b, y_b along the trailing edge are assumed to apply all along the corresponding rays $t_m(x_b, y_b)$ from the tip, then the

FIGURE 10.—Sketch for approximate cancellation of extraneous lift introduced behind the leading edge by the tip correction.

lifting pressure will be exactly canceled along the trailing edge and the remaining variation of pressure in the wake will have very little effect on the flow over the wing.

The cancellation fields are of the previously used oblique type, with a replaced by

$$t_m = \frac{\beta(y_b - s)}{x_b - \frac{\beta s}{m}} \quad (27)$$

Let the particular point at which the line $t_m = -1$ intersects the trailing edge be designated by x^*, y^* and other symbols referring to that point be similarly starred. Then the velocity induced at any point x, y on the wing by removal of $(\Delta u)_{tp}$ along the trailing edge will be (from equation (24))

$$\frac{-\Delta u^*}{\pi} \cos^{-1} \frac{2(t^* - m_i) - (m_i + 1)(1 - t^*)}{(1 - m_i)(t^* + 1)} - \frac{1}{\pi} \int_{-1}^{t_m(x_0, y_0)} \frac{d(\Delta u)_{tp}}{dt_m} \cos^{-1} \frac{(1 - t_m)(t_b - m_i) - (m_i - t_m)(1 - t_b)}{(1 - m_i)(t_b - t_m)} dt_m \quad (28)$$

where Δu^* is given by equation (17), t^* and t_b are calculated by

$$t^* = \frac{\beta(y - y^*)}{x - x^*} \quad (29)$$

and

$$t_b = \frac{\beta(y - y_b)}{x - x_b} \quad (30)$$

respectively, and x_0, y_0 is the point of intersection of the Mach forecone from x, y with the trailing edge.

The derivative $\frac{d}{dt_m} (\Delta u)_{tp}$ would have to be determined numerically or graphically from a plot of the calculated values of $(\Delta u)_{tp}$ against t_m . In order to avoid this procedure, it is preferable to rewrite expression (28) as

$$\frac{-\Delta u^*}{\pi} \cos^{-1} \frac{2(t^* - m_i) - (m_i + 1)(1 - t^*)}{(1 - m_i)(t^* + 1)} - \frac{1}{\pi} \int_{\Delta u^*}^{(\Delta u)_{tp}(x_0, y_0)} \cos^{-1} \frac{(1 - t_m)(t_b - m_i) - (m_i - t_m)(1 - t_b)}{(1 - m_i)(t_b - t_m)} d(\Delta u)_{tp} \quad (31)$$

and integrate by plotting the inverse cosine function against $(\Delta u)_{tp}$.

As long as the aspect ratio of the wing is greater than $1/\beta$ (a condition already imposed by the exclusion of the problem shown in fig. 1 (a)), Δu^* will be more than half $(\Delta u)_{tp}$ at any other point on the trailing edge. Since, moreover, the integral term in equation (31) has zero slope at the Mach cone ($t^* = 1$), while the first term starts with infinite slope, it is apparent that the secondary correction may be simplified still further by omitting the calculation of the integral. For points near the trailing edge, the loading can usually be faired to zero with sufficient accuracy.

Secondary correction at the tip.—A similar method of approximating the secondary correction at the tip cannot be formulated with equal confidence. Since, however, over most of the wing the symmetrical correction $(\Delta u)_o$ contributes the larger part of the total subsonic-trailing-edge effect, it will again be assumed that the entire effect constitutes a single conical field, with its apex at $c_0, 0$. The u velocity along each ray t_0 will have the value $(\Delta u)_{T.E.}(x_b, s)$ of the trailing-edge correction at the intersection x_b, s of the ray with the tip. The canceling fields will have the same form as those (equation (10)) used in deriving the primary tip correction, and the total approximate correction to the u velocity will be

$$-\frac{1}{\pi} \int_{t_0=1}^{(\Delta u)_{T.E.}(x_0, s)} \cos^{-1} \frac{t_0 + t_b + 2t_0 t_b}{t_b - t_0} d(\Delta u)_{T.E.} \quad (32)$$

in which

$$t_b = \frac{\beta(y - s)}{x - x_b} \quad (33)$$

x_0 is the value of x_b which makes $t_b = -1$, and $(\Delta u)_{T.E.}$ is calculated for $x = x_b, y = s$ by equation (26b).

NUMERICAL EXAMPLE

Before proceeding to consider the problem of interaction between the leading and trailing edges, which introduces some radically different effects, the results so far obtained will be illustrated by a numerical example. The loading over an untapered wing, with $\beta \cot \Lambda = 0.6$ and reduced aspect ratio $\beta A = 1.92$, has been calculated at four spanwise stations: 25-, 50-, 75-, and 95-percent semispan. The wing plan form and section lift distributions are shown in figure 11.

 FIGURE 11.—Load distributions calculated for four streamwise sections of an untapered wing; $m=0.6$; $BA=1.92$.

The results of the calculations are presented in the form of values of $\beta(\Delta p/q\alpha)$ (equation (5)).

The various components of lift are presented separately as calculated. In figures 11 (a) and (b), the discontinuities in slope show the effect of the cancellation of the finite velocity u_0 at the trailing-edge apex. The integrated part of the trailing-edge correction (component 2) has zero slope at the Mach line. The two outboard sections (figs. 11 (c) and (d)) are intersected by the Mach cone from the tip, as indicated by the finite drop in the load curves. Cancellation of the finite tip effect at the trailing edge (component 4 in both figures) results in a sharp discontinuity in pressure gradient along the reflected Mach line, at 91-percent chord at $y/s=0.75$ and at 78-percent chord when $y/s=0.95$. The cancellation of the trailing-edge corrections at the tip, which affects only the last section shown, results in another break in the load curve at 49-percent chord. Further corrections enter at the rear of the section as a result of successive cancellations of the superposed pressures at the tip and trailing edge. Their effect has been only estimated.

SWEPT-BACK WINGS WITH INTERACTING TRAILING AND LEADING EDGES

When, as in figure 1 (b), the Mach cone from the trailing-edge apex includes a region ahead of the leading edge, the previously calculated trailing-edge corrections to u must be canceled in that region, since they represent a discontinuity in pressure which cannot be supported in the free stream. Thus there must be calculated a leading-edge correction, which is one of the previously defined secondary corrections. However, the location of the disturbed field ahead of the wing causes its influence on the wing to be so much more widespread than that of the other secondary corrections as to require more careful consideration. A new type of flow field is also required, as discussed in the following paragraphs.

LEADING-EDGE CORRECTIONS

Elementary solution for the region ahead of the leading edge.—In general, the elementary solution required for the cancellation of pressure in the plane of the wing ahead of the leading edge is one that:

1. Provides constant streamwise velocity over an infinite sector bounded on one side by the leading edge of the wing (extended) and on the other by an arbitrary ray extending outward into the stream from some point x_b, y_b on the leading edge. (See fig. 12.)
2. Induces no vertical velocity, or downwash, on the wing.
3. Induces no lift except on the wing and within the sector described in condition 1.

At first glance these conditions would appear to be satisfied by the oblique solutions used at the trailing edge, if properly oriented with respect to the wing, and the same form of solution might be expected to apply. In reference 4, however, it has been pointed out that the downwash connected with the latter solution remains constant over the wing only if the wing area does not include the line $y=\text{constant}$ extending downstream from the apex of the element. In the case of the leading-edge element this condition is violated (fig. 12) and an additional term is needed to bring the downwash to zero throughout the area of the wing affected by the element.

FIGURE 12—Leading-edge element and induced-velocity function.

The solution applicable to this case has been given in reference 4. The u component of the velocity in the plane of the wing is as follows:

$$u = r \cdot p \cdot \frac{u_b}{\pi} \left[\cos^{-1} \frac{(t_a - m)(1 + t_b) - (m - t_b)(1 + t_a)}{(1 + m)(t_b - t_a)} - \frac{2m}{(1 + m)t_a} \sqrt{(t_a - m)(1 + t_a)} \sqrt{\frac{1 + t_b}{m - t_b}} \right] \quad (34)$$

where u_b is the constant streamwise perturbation velocity over the element, and t_b refers as before to a ray from its apex. The ray bounding the element originates at a point on the trailing edge and has been designated, from equation (24), as t_a . When the correction is being made for the symmetrical trailing-edge element, t_a is replaced in equation (34) by t_0 .

For brevity, the two parts of the correction function will be referred to as

$$C(t_a) = r \cdot p \cdot \cos^{-1} \frac{(t_a - m)(1 + t_b) - (m - t_b)(1 + t_a)}{(1 + m)(t_b - t_a)} \quad (35)$$

and

$$R(t_a) = r \cdot p \cdot \frac{-2m}{(1 + m)t_a} \sqrt{(t_a - m)(1 + t_a)} \sqrt{\frac{1 + t_b}{m - t_b}} \quad (36)$$

The variation with t_b of these functions and the induced velocity (equation (34)) are illustrated in figure 12.

Leading-edge correction to the loading.—The single conical field of $(\Delta u)_0$ will be considered first. (See fig. 13.) The velocity field to be superposed ahead of the leading edge to cancel the velocity $(\Delta u)_0$ induced in the plane of the wing by the symmetrical solution (equation (20)) can be built up, as shown in figure 13, of overlapping constant-velocity sec-

FIGURE 13—Cancellation of the pressure field introduced ahead of the leading edge in the course of canceling u_0 behind the trailing edge.

tors having one edge along the leading edge of the wing and one along the extended ray t_0 from the apex of the trailing edge. The magnitude of the constant velocity on each element is $\frac{d(\Delta u)_0}{dt_0} dt_0$ or, from equation (20),

$$\frac{u_0 dt_0}{K'(m_i) \sqrt{(1-t_0^2)(t_0^2-m_i^2)}} \quad (37)$$

Applying equation (34) to the cancellation of the symmetrical-correction velocities $(\Delta u)_0$ ahead of the wing results in the following induced velocity increment at any point (x, y) on the wing:

$$(\Delta_2 u)_0 = \frac{1}{\pi} \int_{\tau_0}^1 \frac{d(\Delta u)_0}{dt_0} [C(t_0) + R(t_0)] dt_0 \quad (38)$$

where τ_0 is that value of t_0 for which $t_0 = -1$, and designates the most rearward leading-edge element containing the point x, y within its Mach cone. In terms of x and y ,

$$\tau_0 = \frac{m(x+\beta y)}{(x+\beta y) - (1+m)c_0} \quad (39)$$

Integration of $\frac{d(\Delta u)_0}{dt_0} C(t_0) dt_0$ is not feasible by elementary means. For graphical integration it is advisable to rewrite $\frac{d(\Delta u)_0}{dt_0} dt_0$ as $d(\Delta u)_0$ to avoid the infinite value of the derivative at $t_0 = 1$.

The second term of the product in equation (38) can be integrated in closed form as follows:

$$\int_{\tau_0}^1 \frac{d(\Delta u)_0}{dt_0} R(t_0) dt_0 = \frac{-4m^{3/2}u_0 K(k)}{m_i(1+m)K'(m_i)} \sqrt{\frac{x+\beta y}{mx-\beta y}} Z(\psi, k) \quad (40)$$

where

$$k = \sqrt{\frac{2m_i(1-\tau_0)}{(1-m_i)(\tau_0+m_i)}}$$

and

$$Z(\psi, k) = E(\psi, k) - \frac{E(k)}{K(k)} F(\psi, k) \quad (41)$$

with

$$\psi = \sin^{-1} \sqrt{\frac{\tau_0+m_i}{2\tau_0}}$$

The function $Z(\psi, k)$ is tabulated in reference 16; a plot of $\frac{Z(\psi, k)}{k \sin \psi}$ against ψ is given in figure 14.

Similarly, for each oblique trailing-edge element a (see fig. 15), a canceling field can be built up ahead of the leading edge by the superposition of sectors bounded by the leading edge and by rays t_a from the apex x_a, y_a of the element a , and having a constant velocity of the magnitude

$$\frac{\partial(\Delta u)_a}{\partial t_a} dt_a = -\frac{1}{\pi} u_a \frac{\partial}{\partial t_a} \cos^{-1} \frac{(1-a)(t_a-m_i)-(m_i-a)(1-t_a)}{(1-m_i)(t_a-a)} dt_a \quad (42)$$

(from equation (24)). If the symbol $\Delta u_{L.E.}$ is used to designate the total leading-edge correction to the u component of velocity at any point, then the part due to canceling the field of a single oblique trailing-edge element a is

$$\frac{d\Delta u_{L.E.}}{da} da = \frac{1}{\pi} \int_{\tau_a}^1 \frac{\partial(\Delta u)_a}{\partial t_a} [C(t_a) + R(t_a)] dt_a \quad (43)$$

where

$$\tau_a = \frac{m(m_i-a)(x+\beta y) - m_i c_0(1+m)a}{(m_i-a)(x+\beta y) - m_i c_0(1+m)} \quad (44)$$

is the value of t_a for which $t_a = -1$ and the leading-edge correction function vanishes.

When the expression (equation (42)) for $\frac{\partial(\Delta u)_a}{\partial t_a}$ is substituted in equation (43), it is again impractical to attempt to write a closed expression for the integral of the first term $\frac{\partial(\Delta u)_a}{\partial t_a} C(t_a)$ of the product. The integral of the second term is

$$\begin{aligned} \int_{\tau_a}^1 \frac{\partial(\Delta u)_a}{\partial t_a} R(t_a) dt_a = & \\ & \frac{-4m}{\pi(1+m)} \frac{u_a}{a} \sqrt{\frac{(m_i-a)(1-m)(x+\beta y) - m_i c_0(1+m)(1-a)}{(1-m_i)(mx-\beta y)}} \times \\ & K(k_a) \left[\sqrt{1+a} \frac{Z(\psi_a, k_a)}{k_a \sin \psi_a} - \sqrt{1-a} \frac{Z(\psi_0, k_a)}{k_a \sin \psi_0} \right] \quad (45) \end{aligned}$$

FIGURE 14.—The elliptic function $\frac{Z(\psi, k)}{k \sin \psi}$

where

$$k_a = \sqrt{\frac{(1+m_i)(1-\tau_a)}{(1-m_i)(1+\tau_a)}}$$

$$\psi_a = \sin^{-1} \sqrt{\frac{(m_i-a)(1+\tau_a)}{(\tau_a-a)(1+m_i)}}$$

$$\psi_0 = \sin^{-1} \sqrt{\frac{m_i(1+\tau_a)}{\tau_a(1+m_i)}}$$

FIGURE 15.—Cancellation of the pressure field introduced ahead of the leading edge by a single oblique trailing-edge element.

Then the total leading-edge correction to the velocity u at any point x, y is

$$(\Delta u)_{L.E.} = (\Delta_2 u)_0 + \int_0^{a_0'} \frac{d(\Delta u)_{L.E.}}{da} da \quad (46)$$

where $(\Delta_2 u)_0$ is obtained from equations (38) and (40), $\frac{d(\Delta u)_{L.E.}}{da}$ from equations (43) and (45), and

$$a_0' = \frac{(1+m)c_0 - (1-m)(x+\beta y)}{(1+m)m_i c_0 - (1-m)(x+\beta y)} m_i \quad (47)$$

is the value of a at which $\tau_a(x, y, a)$ (equation (44)) is equal to 1.

The last term in equation (46) will seldom be found to contribute any significant amount to the loading, but will be needed in calculating the leading-edge thrust.

FURTHER CORRECTIONS

Omitting for the moment any specification of tip location, it is in any case necessary, as seen in figure 12, to consider the effect of a further cancellation necessitated by the excess

lift introduced behind the trailing edge by the leading-edge cancellation field. To compute this effect by the conical-flow method would be feasible only with the aid of high-speed computing machinery. The previously mentioned cancellation method of reference 5, being more direct, would be somewhat easier to use in this connection, but the calculations would still be very lengthy. It will be shown by numerical example that the effect of the first cancellation at the trailing edge of the leading-edge correction, which is initially quite small, may be estimated with adequate accuracy when the section loading is considered as a whole, provided the fraction of the chord affected is not too large.

If the product $\beta \cot \Lambda$ is low or the aspect ratio high, still further cancellations will be required (see fig. 16) at both leading and trailing edges. It is clear that calculation of the effect of these further cancellations by the conical-flow method is all but impossible. The doublet-distribution method of reference 5 does not appear to offer any considerable advantage in this application since, in canceling lift ahead of a subsonic leading edge, it is necessary to find not only the pressure distribution to be canceled, but the associated sidewash distribution as well.

It is apparent that an alternative method must be sought for describing the flow in the outboard regions of a high-aspect-ratio wing or a wing the sweep of which is large compared to the sweep of the Mach line. If the wing could be

FIGURE 16.—Plan view of central portion of high-aspect-ratio wing, showing pattern of Mach lines arising at leading and trailing edges.

extended indefinitely, it is known that the flow must eventually approach the two-dimensional subsonic flow, in accordance with simple sweep theory. The question then arises, can the flow at a distance of the order of a semispan from the apex of the swept-back wing be related to the two-dimensional asymptotic flow? While the flow field appears to be too complex to obtain an answer to this question on analytical grounds, numerical values, presented in the following paragraph, suggest a practical approach.

NUMERICAL RESULTS (WITHOUT TIP EFFECT)

Load distributions have been calculated by the conical-flow method for three combinations of taper, sweep, and Mach number as follows:

	Untapered		Tapered
$m =$	0.2	0.4	0.4
$m_t =$	0.2	0.4	0.6

These values of m and m_t represent, by virtue of the Prandtl-Glauert transformation, a variety of sweep angles at Mach numbers between 1 and 2; as for example, 0.2 would be the value of m for a wing with 63° sweep of the leading edge at a Mach number of 1.075, or 75° sweep at a Mach number of

1.25. Similarly, $m=0.4$ would correspond to 45° of sweep at $M=1.08$, 60° at $M=1.22$, or 75° at $M=1.80$. The trailing-edge sweep angles at these latter Mach numbers, if $m_t=0.6$, are $34^\circ 13'$, 49° , and 68° , respectively.

Figure 17 presents the lift distributions at two stations of the tapered wing. Each component is plotted independently in order to show the magnitudes at the leading edge. Section A-A contains the intersection of the trailing-edge Mach line with the leading edge, so that the value of the leading-edge correction is zero at the leading edge of this section. At points farther back along the leading edge, as at $\beta y/c_0=0.8$, the correction is minus infinity. However, it is seen to increase to a small positive value within a fraction of the chord length at this station.

At both stations it is necessary to estimate the effect of cancellation of the leading-edge correction at the trailing edge to satisfy the Kutta condition. Cancellation would be carried out by means of oblique elements of the type used previously (equation (24)) in canceling lift at the trailing edge. The pressure to be canceled is initially (i. e., at x_2, y_2 (fig. 16)) zero. Then the lift induced on the wing by this cancellation may be presumed to have the same general shape as the oblique trailing-edge correction of figure

FIGURE 17.—Load distributions calculated by the conical-flows method for two streamwise sections of a tapered swept-back wing; $m=0.4$; $m_t=0.6$.

 FIGURE 18.—Load distributions calculated by the conical-flows method for two streamwise sections of an untapered wing; $m=0.4$.

11, falling along a modified inverse cosine curve from the value of the error at the trailing edge to zero, with zero slope, at the boundary of the region affected. With this boundary (the Mach line from the point x_2, y_2), it is possible to draw a satisfactory estimate (dotted curve) of the correction needed to bring the pressure once more to zero at the trailing edge.

The untapered wing with the same sweep ($m=0.4$) relative to the Mach lines is shown in figure 18, with the load distributions calculated at the same stations.

Four section lift distributions are presented (fig. 19) for $m=0.2$. At $\frac{\beta y}{c_0}=0.15$ only the rear 60 percent is influenced by the subsonic trailing edge. The reflection of this influence at the leading edge alters the pressure over the rear 40 percent of the section. At section B-B, the leading- and trailing-edge interaction affects the entire section. A further reflection of this effect at the trailing edge must be estimated.

At section C-C the influence of cancellation of the leading-edge correction at the trailing edge extends over the whole of the chord and any estimate of its magnitude would be necessarily arbitrary. Also, a second pair of reflections must be taken into account. The final pressure distribution has therefore been drawn as a band within which the true

curve may be shown to lie. Its height is the error introduced at the trailing edge by the first leading-edge correction, except very near the leading edge, where an infinite negative correction is known to be introduced by the second leading-edge correction. The calculations were also carried out for $\beta y/c_0=0.45$. The margin of uncertainty was found not to have increased by any appreciable amount. (See fig. 19 (d).)

APPLICATION OF TWO-DIMENSIONAL FORMULAS TO CALCULATION OF LOAD DISTRIBUTION

Correlation of two-dimensional and swept-back-wing loadings.—It is apparent from the calculated results that, whenever the plan form and the Mach number are such that the trailing-edge Mach line intersects the leading edge, the load distribution behind the Mach lines from the point of intersection resembles in shape the theoretical load distribution over an infinitely long flat plate in incompressible flow. However, as the results have been plotted, the quantitative agreement is not good, particularly in the case of the tapered wing. On the other hand, if the load distributions in cross sections normal to the stream are examined, a near proportionality of the curves is observed. In order to determine the factor of proportionality, it is only necessary to find the ratio of the strengths of the singularities at the

FIGURE 19.—Load distributions calculated by the conical-flows method for four streamwise sections of an untapered wing; $m=0.2$.

leading edge. Then an approximate expression for the loading on the outer portions of a high-aspect-ratio wing can be obtained by adjusting the two-dimensional loading by that factor.

Both the swept-back-wing and the subsonic two-dimensional loadings approach infinity as the reciprocal of the square root of the distance to the leading edge. In sections normal to the stream, the distance from any point x, y to the leading edge may be written $\frac{1}{\beta}(mx - \beta y)$. The value at the leading edge of the coefficient of $(mx - \beta y)^{-1/2}$ will be referred to as the strength of the leading-edge singularity.

The subsonic two-dimensional perturbation velocity has the form

$$u = B \sqrt{\frac{1-\eta}{\eta}} \quad (48)$$

where η is the distance to the leading edge, expressed as a fraction of the chord, and B is a constant. If the section of the swept-back wing is taken perpendicular to the stream (x constant), the chord length is

$$\frac{1}{\beta} [mx - m_i(x - c_0)] \quad (49)$$

and

$$\eta = \frac{mx - \beta y}{mx - m_i(x - c_0)} \quad (50)$$

Substitution for η in equation (48) gives

$$u = B \sqrt{\frac{\beta y - m_i(x - c_0)}{mx - \beta y}} \quad (51)$$

Then the strength of the leading-edge singularity in u is

$$B \sqrt{mx - m_i(x - c_0)} \quad (52)$$

The leading-edge singularity in the loading on the swept-back wing is initially (region I, fig. 16) that in the triangular-wing loading. Introduction of the leading-edge corrections to the load, in region II, reduces the strength of the singularity there through the terms $R(t_0)$ and $R(t_a)$. (The inverse-cosine function is always finite.) The coefficient of $(mx - \beta y)^{-1/2}$ in u_Δ is, from equation (6),

$$\frac{mxu_0}{\sqrt{mx + \beta y}}$$

reducing to

$$C_\Delta = u_0 \sqrt{\frac{mx}{2}} \quad (53)$$

at the leading edge.

From equations (40) and (45), decrements to this coefficient may be derived for the portion of the leading edge just behind the intersection x_1, y_1 with the trailing-edge Mach line, as follows:

$$(\Delta C)_0 = \frac{-4mu_0K(k)}{\pi m_i K'(m_i)} \sqrt{\frac{mx}{1+m}} Z(\psi, k) \quad (54)$$

and, for each value of a from 0 to that value a_0' which makes τ_a equal to one,

$$\frac{d\Delta C}{da} da = \frac{-4m}{\pi^2 \sqrt{1+m}} \frac{u_a}{a} \sqrt{\frac{(m_i - a)x - (1-a)m_i c_0}{1-m_i}} K(k_a) \times \left[\sqrt{1+a} \frac{Z(\psi_a, k_a)}{k_a \sin \psi_a} - \sqrt{1-a} \frac{Z(\psi_0, k_a)}{k_a \sin \psi_0} \right] \quad (55)$$

where τ_0 (equation (39)) and τ_a (equation (44)) reduce to

$$\tau_0 = \frac{mx}{x - c_0}$$

and

$$\tau_a = \frac{(m_i - a)mx - m_i c_0 a}{(m_i - a)x - m_i c_0}$$

and the arguments and moduli of the elliptic integrals follow as for equations (40) and (45).

The coefficient of $(mx - \beta y)^{-1/2}$ at the leading edge is, therefore, in region II, figure 16,

$$C_\Delta + (\Delta C)_0 + \int_0^{a_0'} \frac{d\Delta C}{da} da \quad (56)$$

with a_0' reducing to

$$a_0' \left(x, \frac{m}{\beta} x \right) = m_i \frac{c_0 - (1-m)x}{m_i c_0 - (1-m)x} \quad (57)$$

Equating the two coefficients, expressions (56) and (52), gives for any one section

$$B = \frac{1}{\sqrt{mx - m_i(x - c_0)}} \left[C_\Delta + (\Delta C)_0 + \int_0^{a_0'} \frac{d\Delta C}{da} da \right] \quad (58)$$

For convenience, a nondimensional coefficient

$$\sigma(x) = \frac{1}{V\alpha\sqrt{c_0}} \left[C_\Delta + (\Delta C)_0 + \int_0^{a_0'} \frac{d\Delta C}{da} da \right] \quad (59)$$

is defined, so that

$$B = V\alpha \frac{\sigma(x)\sqrt{c_0}}{\sqrt{mx - m_i(x - c_0)}}$$

By substituting for B in equation (51), the loading on the outer portions of a swept-back wing is obtained as

$$\frac{u}{V\alpha} = \sigma(x) \sqrt{\frac{c_0[\beta y - m_i(x - c_0)]}{[mx - m_i(x - c_0)](mx - \beta y)}} \quad (60)$$

Numerical results.—The closeness with which the foregoing procedure predicts the theoretical loading over swept-back wings is indicated by figures 20, 21, and 22, where the previously calculated load distributions are compared with those calculated by equation (60). Even in the case of the highly tapered wing, the agreement is seen to be good. At the most inboard section of the $m=0.2$ wing (fig. 19 (a)) there is, of course, no agreement over that portion, forward of the 60-percent-chord point, where the flow is essentially conical. At station B-B, however, the agreement is very good. At sections C-C and D-D, where the exact theoretical

FIGURE 20.—Load distributions on the tapered wing as calculated by the conical-flows method, compared with the two-dimensional approximation.

loading had not been determined, the two-dimensional-type loading lies within the band prescribed by the conical-flow calculations. Since the discrepancy between the corrected two-dimensional loading and the exact theoretical distribution is already, at section B-B (fig. 22 (b)), less than the width of the bands in figures 22 (c) and (d) and must diminish to zero at infinity, it may be supposed that the corrected two-dimensional curve is at least as satisfactory an approximation to the correct curves at sections C-C and outboard as at section B-B. It is probably more satisfactory than can be obtained by a limited application of the conical-flow method.

The load distributions derived by simple sweep theory are included in the last part of each figure to show the magnitude of the plan-form effect and also, in the case of the untapered wings, the curves that the load distributions must

FIGURE 21.—Load distributions on the untapered wing, $m=0.4$, as calculated by the conical-flows method, compared with the two-dimensional approximation.

 FIGURE 22.—Load distributions on the untapered wing, $m=0.2$, as calculated by the conical-flows method, compared with the two-dimensional approximation.

approach as the distance from the plane of symmetry is increased. In figures 21 (b) and 22 (b), comparison is also made with results of the slender-wing theory of reference 3.

Discussion of the σ function.—In the calculation of the pressure coefficient at points toward the rear of most of the sections considered in figures 20, 21, and 22, it was necessary to find $\sigma(x)$ for values of x greater than x_3 (fig. 16). In deriving $\sigma(x)$, it was mentioned that expression (56) applied to region II. In region III, the strength of the leading-edge

singularity is affected by further modifications of the flow taking place in region IIb, so that additional terms in $\sigma(x)$ should be considered when x is greater than x_3 . Evaluation of these terms by presently known methods would require, as suggested earlier, the aid of high-speed computing machinery. However, the successive terms are all initially zero and enter with zero slope at x_3 , zero slope and curvature at x_5 , and so on, so that the three-term expression for σ given by equation (59) may be used with satisfactory accuracy

for some distance beyond the last value of x for which it is strictly valid. In practice, the third term in equation (58) may also be neglected for values of x only slightly greater than x_1 .

Charts have been prepared (fig. 23) giving $\left(\frac{\beta}{m} \sqrt{\frac{1-m}{m}}\right) \sigma$ as a function of $\frac{x-x_1}{c_0}$ for several values of the ratio m/m_t . This last parameter is the ratio of the tangents of the semi-apex angles of the leading and trailing edges and is constant

through the Mach number range for any one wing. The value of x_1 is readily determined:

$$x_1 = \frac{c_0}{1-m} \quad (61)$$

The curves were computed using equation (59) and are therefore exact only up to $x=x_3$ (shown by a vertical mark on each curve). Cross marks are drawn at the points $x=x_5$ to indicate a more practical limit to which use of the curves

FIGURE 23.—Charts for determining σ , the strength of the leading-edge singularity.

FIGURE 23—Continued.

may be extended. (These points are off the scale for $m_t=0.8$ and 0.9 in figure 23 (a).) When the wings are untapered ($m/m_t=1.0$), asymptotes

$$\frac{\beta \sigma(\infty)}{m} \sqrt{\frac{1-m}{m}} = \frac{1}{\sqrt{1+m}}$$

derived from simple sweep theory, may be drawn.

The curves, for the most part, are regular enough to permit interpolation within intervals of 0.2 in m_t . However, at $m_t=1.0$ the lines diminish to a point on the vertical axis; a curve for $m_t=0.9$ was therefore inserted in the charts for values of m/m_t equal to or greater than 0.5 . When m/m_t is less than 0.5 , $m=0.9$ represents, if the leading edge extends beyond x_1, y_1 , such extreme taper that the successive reflection of the Mach lines (at $x_3, x_5, \dots$) take place within a very small fraction of a chord length and no useful curve can be drawn. No curves are drawn for values of m_t smaller than 0.2 because of the tip-interference limitation mentioned in the introduction.

Calculation of tip effect.—The foregoing assumption of two-dimensional flow can be extended to give fairly simple

approximate formulas for the tip effect on a high-aspect-ratio wing. It is assumed that the velocity distribution to be canceled in the stream outboard of the tip is cylindrical; that is, is an extension of the velocity distribution calculated for the tip section along lines parallel to the leading edge. For this purpose the approximate load distribution given by equation (60) is used, still further simplified by assuming σ to remain constant at its value at the leading edge of the tip section. (Where the wing is tapering to a point and σ is changing very rapidly, the tip region is so small that the entire calculation of tip effects could probably be omitted.)

The assumption of constant σ results in a failure to cancel exactly the lift along the tip. The assumption of cylindrical flow, while reasonable for the untapered wing (compare fig 21 (a) with fig. 21 (b), for example) would appear to be too drastic for the tapered wing, where neither the chord nor the loading remains constant. However, as has been mentioned earlier, the major part of the tip effect results from the cancellation of the infinite pressure along the leading edge, and this part will be accurately calculated. The effect of the residual lift on the rearward portion of the tip section and in the stream should be small.

The distribution of perturbation velocity at the tip station $y=s$, with the simplification of constant σ , is, from equation (60), approximately

$$u(x_c, s) = \sigma_s V \alpha \sqrt{\frac{[\beta s - m_t(x_c - c_0)] c_0}{[m x_c - m_t(x_c - c_0)](m x_c - \beta s)}} \quad (62)$$

where x_c, s are the coordinates of a point on the tip and σ_s is the value of σ at the leading edge of the tip section.

This expression may be more conveniently written in terms of the parameter

$$\mu = 1 - \frac{m}{m_t} \quad (63)$$

and the variable

$$\xi_c = \frac{x_c - \frac{\beta s}{m}}{c_t} \quad (64)$$

which is the distance of x_c, s from the leading edge (see fig. 24) expressed as a fraction of the tip chord c_t . Since

$$c_t = \left(c_0 + \frac{\beta s}{m_t}\right) - \frac{\beta s}{m}$$

equation (62) may be written

$$u(\xi_c, s) = \frac{\sigma_s V \alpha}{\sqrt{m \lambda}} \sqrt{\frac{1 - \xi_c}{(1 - \mu \xi_c) \xi_c}} \quad (65)$$

where λ is the taper ratio c_t/c_0 .

If the velocity distribution u is assumed to be constant beyond $y=s$ along lines parallel to the leading edge, it may be canceled by the superposition of conical flow fields of which the constant-velocity regions have one edge along the tip and the other parallel to the leading edge, with apexes displaced along the tip by increments in ξ_c . The velocity induced at a point x, y by each such element would be (equation (11))

$$\frac{u_c}{\pi} \cos^{-1} \frac{m + t_c + 2mt_c}{t_c - m} \quad (66)$$

where

$$t_c = \frac{\beta(y - s)}{x - x_c} \quad (67)$$

and u_c is the velocity on each sector.

Following the procedure used in deriving equation (14), the corresponding equation may be written for the pressures induced by canceling the cylindrical flow

$$\left(\frac{\Delta u}{V \alpha}\right)_{tip} = \frac{-\sqrt{m(1+m)(x-x_0)}}{\pi V \alpha} \int_{\frac{\beta s}{m}}^{x_0} \frac{u(x_c, s) dx_c}{[(1+m)x - x_0 - m x_c] \sqrt{x_0 - x_c}} \quad (68)$$

where x_0, s is the intersection of the Mach forecone from x, y with the tip.

FIGURE 24.—Sketch for derivation of approximate tip correction to loading at x, y .

If the distances of x, y and x_0, s back of the leading edge, measured as fractions of the tip chord, are

$$\xi = \frac{1}{c_t} \left(x - \frac{\beta y}{m}\right) \quad (69)$$

and

$$\xi_0 = \frac{1}{c_t} \left(x_0 - \frac{\beta s}{m}\right) \quad (70)$$

it can be shown that

$$(1+m)(x-x_0) = m c_t (\xi - \xi_0) \quad (71)$$

from which equation (68) can be written (with the substitution for $u(x_c, s)$ from equation (65))

$$\left(\frac{\Delta u}{V \alpha}\right)_{tip} = -\frac{\sigma_s \sqrt{\xi - \xi_0}}{\pi \sqrt{m \lambda}} \int_0^{\xi_0} \frac{d\xi_c}{\xi - \xi_c} \sqrt{\frac{1 - \xi_c}{(\xi_0 - \xi_c)(1 - \mu \xi_c) \xi_c}} \quad (72)$$

In integrating equation (72), three cases must be distinguished: (1) $\xi < 1$ (always true for the untapered wing),

(2) $1 < \xi < \frac{1}{\mu}$ (when the point x, y lies more than a tip-chord length behind the leading edge), and (3) $\xi > \frac{1}{\mu}$

(a possible condition for some points near the trailing edge of a highly swept or tapered wing).

In the first case ($\xi < 1$)

$$\left(\frac{\Delta u}{V\alpha}\right)_{tip} = \frac{-\sigma_s}{\sqrt{m\lambda}} \left[\frac{m}{m_t(1-\mu\xi)} \sqrt{\frac{\xi-\xi_0}{1-\mu\xi_0}} K_0 + \sqrt{\frac{1-\xi}{\xi(1-\mu\xi)}} \Lambda_0(\psi_1, k) \right] \quad (73a)$$

where

$$k = \sqrt{\frac{m\xi_0}{m_t(1-\mu\xi_0)}}$$

$$\psi_1 = \sin^{-1} \sqrt{\frac{(1-\xi)(1-\mu\xi_0)}{(1-\xi_0)(1-\mu\xi)}}$$

and Λ_0 is the function (equation (16)) plotted in figure 6.

In the second case ($1 < \xi < \frac{1}{\mu}$)

$$\left(\frac{\Delta u}{V\alpha}\right)_{tip} = -\frac{\sigma_s}{\sqrt{m\lambda}} \frac{K_0}{\xi \sqrt{1-\mu\xi_0}} \left[\sqrt{\xi-\xi_0} - \sqrt{(\xi-1)\xi_0} \frac{Z(\psi_2, k)}{k \sin \psi_2} \right] \quad (73b)$$

where

$$\psi_2 = \sin^{-1} \sqrt{\frac{m_t(1-\mu\xi)}{m\xi}}$$

and Z is the function (equation (41)) plotted in figure 14.

In the third case ($\xi > \frac{1}{\mu}$),

$$\left(\frac{\Delta u}{V\alpha}\right)_{tip} = \frac{-\sigma_s}{\sqrt{m\lambda\xi}} \frac{\Lambda_0(\psi_3, k)}{\sin \psi_3} \quad (73c)$$

where

$$\psi_3 = \sin^{-1} \sqrt{\frac{\mu\xi-1}{\xi-1}}$$

Along the Mach line from the leading-edge tip all three equations reduce to the value

$$\frac{\Delta u^*}{V\alpha} = \frac{-\sigma_s}{\sqrt{m\lambda\xi}} \quad (74)$$

By the procedure just described, approximate cancellation of all pressure differences outboard of the tip has been effected, but the pressures induced by such cancellation now violate the condition of zero lift in the wake. Approximate cancellation of the induced pressure differences in the wake region can be accomplished, as before, by making use of the known value of the tip-induced velocity at the trailing edge of the wing, but assuming the entire error to originate at the leading edge of the tip. Equation (31) is directly applicable, with Δu^* given by equation (74) and $(\Delta u)_{tip}$ by

equation (73). On the trailing edge of an untapered wing, $\xi=1$ and

$$\left(\frac{\Delta u}{V\alpha}\right)_{\xi=1} = \frac{-\sigma_s}{\sqrt{m}} k' K_0 \quad (75)$$

There is no corresponding simplification for the tapered wing.

Numerical examples, tip effect.—Equations (73) and (31) have been used to calculate the tip effect in two cases, namely: $m=m_t=0.4$, $\beta s=0.94c_0$; and $m=0.4$, $m_t=0.6$, $\beta s=0.86c_0$. The tip effect has been calculated for each wing at $\beta y=0.8c_0$, where the loading was previously calculated (figs. (17b) and (18b)) assuming the wing to extend indefinitely. The tip locations were selected so that in each case only one reflection of the primary tip effect affected the section at $\beta y=0.8c_0$.

Figure 25 shows the results of the calculations. The heavy solid curve in each case was calculated entirely by the corrected two-dimensional theory—that is, by equations (60), (73), and (31). As a check on the accuracy of the cylindrical-flow approximation for the flow outboard of the tip location, the accurate theoretical loading was calculated

(a) Untapered wing; $m=0.4$; $\beta A=1.88$. Section at $\beta y=0.8c_0$, or 85 percent semispan

FIGURE 25.—Load distribution over streamwise section near tip as calculated by two-dimensional formulas, compared with more accurate theoretical values.

(b) Tapered wing; $m=0.4$; $m_t=0.6$. Section at $\beta y=0.8c_o$, or 93 percent semispan

FIGURE 25—Continued

for one point within the region of influence of the tip in each case. The procedure employed for the exact calculation was as follows:

The accurate loadings with no side-edge effects had already been calculated, as has been noted, by the conical-flow method. A primary tip correction was calculated for each case by equation (15). This correction is the effect of canceling the unmodified triangular-wing loading off the tip station. The remaining pressure differences to be canceled consisted of those introduced by the leading-edge and trailing-edge corrections. These pressures were computed by means of equations (26) and (46) of the present report and canceled by the method of reference 5.

The results are designated by the circled points on each figure. At the point at which the section enters the tip Mach cone in each case, a second circled point indicates the accurate theoretical loading. The value differs from that calculated by the approximate formulas only as the two loadings without tip effects differ.

It may be pointed out in concluding this section on load calculations that, while the formulas have been developed for plan forms with streamwise tips, the procedure may be adapted by obvious means to raked tips as well. However, in every case the deviation in the tip regions of the physical flow from the assumed potential flow must be borne in mind.

III—LIFT⁶

GENERAL PROCEDURE FOR CONICAL FLOWS

The total lift for any wing is, of course, the integral of the loading over the wing area. In general, however, it is difficult to obtain an analytic expression for the lift by a direct integration of the lift distribution. In the conical-flow method, advantage may be taken of the simplicity of the component fields by integrating the lift associated with each one and then combining the results in the same way as the pressure fields.

Conical elements of area are employed for the integrations. These are infinitesimal triangles bounded by two adjacent rays of the conical field and the intercepted boundary of the wing plan form. Over each of the infinitesimal triangles the velocity u of the conical field will be constant. Thus it remains only to perform a single integration, with respect to the conical variable of the field, to obtain the total lift associated with that field.

GENERAL FORMULA FOR THE LIFT INDUCED BY A SINGLE TIP ELEMENT

The lift $(\Delta L)_a$ induced on the wing by a single canceling tip element is obtained first. Although the notation of the solution (equation (11)) used to cancel the triangular-wing loading is employed, the derivation will hold generally for any canceling element bounded on one side by the tip of a swept-back wing, since no use is made of the fact that the other boundary of the element passes through the origin of the x, y axes. We write

$$(\Delta L)_a = 2\rho V \int_{-1}^0 (\Delta u)_a \frac{dS}{dt_a} dt_a \quad (76)$$

where $(\Delta u)_a$ (equation (11)) is the streamwise increment of velocity induced by the canceling field and $\frac{dS}{dt_a} dt_a$ (fig. 26) is the element of wing area S for integration. For simplicity it will be specified that the Mach cone from the apex of the element does not include the apex of the trailing edge nor any part of the opposite tip. Then (see fig. 26)

$$\frac{dS}{dt_a} = \frac{m_t^2}{2\beta} \left(\frac{x_t - x_a}{m_t - t_a} \right)^2 \quad (77)$$

⁶ It may be noted that, as a result of the reversibility property (reference 17), the formulas for the lift given herein for swept-back wings are equally applicable to the swept-forward wings having the same plan forms but reversed in heading.

When $m_t = m$, this reduces to

$$\frac{L_0}{q\alpha} = \frac{8s^2}{3ma_t^2} \frac{\beta u_0}{V\alpha} [(m+a_t)\sqrt{m^2-a_t^2} - (m-a_t)] \quad (85b)$$

It should be noted that, for a given plan form, $\frac{L_0}{q\alpha}$ varies with Mach number only as u_0 .

WING WITH SUPERSONIC TRAILING EDGE (TIP CORRECTION)

Proceeding to the calculation of the tip correction to the lift, we integrate the change in lift $(\Delta L)_a$ (equation (78)) induced by each element a over the range $a_t \leq a \leq m$. The quantity $u_\Delta(m)$ is substituted for u_a of the initial canceling element and $\frac{du_\Delta}{da} da$ for u_a for the remaining ones. As in calculating the tip-induced pressure correction, the difficulty is encountered that $u_\Delta(m)$ is infinite, and therefore the total lift correction must be written in terms of limiting values. Following the substitution

$$x_t - x_a = \beta s \left(\frac{1}{a_t} - \frac{1}{a} \right) \quad (86)$$

in equation (78), it is convenient to define the function

$$G(a) = \frac{(a-a_t)^2}{a_t^2 a^2} g(a)$$

Then the total induced lift may be written

$$\Delta L = 2\rho V m_t^2 \beta s^2 \lim_{a \rightarrow m} \left[-u_\Delta(a)G(a) + \int_{a_t}^a \frac{du_\Delta}{da} G(a) da \right] \quad (87)$$

Integrating by parts results in cancellation of the first term inside the brackets. Since $G(a_t)$ is zero, equation (87) reduces to

$$\left(\frac{\Delta L}{q\alpha} \right)_{tip} = -4m_t^2 \beta s^2 \int_{a_t}^m \frac{u_\Delta(a)}{V\alpha} G'(a) da \quad (88a)$$

$$\begin{aligned} \left(\frac{\Delta L}{q\alpha} \right)_{tip} = & -\frac{4s^2}{3ma_t^2} \frac{\beta u_0}{V\alpha} \left(2(m+a_t)\sqrt{m^2-a_t^2} + \sqrt{\frac{ma_t(m^2-a_t^2)}{(1+m)(1+a_t)}} \left\{ \frac{3}{m}(m-a_t) - 2m + \frac{(m-a_t)^2}{m(1+m)^2} \left[\frac{2}{a_t} - \frac{(1-m)^3}{2(m+a_t)} \right] - \right. \right. \\ & \left. \left. \frac{2m^2(1+a_t)^3}{a_t(1+m)^2(m+a_t)} - \frac{m+a_t}{2} \right\} + \sqrt{\frac{2}{1+m}} \left\{ \frac{(m-a_t)(m+2a_t)}{ma_t} F(\psi, k) - \left[\frac{2(m+a_t)}{a_t} - \frac{a_t}{m} - \frac{(m-a_t)^2}{2ma_t(1+m)} \right] E(\psi, k) \right\} \right) \end{aligned} \quad (88c)$$

where

$$\psi = \sin^{-1} \sqrt{\frac{m-a_t}{m(1+a_t)}} \text{ and } k = \sqrt{\frac{1-m}{2}}$$

The primary tip correction, however, is usually quite large. It may therefore be desirable to take into account the secondary correction resulting from its cancellation at the subsonic trailing edge. Rather than compute a single secondary correction to the lift, as an additional item, it is again found advantageous to treat each superposed field individually, that is, to cancel each conical tip field at the trailing edge and find the net effect on the lift, then integrate over all the tip elements for a combined primary and secondary tip correction.

⁷ Or see reference 10 for an approximate formula valid when m is close to one.

where

$$G'(a) = \frac{a-a_t}{a_t^2 a^2} \left[\left(\frac{a_t}{a} + \frac{m_t-a_t}{m_t-a} \right) g(a) - \frac{a-a_t}{2(m_t-a)\sqrt{(m_t+m_t^2)(a+a^2)}} \right]$$

is the derivative of $G(a)$.

Equation (88a) has been integrated (appendix C) in terms of an incomplete elliptic integral of the third kind. If the necessary tables are not available, it may be preferable to integrate numerically.⁷ In that case it is noted that

$$\frac{1}{\sqrt{m^2-a^2}} = \frac{d}{da} \sin^{-1} \frac{a}{m}$$

and $u_\Delta da$ is rewritten as

$$mu_0 d \left(\sin^{-1} \frac{a}{m} \right)$$

Equation (88a) then becomes

$$\left(\frac{\Delta L}{q\alpha} \right)_{tip} = -4m_t^2 m \beta s^2 \frac{u_0}{V\alpha} \int_{\sin^{-1} \frac{a_t}{m}}^{\frac{\pi}{2}} G'(a) d \left(\sin^{-1} \frac{a}{m} \right) \quad (88b)$$

In this way infinite values in the integrand are avoided.

WING WITH SUBSONIC TRAILING EDGE

The expressions (equations (85)) for the uncorrected lift apply regardless of whether the trailing edge is subsonic or supersonic. The formulas for the tip correction may serve as a first approximation when the trailing edge is subsonic if the accuracy of a second correction is not required. For that purpose the special value for the untapered wing will be of interest:

If the wing is untapered the elliptic integrals in equation (88a) (see appendix C) reduce to the first and second kind and the primary induced lift may be written in the following closed form:

Tip correction with subsonic trailing edge.—For the cancellation at the trailing edge of a pressure field originating at a point x_a, s on the wing tip, equation (82) is applied, with the parameter a , which defines one boundary of the oblique canceling field, replaced by t_a , referring to a ray from x_a, s . The velocity u_a is the gradient

$$\frac{d\Delta u}{dt_a} dt_a$$

of the field (equation (11)) to be canceled. The distance from the apex of the canceling field to the wing tip is expressible as

$$-\frac{x_t - x_a}{\beta} \frac{m_t t_a}{m_t - t_a}$$

Then the effect on the lift of canceling the single field from x_a, s is

$$(\Delta_2 L)_a = -\rho V m_i^2 (x_i - x_a)^2 \int_{-1}^0 \frac{t_a}{(m_i - a)^2} \frac{d\Delta u}{dt_a} \times \left[\sqrt{\frac{(m_i - t_a)(1 - t_a)}{m_i}} - \frac{m_i - t_a}{m_i} \right] dt_a \quad (89)$$

which may be integrated, after substitution for $\frac{d\Delta u}{dt_a}$, to give

$$(\Delta_2 L)_a = -\rho V m_i^2 u_a \frac{(x_i - x_a)^2}{\beta(m_i - a)} \left\{ \sqrt{\frac{a(1+a)}{m_i(1+m_i)}} [1 - E_0(k)] - \frac{a}{m_i} \left[1 - \frac{\Lambda_0(\psi, k)}{\sin \psi} \right] \right\} \quad (90)$$

in which

$$k = \sqrt{\frac{1 - m_i}{1 + m_i}}$$

and

$$\psi = \sin^{-1} \sqrt{\frac{m_i - a}{m_i(1 - a)}}$$

If the foregoing result is added to the lift associated with the original tip element, given by equations (78) and (79), it is found that the latter lift is exactly canceled by the algebraic terms in the reflected lift, leaving

$$(\Delta L)_a = \rho V m_i^2 u_a \frac{(x_i - x_a)^2}{\beta(m_i - a)} \left[\sqrt{\frac{a(1+a)}{m_i(1+m_i)}} E_0 - \frac{a}{m_i} \frac{\Lambda_0(\psi, k)}{\sin \psi} \right] \quad (91)$$

for the lift induced by one tip element and its cancellation at the trailing edge. It will generally be found that further steps in the cancellation process are unnecessary for engineering accuracy.

For the total tip-induced correction to the lift, it is necessary to write as before

$$(\Delta L)_{itp} = 2\rho V m_i^2 \beta s^2 \lim_{a \rightarrow m} \left[-u_\Delta(a) J(a) + \int_a^m \frac{du_\Delta}{da} J(a) da \right] \quad (92)$$

where $J(a)$ is

$$\frac{(a - a_i)^2}{a_i^2 a^2} \frac{1}{m_i - a} \left[\sqrt{\frac{a(1+a)}{m_i(1+m_i)}} E_0 - \frac{a}{m_i} \frac{\Lambda_0(\psi, k)}{\sin \psi} \right]$$

An integration by parts reduces equation (92) to

$$(\Delta L)_{itp} = -2\rho V m_i^2 \beta s^2 \int_{a_i}^m u_\Delta(a) J'(a) da \quad (93)$$

with

$$J'(a) = \frac{a - a_i}{a_i^2 a^2} \frac{1}{m_i - a} \left\{ \left[\left(\frac{a_i}{a} + \frac{m_i - a_i}{m_i - a} \right) - \frac{a - a_i}{2(1+a)} \left(\frac{1}{a} - \frac{1+m_i}{m_i - a} \right) \right] \sqrt{\frac{a(1+a)}{m_i(1+m_i)}} E_0(k) - \frac{a - a_i}{1 - a^2} \sqrt{\frac{a(1+a)}{m_i(1+m_i)}} K_0(k) - \frac{a}{m_i} \left[\left(\frac{a_i}{a} + \frac{m_i - a_i}{m_i - a} \right) + \frac{(1 - m_i)(a - a_i)}{2(1 - a)(m_i - a)} \right] \frac{\Lambda_0(\psi, k)}{\sin \psi} \right\} \quad (94)$$

If the wing is untapered, $J'(a)$ becomes indeterminate when $a = m$. The limiting value is

$$J'(m) = \frac{m - a_i}{m^3 a_i^2 (1 - m^2)} \left\{ \left[\frac{1 - 3m}{3} \left(\frac{a_i}{m} + \frac{1 - a_i}{1 - m} \right) - \frac{m - a_i}{10m} \left(3 - \frac{8m^2}{1 - m^2} \right) \right] E_0(k) + 2m \left[\frac{1}{3} \left(\frac{a_i}{m} + \frac{1 - a_i}{1 - m} \right) - \frac{m - a_i}{10m} \left(\frac{1 + 3m}{1 - m^2} \right) \right] K_0(k) \right\}$$

Further integration must be performed numerically. In order to avoid infinite values in the integrand, note again that

$$u_\Delta(a) = m u_0 \frac{d}{da} \sin^{-1} \frac{a}{m} \quad (95)$$

so that equation (93) may be rewritten

$$\left(\frac{\Delta L}{q\alpha} \right)_{itp} = -4m m_i^2 s^2 \frac{\beta u_0}{V\alpha} \int_{\sin^{-1} \frac{a_i}{m}}^{\pi/2} J'(a) d\left(\sin^{-1} \frac{a}{m} \right) \quad (96)$$

Trailing-edge corrections.—In deriving the trailing-edge corrections to the total lift, primary and secondary effects will again be combined. Further corrections will be omitted.

For the symmetrical wake correction, the element of area is obtained from equation (80) by setting y_a equal to zero, and substituting t_0 for t_a . Then the decrement in lift induced by the application of the symmetrical canceling element at the trailing edge is, from equation (20),

$$(\Delta_1 L)_0 = -2\rho V \beta s^2 \frac{u_0}{K'(m_i)} \int_{m_i}^1 F(\phi, \sqrt{1 - m_i^2}) \frac{dt_0}{t_0^2} \quad (97)$$

or

$$\frac{(\Delta_1 L)_0}{q\alpha} = \frac{-4s^2}{m_i} \frac{\beta u_0}{V\alpha} \left[1 - \frac{1}{K'_0(m_i)} \right] \quad (98)$$

where

$$K'_0(m_i) = \frac{2}{\pi} K(\sqrt{1 - m_i^2})$$

The effect of canceling the pressure field induced by the symmetrical wake correction at the wing tips is obtained with the aid of the previously derived formula (equation (78)) for the lift associated with a single tip element. The parameter defining the boundary of the canceling tip element is now t_0 instead of a , and the velocity on the canceling sector is

$$\frac{d(\Delta u)_0}{dt_0} dt_0 = \frac{u_0 dt_0}{K'(m_i) \sqrt{(1 - t_0^2)(t_0^2 - m_i^2)}} \quad (99)$$

The distance from the apex of the canceling sector to the trailing edge may be expressed as

$$\beta s \left(\frac{1}{m_i} - \frac{1}{t_0} \right) \quad (100)$$

so that the secondary effect of the symmetrical trailing-edge correction becomes

$$(\Delta_2 L)_0 = 2\rho V m_i^2 \beta s^2 \frac{u_0}{K'(m_i)} \int_{m_i}^1 \left(\frac{1}{m_i} - \frac{1}{t_0} \right)^2 \frac{g(t_0) dt_0}{\sqrt{(1-t_0^2)(t_0^2-m_i^2)}} \quad (101)$$

or

$$\frac{(\Delta_2 L)_0}{q\alpha} = \frac{4s^2 \beta u_0}{m_i V\alpha} \left[1 - \frac{1}{K_0'(m_i)} - \frac{2^{3/2}}{\sqrt{1+m_i}} \frac{K_0(k) - E_0(k)}{K_0'(m_i)} \right] \quad (102)$$

with $k = \sqrt{\frac{1-m_i}{2}}$.

Addition of this secondary correction to the primary effect given in equation (98) results in the single correction

$$\left(\frac{\Delta L}{q\alpha} \right)_0 = \frac{-8s^2 \beta u_0}{m_i V\alpha} \sqrt{\frac{2}{1+m_i}} \frac{K_0(k) - E_0(k)}{K_0'(m_i)} \quad (103)$$

By a similar procedure, the effect of canceling one of the oblique trailing-edge fields at the tip is readily obtained and added to the primary effect given by equation (82) to yield

$$(\Delta L)_a = \rho V \beta (s - y_a)^2 \frac{u_a}{a} \frac{1}{\sqrt{m_i}} \left[E_0(k) \sqrt{(m_i - a)(1 - a)} - \frac{m_i - a}{\sqrt{1 + m_i}} \sqrt{\frac{1 + a}{a}} \Lambda_0(\psi, k) \right] \quad (104)$$

with $k = \sqrt{\frac{1-m_i}{1+m_i}}$ and $\psi = \sin^{-1} \sqrt{\frac{(1+m_i)a}{m_i(1+a)}}$ as the combined primary and secondary correction to the lift due to a single oblique trailing-edge cancellation.

For the total correction to the lift due to cancellation of the gradient of the triangular-wing loading in the wake, equation (104) is integrated graphically or numerically across the span as follows:

$$\frac{\Delta L}{q\alpha} = \frac{-4m \beta u_0}{\sqrt{m_i} V\alpha} \int_0^{at} \frac{(s - y_a)^2}{(m^2 - a^2)^{3/2}} \left[E_0(k) \sqrt{(m_i - a)(1 - a)} - \frac{m_i - a}{\sqrt{1 + m_i}} \sqrt{\frac{1 + a}{a}} \Lambda_0(\psi, k) \right] da \quad (105)$$

Numerical examples to be presented will show this component of the lift to be very small, in general.

WING WITH INTERACTING LEADING AND TRAILING EDGES

In computing the load distribution it was found that, when interaction takes place between the flow fields of the leading and trailing edges, the wing plan form appears to comprise two principal regions separated (see fig. 16) by the Mach line arising at the point of intersection x_1, y_1 of the trailing-edge Mach line and the leading edge. Ahead of this line (region I) the flow is most readily described in terms of conical fields. Behind this line the flow is more nearly two-dimensional. On this basis, the total lift will be found in two parts, using for region I the conical-flow

expressions for the loading, and for the remainder of the wing the quasi-two-dimensional approximation.

LIFT ON INBOARD PORTION OF WING

The uncorrected triangular-wing loading will first be integrated over region I, shown shaded in figure 28. For

FIGURE 28.—Inboard portion (region I) of high-aspect-ratio wing.

this purpose the region is considered in two parts, separated by the ray a_2 from the wing apex to the point x_2, y_2 . When a is less than a_2 , the element of area is as before

$$\frac{m_i^2 c_0^2}{2\beta(m_i - a)^2} da$$

When $a > a_2$, the element of area is

$$\frac{(1+m)^2 c_0^2}{2\beta(1-m)^2(1+a)^2} da$$

Thus, the uncorrected lift in the entire shaded region is

$$L_0 = \frac{2\rho V c_0^2}{\beta} \left[\int_0^{a_2} \frac{m_i^2}{(m_i - a)^2} u_{\Delta} da + \int_{a_2}^m \frac{(1+m)^2}{(1-m)^2(1+a)^2} u_{\Delta} da \right] \quad (106)$$

or

$$\frac{L_0}{q\alpha} = \frac{4m}{\beta} \frac{u_0}{V\alpha} c_0^2 \left\{ \frac{1+m}{(1-m)^3} \left[\frac{1}{\sqrt{1-m^2}} \cos^{-1} \frac{m^2+a_2}{m(1+a_2)} - \frac{\sqrt{m^2-a_2^2}}{1+a_2} \right] + \frac{m_i^2}{m_i^2-m^2} \left(\frac{m}{m_i} - \frac{\sqrt{m^2-a_2^2}}{m_i-a_2} \right) + \left(\frac{m_i}{\sqrt{m_i^2-m^2}} \right)^3 \left[\cos^{-1} \frac{m^2-m_i a_2}{m(m_i-a_2)} - \cos^{-1} \frac{m}{m_i} \right] \right\} \quad (107)$$

with

$$a_2 = \frac{2mm_i}{1+m+m_i-mm_i} \quad (108)$$

When $m_i = m$ (untapered wing), the second part of equation (107) becomes indeterminate. In this case,

$$\frac{L_0}{q\alpha} = \frac{4m}{\beta} \frac{u_0}{V\alpha} c_0^2 \left\{ \frac{1+m}{(1-m)^3} \left[\frac{1}{\sqrt{1-m^2}} \cos^{-1} \frac{m^2+a_2}{m(1+a_2)} - \frac{\sqrt{m^2-a_2^2}}{1+a_2} \right] + \frac{1}{3} \left[\left(1 + \frac{m}{m-a_2} \right) \sqrt{\frac{m+a_2}{m-a_2}} - 2 \right] \right\} \quad (109)$$

The trailing-edge corrections to the loading are to be integrated over the part of the shaded region behind the trailing-edge Mach lines. Integration of the symmetrical wake correction (equation (20)) yields

$$\frac{(\Delta L)_0}{q\alpha} = \frac{-16m^2 c_0^2}{\beta(1+m_i)(1-m)^2} \frac{u_0}{V\alpha} \left\{ 1 - \frac{2}{1-m_i} \left[1 - \frac{E_0'(m_i)}{K_0'(m_i)} \right] \right\} \quad (110)$$

For each oblique element, the reduction in lift is given by

$$\frac{1}{q\alpha} \frac{d\Delta L}{da} da = -\frac{2u_a}{\beta V\alpha} \frac{1+m_i}{1+a} (m_i-a)(x_2-x_a)^2 \left[\sqrt{\frac{(1+m_i)(1-a)}{2(m_i-a)}} - 1 \right] \quad (111)$$

with $u_a = \frac{du_\Delta}{da} da$, $x_a = \frac{m_i c_0}{m_i - a}$ and

$$x_2 = \left(\frac{1+m}{1-m} + m_i \right) \frac{c_0}{1+m_i} \quad (112)$$

The total lift in region I is then given by

$$\left(\frac{L}{q\alpha} \right)_I = \frac{L_0}{q\alpha} + \frac{(\Delta L)_0}{q\alpha} + \frac{2}{q\alpha} \int_0^{a_2} \frac{d\Delta L}{da} da \quad (113)$$

The quantity $\frac{\beta^2}{m^2 c_0^2} \left(\frac{L}{q\alpha} \right)_I$ is plotted against m_i in figure 29 for several values of the ratio m/m_i .

LIFT ON OUTER PORTIONS OF WING

In order to find the total lift (except for tip losses) on the remainder of the wing (fig. 30), a double integration with respect to x and y is performed on equation (60). A first integration, with respect to y , yields for the indefinite integral

$$\int \frac{u}{V\alpha} dy = \frac{\sigma(x)}{\beta} \sqrt{c_0} \left[\sqrt{\frac{(mx-\beta y)(m_i c_0 - m_i x + \beta y)}{m_i c_0 - (m_i - m)x}} + \sqrt{m_i c_0 - (m_i - m)x} \tan^{-1} \sqrt{\frac{mx-\beta y}{m_i c_0 - m_i x + \beta y}} \right] \quad (114)$$

The values of βy to be substituted as limits in equation (114) are indicated in figure 30. Along the leading edge, the right-hand member of equation (114) reduces to zero; along the trailing edge it becomes

$$\frac{\pi}{2} \frac{\sigma(x)}{\beta} \sqrt{c_0} \sqrt{m_i c_0 - (m_i - m)x}$$

Then the total lift on the outboard region (both wing halves), except for tip losses, is

$$\left(\frac{L}{q\alpha} \right)_{II} = \frac{8\sqrt{c_0}}{\beta} \left[\int_{x_1}^{x_2} \sigma(x) \left(f_1 \tan^{-1} \frac{f_2}{f_3} + \frac{f_2 f_3}{f_1} \right) dx + \frac{\pi}{2} \int_{x_2}^{x_1} \sigma(x) f_1 dx - \int_{\frac{\beta s}{m}}^{x_1} \sigma(x) \left(f_1 \tan^{-1} \frac{f_4}{f_5} + \frac{f_4 f_5}{f_1} \right) dx \right] \quad (115)$$

where

$$f_1 = \sqrt{m_i c_0 - (m_i - m)x}$$

$$f_2 = \sqrt{(1+m)(x-x_1)}$$

$$f_3 = \sqrt{m(x-\beta s/m)}$$

$$f_4 = \sqrt{(1+m_i)(x_2-x)}$$

$$f_5 = \sqrt{m_i(x_i-x)}$$

The indicated integrations may be performed numerically or graphically, using values of $\sigma(x)$ taken from the charts of figure 23.

TIP-INDUCED CORRECTION TO THE LIFT

In deriving a tip correction to the lift, the same simplifying assumption of completely cylindrical flow will be adopted concerning the pressure field to be canceled as was used in obtaining a tip correction to the loading. As in the preceding section, a combined primary and secondary tip correction will be derived. All further corrections will be omitted.

If the notation of equation (63) is used the distance from the apex $x_{e,s}$ of a canceling element to the trailing-edge tip is $c_i(1-\xi_c)$, and the lift induced by the element and its cancellation at the trailing edge is, from equation (91),

$$(\Delta L)_c = \rho V m_i^2 u_c \frac{c_i^2(1-\xi_c)^2}{\beta(m_i-m)} \left[\sqrt{\frac{m(1+m)}{m_i(1+m_i)}} E_0(k) - \frac{m}{m_i} \frac{\Lambda_0(\psi, k)}{\sin \psi} \right] \quad (116)$$

where

$$k = \sqrt{\frac{1-m_i}{1+m_i}}$$

as before, and

$$\psi = \sin^{-1} \sqrt{\frac{m_i - m}{m_i(1-m)}}$$

since the outer boundary of each element now has the slope $\frac{m}{\beta}$.

It is seen that only u_c and $(1-\xi_c)^2$ in the coefficient of equation (116) vary with the element. For the first element ($\xi_c=0$), the velocity u_c is the initial value of the uncorrected velocity along the tip section given in equation (65), and, for the other elements, the differential of that velocity. Then

FIGURE 29.—Chart for the computation of lift in region I.

FIGURE 30.—Boundaries of outboard region of high-aspect-ratio wing, for use as limits of integration in equation (114).

the combined primary and secondary tip correction on both wing halves is

$$\frac{\Delta L}{q\alpha} = -\frac{4m_t^2 c_t^2 \sigma_s}{\beta(m_t - m)\sqrt{m\lambda}} \left[\sqrt{\frac{m(1+m)}{m_t(1+m_t)}} E_0(k) - \frac{m}{m_t} \frac{\Lambda_0(\psi, k)}{\sin \psi} \right] \lim_{\xi_c \rightarrow 0} \left[(1 - \xi_c)^2 \sqrt{\frac{1 - \xi_c}{\xi_c(1 - \mu \xi_c)}} + \int_{\xi_c}^1 (1 - \xi_c)^2 \frac{d}{d\xi_c} \sqrt{\frac{1 - \xi_c}{\xi_c(1 - \mu \xi_c)}} d\xi_c \right] \quad (117)$$

Integration by parts gives, finally,

$$\frac{\Delta L}{q\alpha} = -\frac{8\pi m_t^2 c_t^2 \sqrt{m}}{3\beta(m_t - m)^3 \sqrt{\lambda}} \sigma_s \left[\sqrt{\frac{m(1+m)}{m_t(1+m_t)}} E_0(k) - \frac{m}{m_t} \frac{\Lambda_0(\psi, k)}{\sin \psi} \right] \left[(3m - m_t) K_0(\sqrt{\mu}) - 2m_t \left(2 - \frac{m_t}{m} \right) E_0(\sqrt{\mu}) \right] \quad (118a)$$

If the wing is untapered, equation (118a) takes on the value

$$\frac{\Delta L}{q\alpha} = -\frac{\pi c_0^2 \sqrt{m}}{\beta(1 - m^2)} \sigma_s [2m K_0(k) + (1 - 3m) E_0(k)] \quad (118b)$$

Except for the occurrence of σ_s, c_t and λ in the coefficients, the tip correction obtained in the foregoing way is a function of m and m_t only, independent of the tip location. Values of $\frac{\beta \sqrt{\lambda}}{\sigma_s c_t^2} \left(\frac{\Delta L}{q\alpha} \right)_{tip}$ have been plotted in figure 31 in a form similar to the chart of $\left(\frac{L}{q\alpha} \right)_i$ (fig. 29).

FIGURE 31.—Chart for the correction of the lift for tip effect, using two-dimensional formulas.

APPLICATION OF LIFT FORMULAS

CASES COMPUTED

The lift-curve slope $C_{L\alpha}$ has been calculated for two families of untapered wings with varying aspect ratios as follows:

$m=0.2$		$m=0.4$	
$\beta \frac{s}{c_0}$	βA	$\beta \frac{s}{c_0}$	βA
0.3	0.6	0.6	1.2
.4	.8	.8	1.6
.6	1.2	1.2	2.4
		1.6	3.2

and for two tapered wings:

$m=0.4, m_t=0.6$		
$\beta \frac{s}{c_0}$	βA	λ
0.6	1.6	$\frac{1}{2}$
.8	2.4	$\frac{1}{3}$

It should be noted that the untapered-wing cases (except for the last one under $m=0.4$) represent three wings of fixed geometry at two different Mach numbers such that β is doubled in going from the first to the second. No calculation was made for $m=0.2$ to correspond to the last case

under $m=0.4$ because at the lower Mach number it was not possible to calculate satisfactory values of σ out to the wing tip. The tapered wings were chosen to show, by comparison with the first two of the untapered $m=0.4$ wings, the effect of taper with the span held constant and, by comparison with the second and third untapered $m=0.4$ wings, the effect of taper with a given aspect ratio.

SUMMARY OF COMPUTATIONS

With $m=0.4$ and $\beta s/c_o=0.6$, the trailing-edge Mach lines do not intersect the leading edge, and the values of C_{L_α} were

obtained entirely by means of the conical-flow formulas, as follows:

Component of lift	Equation No.	Tapered wing, $\beta A=1.6$		Untapered, $\beta A=1.2$	
		$\beta^2 L/q\alpha c_o^2$	% total	$\beta^2 L/q\alpha c_o^2$	% total
Uncorrected triangular wing.....	(85)	2.093	121.1	2.595	143.0
Tip effect.....	(96)	-.190	-11.0	-.422	-23.3
Symmetrical trailing-edge correction.....	(103)	-.159	-9.2	-.340	-18.7
Oblique trailing-edge correction.....	(105)	-.015	-0.9	-.019	-1.0
Totals.....		1.729	100.0	1.814	100.0
$\beta C_{L_\alpha} = \beta L/q\alpha S$, per radian.....		1.920		1.512	

The calculations for the remaining values of βA are summarized in the following table:

Component of lift	Obtained from	Untapered wings						Tapered wing $m=0.4$; $m_t=0.6$; $\beta s=0.8$; $\beta A=2.4$
		$m=0.2$			$m=0.4$			
		$\beta A=0.6$	$\beta A=0.8$	$\beta A=1.2$	$\beta A=1.6$	$\beta A=2.4$	$\beta A=3.2$	
Lift on inboard portion.....	Fig. 29 or equation (113).....	0.366	0.366	0.366	2.128	2.128	2.128	1.981
Lift on outboard portion.....	Equation (115).....	.180	.386	.830	.849	2.593	4.459	.462
Tip correction.....	Fig. 31 or equation (118).....	-.085	-.090	-.098	-.363	-.392	-.415	-.092
Totals, $\beta^2 L/q\alpha c^2$		.461	.662	1.098	2.614	4.329	6.172	2.351
$\beta C_{L_\alpha} = \beta L/q\alpha S$, per radian.....		.77	.83	.92	1.63	1.80	1.93	2.20

DISCUSSION OF RESULTS

The results of the calculations are plotted against the reduced aspect ratio βA in figure 32. The curves for the untapered wings may be seen to be approaching, at the upper end, the value $2\pi m/\sqrt{1-m^2}$ given by simple sweep theory.

At the lower end, the curves should approach the origin along the line $C_{L_\alpha} = \frac{\pi}{2} A$ given by low-aspect-ratio theory (reference 13). The two points on the $m=0.2$ curve for $\beta A < 1$ are not entirely accurate because no account was taken of the interference between the flow fields from the tips. The points are included, however, because, with so much sweep, the wing areas affected are small and the interference effects should be negligible. The resulting curve appears consistent with the corresponding curve calculated

by the slender-wing theory of reference 3, although a disparity in plan form lessens the significance of the comparison.

The slender-wing-theory values are also plotted for $m=0.4$. In that case, however, the assumption of extreme slenderness is no longer justified and introduces an appreciable error. (It should be mentioned that the asymptote for the slender-wing-theory curves is *below* the value given by simple sweep theory by the factor $\sqrt{1-m^2}$.)

An estimate of the accuracy of the lift formulas of the present report, compared with results which would take into account all the successive reflections at the tips and trailing edge, may be made from the following observations:

The values obtained (in the first table) from equations (96) and (103), which combine primary and secondary corrections, differ from values obtainable for the primary corrections alone by only 1 percent of the total lift in the case of the tapered wing, and 4 percent of the total lift for the untapered wing. Third-order corrections would be only a fraction of those small corrections and would, in turn, be partly canceled out by a fourth-order correction.

The results in the second table, incorporating the two-dimensional approximations, agree within 2 or 3 percent with values calculated entirely by the conical-flow method.

IV—DRAG DUE TO LIFT

The drag due to lift of a wing with supersonic leading edge is simply the lift times the angle of attack. When the leading edge is subsonic, the drag is reduced by a suction force due to the upwash around the leading edge. In the linearized theory this force appears as the limit of the product of an infinite velocity across an infinitesimal frontal area.

The formula for the suction force on a subsonic leading edge has been derived (see, e. g., Hayes, reference 18) by

FIGURE 32.—Variation of lift-curve slope with aspect ratio.

assuming the flow near the leading edge to be essentially two-dimensional and applying the results of two-dimensional potential theory. The simple result obtained in that manner has been verified for the swept-back wing of finite span by application of the somewhat different approach of reference 19.

By the two-dimensional approach, the suction force is found to be proportional to the square of the strength of the leading-edge singularity in the perturbation velocity u . The latter is the quantity discussed earlier in connection with the adjustment of the two-dimensional loading to the loading on the swept-back wing. With the use of the previous terminology it is possible to write for the longitudinal component of the suction force per unit streamwise length of leading edge,

$$\frac{dT}{dx} = \frac{\rho\pi}{m} \sqrt{1-m^2} C_\Delta^2 \quad (119)$$

where C_Δ (equation (53)) is the value, at the leading edge, of the coefficient of $(mx-\beta y)^{-1/2}$ in u_Δ .

Then, if the trailing-edge Mach line does not intersect the leading edge, the thrust is merely

$$\left. \begin{aligned} T &= \rho\pi u_0^2 \sqrt{1-m^2} \int_0^{\beta s} x dx \\ &= \frac{\rho\pi u_0^2 \beta^2 s^2}{2m^2} \sqrt{1-m^2} \end{aligned} \right\} \quad (120)$$

The total drag due to lift is obtained by subtracting the thrust from the product of the lift and the angle of attack, or, in coefficient form,

$$C_D = \alpha C_L - C_T \quad (121)$$

where C_T is the thrust coefficient T/qS . Thus, in the foregoing case,

$$C_D = \frac{\alpha^2}{S} \left[\frac{L}{q\alpha} - \pi \left(\frac{\beta s}{m} \right)^2 \left(\frac{u_0}{V\alpha} \right)^2 \sqrt{1-m^2} \right] \quad (122)$$

When a portion of the leading edge is influenced by the trailing edge, the leading-edge singularity takes on, for that portion, the value given by expression (56), which then replaces C_Δ in equation (119) for the thrust. The total thrust is

$$\left. \begin{aligned} 2 \int_0^{\beta s} \frac{dT}{dx} dx &= 2 \frac{\rho\pi}{m} \sqrt{1-m^2} \left\{ \int_0^{x_1} C_\Delta^2 dx + \int_{x_1}^{\beta s} \left[C_\Delta + (\Delta C)_0 + \int_0^{a_0} \frac{d\Delta C}{da} da \right]^2 dx \right\} \end{aligned} \right\} \quad (123)$$

where

$$x_1 = \frac{c_0}{1-m}$$

locates the intersection of the trailing-edge Mach line with the leading edge. Integrating the first term and reducing so coefficient form gives

$$C_T = \frac{\pi\alpha^2 \sqrt{1-m^2}}{S} \left[\left(\frac{u_0}{V\alpha} \right)^2 x_1^2 + \frac{4c_0}{m} \int_{x_1}^{\beta s} \sigma^2 dx \right] \quad (124)$$

so that

$$C_D = \frac{\alpha^2}{S} \left\{ \frac{L}{q\alpha} - \pi \sqrt{1-m^2} \left[\left(\frac{u_0}{V\alpha} \right)^2 x_1^2 + \frac{4c_0}{m} \int_{x_1}^{\beta s} \sigma^2 dx \right] \right\} \quad (125)$$

In figure 33, $\frac{1}{\beta}$ times the drag-rise factor $\frac{C_D}{C_L^2}$ is plotted against the reduced aspect ratio βA for two combinations of sweep and Mach number, $m=0.2$ and $m=0.4$, for untapered wings. Comparison is made with a theoretical minimum for slender wings in supersonic flight obtained by R. T. Jones (reference 18) and assuming the wing to be narrow compared with the Mach cone, Jones has derived a minimum wave-drag coefficient

$$C_{D_w} = \frac{\beta^2}{2\pi A_x} C_L^2 \quad (126)$$

where A_x is the aspect ratio defined in the streamwise, instead of the spanwise, direction; that is, if l (numerically equal to x_l) is the over-all length of the wing in the stream direction,

$$A_x = l^2/S \quad (127)$$

FIGURE 33.—Variation of drag-rise factor with aspect ratio for untapered wings.

The wave drag is to be added to the vortex drag, which is the induced drag of subsonic flow, calculated from the spanwise loading. Using the minimum induced drag obtained from lifting-line theory gives as the minimum supersonic drag-rise factor⁸

$$\frac{C_D}{C_L^2} = \frac{1}{\pi A} + \frac{\beta^2}{2\pi A_x} \quad (128)$$

It may be seen that the drag rise of the constant-chord swept-back wings is fairly close to this minimum, especially at the lower values of m for which equation (128) was derived.

V—SUMMARY OF FORMULAS

The formulas for the loading, lift, and drag coefficients are summarized in the following table, in which the equations are identified by number.

⁸ This result has since been published in The Journal of the Aeronautical Sciences, vol. 18, no. 2, Feb. 1951, pp. 75-81.

APPENDIX A

SYMBOLS

GENERAL			
V	free-stream velocity	ξ	streamwise distance of x, y back from leading edge, as a fraction of the tip chord (equation (69))
M	free-stream Mach number	ξ_0	distance of x_0, s behind leading-edge tip, as a fraction of the tip chord (equation (70))
β	$\sqrt{M^2 - 1}$	ξ_c	distance of x_c, s behind leading-edge tip, as a fraction of the tip chord (equation (64))
u, v, w	perturbation velocities in streamwise, cross-stream, and vertical directions, respectively	CONICAL COORDINATES	
ρ	density of air	In the following, all slopes are measured counterclockwise from a line extending downstream from the apex of the wing or of the pertinent canceling sector:	
q	dynamic pressure $(\frac{1}{2} \rho V^2)$	m	$\frac{\text{slope of leading edge}}{\text{slope of Mach lines}} = \beta \cot \Lambda$
Δp	pressure difference between upper and lower surfaces, or local lift	m_t	$\frac{\text{slope of trailing edge}}{\text{slope of Mach lines}}$
α	angle of attack, radians	a	$\frac{\text{slope of ray from the origin}}{\text{slope of Mach lines}} = \beta \frac{y}{x}$
L	lift	a_0	the value of a corresponding to a primary canceling element of which the apex lies on the Mach forecone of the point at which the load is being calculated (equation (13) for tip corrections, equation (25) for trailing-edge corrections)
T	leading-edge thrust, or component of leading-edge suction force in flight direction	a_0'	limiting value of a for leading-edge correction (equation (47))
C_L	lift coefficient $(\frac{L}{qS})$	a_2	$a(x_2, y_2)$ (equation (108))
C_{L_α}	lift-curve slope $(\frac{dC_L}{d\alpha})$	a_t	$a(x_t, s)$
C_D	drag coefficient $(\frac{D}{qS})$	t_a	$\frac{\text{slope of ray from apex of element } a}{\text{slope of Mach lines}} = \beta \frac{y - y_a}{x - x_a}$
C_T	thrust coefficient $(\frac{T}{qS})$	t_b	$\frac{\text{slope of ray from } x_b, y_b}{\text{slope of Mach lines}} = \beta \frac{y - y_b}{x - x_b}$
WING DIMENSIONS		t_c	$\frac{\text{slope of ray from } x_c, s}{\text{slope of Mach lines}} = \beta \frac{y - s}{x - x_c}$
c_0	root chord	t_m	$\frac{\text{slope of ray from leading-edge tip}}{\text{slope of Mach lines}} = \beta \frac{y - s}{x - (\beta s/m)}$
c_t	tip chord	t^*	$\frac{\text{slope of ray from } x^*, y^*}{\text{slope of Mach lines}} = \beta \frac{y - y^*}{x - x^*}$
s	semispan	τ_0	limiting value of t_0 for leading-edge correction (equation (39))
S	wing area	τ_a	limiting value of t_a for leading-edge correction (equation (44))
l	over-all length in the streamwise direction	COMPONENTS OF STREAMWISE PERTURBATION VELOCITY	
Λ	angle of sweep of the leading edge	u_Δ	basic (uncorrected) perturbation velocity as given by solution for triangular wing (equation (6) for subsonic leading edge)
λ	taper ratio (c_t/c_0)	u_0	value of u_Δ at $a=0$ (equation (7))
A	aspect ratio $(4s^2/S)$	Δu	correction to u_Δ induced by cancellation of pressure differences outside the wing plan form
A_x	streamwise aspect ratio (l^2/S)	u_a	constant perturbation velocity on sector used in canceling triangular-wing loading
RECTANGULAR COORDINATES		u_b	constant perturbation velocity on sector used in secondary cancellation
x, y	Cartesian coordinates in the stream direction and across the stream, in the plane of the wing	u_c	constant perturbation velocity on sector used outboard of tip in canceling assumed cylindrical field
x_a, y_a	coordinates of apex of conical field used to cancel triangular-wing loading (Equation (8) at tip, equations (21) and (22) at trailing edge)		
x_b, y_b	coordinates of apex of conical field used in secondary cancellations		
x_c, s	coordinates of point on tip; apex of conical field used to cancel assumed cylindrical load		
x_0, y_0	coordinates of intersection of Mach forecone from x, y with edge at which correction is being made		
x_1, y_1	coordinates of intersection of trailing-edge Mach cone with leading edge (x_1 given by equation (61))		
x_2, y_2	coordinates of intersection of Mach line from x_1, y_1 with trailing edge (x_2 given by equation (112))		
x^*, y^*	coordinates of intersection of tip Mach line with trailing edge		
x_t, s	coordinates of intersection of tip and trailing edge		

$(\Delta u)_0$	symmetrical trailing-edge correction to u_Δ (equation (20))
$(\Delta_2 u)_0$	correction induced by canceling $(\Delta u)_0$ at leading edge (equation (38))
$(\Delta u)_a$	correction to u_Δ due to single oblique trailing-edge element (equation (24))
Δu^*	value of tip correction to u_Δ at the point x^*, y^*

ARBITRARY MATHEMATICAL SYMBOLS

C_Δ	value of coefficient of $\frac{1}{\sqrt{mx-\beta y}}$ in u_Δ at the leading edge (equation (53))
$(\Delta C)_0$	decrement in C_Δ due to reflection of $(\Delta u)_0$ at leading edge (equation (54))
$\frac{d\Delta C}{da} da$	decrement in C_Δ due to reflection of $(\Delta u)_a$ at leading edge (equation (55))
σ	Non-dimensional expression for strength of the leading-edge singularity (equation (59))
σ_s	value of σ at leading-edge tip $\left[\sigma \left(\frac{\beta s}{m} \right) \right]$
μ	taper parameter $\left(\frac{m_t - m}{m_t} \right)$
g	function defined by equation (79)
C	inverse-cosine term of leading-edge correction function (equation (35))
R	radical term of leading-edge correction function (equation (36))
$r. p.$	real part

ELLIPTIC INTEGRALS AND FUNCTIONS

k	modulus of elliptic integral, defined where used (also with subscripts)
k'	complimentary modulus ($\sqrt{1-k^2}$)
ϕ or ψ	argument of elliptic integrals, defined where used (also with subscripts)
$F(\phi, k)$	incomplete elliptic integral of the first kind of modulus k and argument ϕ
$K, K(k)$	complete elliptic integral of the first kind; that is, $K = F\left(\frac{\pi}{2}, k\right)$
$E(\phi, k)$	incomplete elliptic integral of the second kind of modulus k and argument ϕ
$E, E(k)$	complete elliptic integral of the second kind; that is, $E = E\left(\frac{\pi}{2}, k\right)$
K_0	$\frac{2}{\pi} K$
E_0	$\frac{2}{\pi} E$
K'	$K(k')$
E'	$E(k')$
Z	zeta function (equation (41))
Λ_0	function used in evaluation of elliptic integral of the third kind, circular case (equation (16))
Ω	function used in evaluation of elliptic integral of the third kind, circular case (equation (B11))

APPENDIX B

EVALUATION OF THE INTEGRAL IN EQUATION (26)

It is first necessary to recall that t_a is a function (equation (23)) of x , y , and a . After substitution for t_a in equation (26), we may integrate by parts to obtain

$$\int_0^{a_0} \cos^{-1} \frac{(1-a)(t_a - m_t) - (m_t - a)(1-t_a)}{(1-m_t)(t_a - a)} \frac{du_\Delta(a)}{da} da =$$

$$-u_0 \left[\cos^{-1} \frac{(1+m_t)\beta y - 2m_t(x-c_0)}{(1-m_t)\beta y} \right.$$

$$\left. (x - \beta y) \sqrt{\frac{\beta y - m_t(x-c_0)}{x - \beta y - m_t c_0}} \times \right.$$

$$\left. \int_0^{a_0} \frac{da}{(\beta y - ax) \sqrt{(1-a)(a_0 - a)(m - a)(m + a)}} \right] \quad (B1)$$

The integral term on the right-hand side of equation (B1) is an elliptic integral of the third kind which may be evaluated through the substitution of

$$\omega = sn^{-1} \sqrt{\frac{2m(a_0 - a)}{(m + a_0)(m - a)}} \quad k = \sqrt{\frac{(1-m)(m + a_0)}{2m(1 - a_0)}}$$

If the value of ω at the lower limit is designated by ω_0 , this substitution gives

$$\int_0^{a_0} \frac{da}{(\beta y - ax) \sqrt{(1-a)(a_0 - a)(m - a)(m + a)}} =$$

$$\frac{1}{\beta y - a_0 x} \sqrt{\frac{2}{m(1 - a_0)}} \int_0^{\omega_0} \frac{1 - \frac{m + a_0}{2m} sn^2 \omega}{1 + n sn^2 \omega} d\omega \quad (B2)$$

where

$$n = \frac{(m + a_0)(mx - \beta y)}{2m(\beta y - a_0 x)} \quad (B3)$$

or

$$\int_0^{a_0} \frac{da}{(\beta y - ax) \sqrt{(1-a)(a_0 - a)(m - a)(m + a)}} =$$

$$\frac{-1}{mx - \beta y} \sqrt{\frac{2}{m(1 - a_0)}} \left[\omega_0 - \left(1 + \frac{mx - \beta y}{\beta y - a_0 x} \right) \Pi_3(\omega_0, k, n) \right] \quad (B4)$$

where

$$\Pi_3(\omega_0, k, n) = \int_0^{\omega_0} \frac{d\omega}{1 + n sn^2 \omega}$$

is the normal form of the elliptic integral of the third kind.

It is first noted that $n > 0$. For this case it can be shown that the substitution

$$\nu = tn^{-1} \left(\sqrt{\frac{n}{k^2}}, k' \right) \quad (\text{B5})$$

gives

$$\Pi_3(\omega_0, k, n) = \omega_0 cn^2(\nu, k') + \frac{sn(\nu, k') cn(\nu, k')}{dn(\nu, k')} \left[\frac{\omega_0}{K_0} \Lambda_0(k, \phi) + \Omega \right] \quad (\text{B6})$$

where

$$\phi = \tan^{-1} \sqrt{\frac{n}{k^2}} \quad (\text{B7})$$

is the amplitude of the elliptic function ν , Λ_0 is the function defined in equation (16), and Ω is an angular function of k, ν and ω_0 which will be discussed later.

If

$$\psi = \sin^{-1} \sqrt{\frac{2a_0}{m+a_0}} \quad (\text{B8})$$

then

$$\omega_0 = F(\psi, k) \quad (\text{B9})$$

$$\text{From equation (B5), } sn(\nu, k') = \sqrt{\frac{n}{n+k^2}}, \quad cn(\nu, k') = \sqrt{\frac{k^2}{n+k^2}}$$

and $dn(\nu, k') = \sqrt{\frac{k^2(1+n)}{n+k^2}}$ may be found, so that equation (B6) may be rewritten without recourse to the Jacobian elliptic functions as

$$\Pi_3(\omega_0, k, n) = \frac{k^2}{n+k^2} F(\psi, k) + \sqrt{\frac{n}{(1+n)(n+k^2)}} \left[\frac{F(\psi, k)}{K_0} \Lambda_0(k, \phi) + \Omega \right] \quad (\text{B10})$$

This expression is to be substituted in equation (B4) and the result used in equation (B1). As previously mentioned, the functions K_0 and Λ_0 are tabulated in reference 11 and Λ_0 is plotted in figure 6. The function Ω is given by⁹

$$\Omega = \tan^{-1} \frac{2 \sum_{j=1}^{\infty} (-1)^{j+1} q^{(j^2)} \sin 2j \frac{\omega_0}{K_0} \sinh 2j \frac{\nu}{K_0}}{1 - 2 \sum_{j=1}^{\infty} (-1)^{j+1} q^{(j^2)} \cos 2j \frac{\omega_0}{K_0} \cosh 2j \frac{\nu}{K_0}} \quad (\text{B11})$$

with

$$q = e^{-\frac{\pi K'}{K}}$$

(tabulated in reference 15).

⁹ The symbol q in equation (B11) is standard notation for the nome of the Jacobian theta function, and is not related to the dynamic pressure q of the text.

APPENDIX C

INTEGRATION FOR LOSS OF LIFT AT THE TIP OF WING WITH SUBSONIC LEADING EDGE

From equations (88a) and (6)

$$\left(\frac{\Delta L}{q\alpha} \right)_{tip} = -\frac{4m_i^2 m s^2 \beta u_0}{V\alpha} \int_{a_i}^m \frac{G'(a)}{\sqrt{m^2 - a^2}} da \quad (\text{C1})$$

where

$$G'(a) = \frac{a - a_i}{a_i^2 a^2 (m_i - a)} \left[\left(\frac{a_i}{a} + \frac{m_i - a_i}{m_i - a} \right) \left(\sqrt{\frac{a + a^2}{m_i + m_i^2}} - \frac{a}{m_i} \right) - \frac{a - a_i}{2\sqrt{m_i + m_i^2} \sqrt{a + a^2}} \right] \quad (\text{C2})$$

The terms in $G'(a)$ are of two types; namely, those that contain $\sqrt{a + a^2}$ and those that do not. The former combine with the radical $\sqrt{m^2 - a^2}$ in equation (C1) to form elliptic integrals of the first, second, and third kinds. The latter give rise to terms in equation (C1) which are integrable by elementary means. It is convenient, therefore, to consider the integral in two parts, writing

$$-\int_{a_i}^m \frac{G'(a)}{\sqrt{m^2 - a^2}} da = I_1 + I_2$$

where I_1 is that part of the integral not requiring elliptic integrals.

Then

$$I_1 = \int_{a_i}^m \frac{a - a_i}{a_i^2 m_i a (m_i - a)} \left(\frac{a_i}{a} + \frac{m_i - a_i}{m_i - a} \right) \frac{da}{\sqrt{m^2 - a^2}}$$

$$= \frac{1}{a_i^2 m_i (m_i^2 - m^2)} \left[\frac{(m_i - a_i)^2}{\sqrt{m_i^2 - m^2}} \cos^{-1} \frac{m_i a_i - m^2}{m(m_i - a_i)} - \frac{m_i a_i - m^2}{m^2 \sqrt{m^2 - a_i^2}} \right] \quad (\text{C3})$$

The remaining terms, involving $\sqrt{a + a^2}$ and $\sqrt{m^2 - a^2}$, are integrated by means of the substitution

$$sn \omega = \sqrt{\frac{m - a}{m(1 + a)}} \quad k = \sqrt{\frac{1 - m}{2}} \quad (\text{C4})$$

The result is

$$I_2 = \frac{1}{a_i^2 m_i \sqrt{2m m_i (1 + m_i)}} \left\{ \left[\frac{m_i - a_i}{m_i} \left(\frac{m_i - a_i}{1 + m_i} - \frac{a_i}{m} \right) - \frac{a_i (m - a_i)}{m^2} \right] F(\psi, k) + \frac{2a_i}{m} \left[\left(1 + \frac{m_i - a_i}{m_i} \right) E(\psi, k) + \left(a_i - \frac{m_i - a_i}{m_i} \right) \sqrt{\frac{m + a_i}{2a_i}} \sin \psi \right] - \frac{(1 + m)(m_i - a_i)^2}{(m_i - m)^2} \left[\left(1 + \frac{m}{m_i} + \frac{m_i - m}{1 + m_i} \right) \Pi_3(\omega_i, k, n) + \frac{2m(1 + m)}{m_i - m} \frac{\partial \Pi_3(\omega_i, k, n)}{\partial n} \right] \right\} \quad (\text{C5})$$

where $\omega_i = \omega(a_i)$, ψ is its amplitude, and

$$n = \frac{m(1+m_i)}{m_i - m} \quad (C6)$$

From equation C(4),

$$\psi = \sin^{-1} \sqrt{\frac{m - a_i}{m(1 + a_i)}} \quad (C7)$$

The elliptic integral

$$\Pi_3(\omega_i, k, n) = \int_0^{\omega_i} \frac{d\omega}{1 + n \operatorname{sn}^2 \omega}$$

is evaluated in equation (B10). Its derivative with respect to the parameter n may be obtained for this case ($n > 0$) in the form

$$\begin{aligned} \frac{\partial \Pi_3}{\partial n} = & \frac{1}{2n} \sqrt{\frac{n}{(n+k^2)(1+n)}} \left\{ \left(\frac{1}{1+n} - \frac{n}{n+k^2} \right) \left[\frac{\Delta_0(\phi, k)}{K_0} F(\psi, k) + \right. \right. \\ & \left. \Omega(\omega_i, n, k) \right] - \sqrt{\frac{n}{(n+k^2)(1+n)}} \left[k^2 \left(\frac{1}{k^2} + \frac{1+n}{n+k^2} \right) F(\psi, k) - \right. \\ & \left. \left. E(\psi, k) - \frac{nsn\omega_i cn\omega_i dn\omega_i}{1+n sn\omega_i} \right] \right\} \quad (C8) \end{aligned}$$

where ϕ and Ω are the angles defined in equations (B7) and (B11) and the elliptic functions $cn\omega_i$ and $dn\omega_i$, obtained from equation (C4), have the values

$$cn\omega_i = \sqrt{\frac{a_i(1+m)}{m(1+a_i)}} \quad dn\omega_i = \sqrt{\frac{(1+m)(m+a_i)}{2m(1+a_i)}} \quad (C9)$$

REPORT 1051

AN ANALYSIS OF BASE PRESSURE AT SUPERSONIC VELOCITIES AND COMPARISON WITH EXPERIMENT¹

By DEAN R. CHAPMAN

SUMMARY

In the first part of the investigation an analysis is made of base pressure in an inviscid fluid, both for two-dimensional and axially symmetric flow. It is shown that for two-dimensional flow, and also for the flow over a body of revolution with a cylindrical sting attached to the base, there are an infinite number of possible solutions satisfying all necessary boundary conditions at any given free-stream Mach number. For the particular case of a body having no sting attached only one solution is possible in an inviscid flow, but it corresponds to zero base drag. Accordingly, it is concluded that a strictly inviscid-fluid theory cannot be satisfactory for practical applications.

An approximate semi-empirical analysis for base pressure in a viscous fluid is developed in a second part of the investigation. The semi-empirical analysis is based partly on inviscid-flow calculations. In this theory an attempt is made to allow for the effects of Mach number, Reynolds number, profile shape, and type of boundary-layer flow. Some measurements of base pressure in two-dimensional and axially symmetric flow are presented for purposes of comparison. Experimental results also are presented concerning the support interference effect of a cylindrical sting, and the interference effect of a reflected bow wave on measurements of base pressure in a supersonic wind tunnel.

INTRODUCTION

The present investigation is concerned with the pressure acting on the base of an object moving at a supersonic velocity. This problem is of considerable practical importance since in certain cases the base drag can amount to as much as two-thirds of the total drag of a body of revolution, and over three-fourths of the total drag of an airfoil. In the past, numerous measurements of base pressure on bodies of revolution have been made both in supersonic wind tunnels and in free flight, but these experimental investigations have had no adequate theory to guide them. As a result, the present-day knowledge of base pressure is undesirably limited and some inconsistencies appear in the existing experimental data.

Various hypotheses as to the fundamental mechanism which determines the base pressure on bodies of revolution were advanced years ago by Lorenz, Gabeaud, and von Kármán. (See references 1, 2, and 3, respectively.) These

hypotheses, which neglect the influence of the boundary layer, do not appear to be adequate for predicting the base pressure or for correlating experiments.

A semi-empirical theory of base pressure for bodies of revolution has been advanced by Cope in reference 4. Cope's analysis and the semi-empirical analysis of the present report were developed independently and are similar in one significant respect; both consider the influence of the boundary layer on base pressure. The basic concepts and the details of the two analyses, though, are entirely different. Cope's equations are developed only for axially symmetric flow, and do not provide for the effects of variations in profile shape on base pressure. He evaluates the base pressure by equating the pressure in the wake, as calculated from the boundary-layer flow, to the corresponding pressure as calculated from the exterior flow. In calculating the pressure from the boundary-layer flow, however, several approximations and assumptions are necessarily made which, according to Cope, result in no more than a first approximation.

The primary purpose of the investigation described in the present report is to formulate a method which is of value for quantitative calculations of base pressure both on airfoils and bodies. The analysis is divided into two parts. Part I consists of a detailed study of the base pressure in two-dimensional and axially symmetric inviscid flow. The purpose of part I is to develop an understanding of the problem in its simplest form, and to study the effects on base pressure of variations in profile shape. In part II a semi-empirical theory is formulated since the results of part I indicate that an inviscid-flow theory cannot possibly be satisfactory for engineering estimates of base pressure. A comparison of the semi-empirical analysis with experimental results is also presented in part II of the report.

Much of the present material was developed as part of a thesis submitted to the California Institute of Technology in 1948. Acknowledgment is made to H. W. Liepmann of the California Institute of Technology for his helpful discussions regarding the theoretical considerations, and to A. C. Charters of the Ballistic Research Laboratories for making available numerous unpublished spark photographs which were taken in the free flight experiments of reference 5.

¹ Supersedes NACA TN 2137, "An Analysis of Base Pressure at Supersonic Velocities and Comparison with Experiment," by Dean R. Chapman, 1950. The present report includes reference to some experiments not discussed therein, and incorporates a more detailed analysis of the effects of variations in profile shape on base pressure in inviscid flow.

I. BASE PRESSURE IN AN INVISCID FLUID

Throughout this part of the report the effects of viscosity are completely ignored and the flow field determined for an inviscid fluid wherein both the existence of a boundary layer and the mixing of dead air with the air outside a free streamline are excluded from consideration. It is assumed throughout that a dead-air region of constant pressure exists just behind the base and is terminated by a single trailing shock wave. As will be seen later, the assumption of zero viscosity oversimplifies the actual conditions; the results obtained with this assumption agree qualitatively with a number of experimental results, but provide quantitative information only on the effects of profile shape on base pressure.

TWO-DIMENSIONAL INVISCID FLOW OVER A SEMI-INFINITE PROFILE

In order to achieve the greatest possible simplicity at the outset, the case of a semi-infinite profile will be considered first. By this is meant a profile of constant thickness which extends from the base to an infinite distance upstream (fig. 1). The problem at hand is to determine the flow pattern in the neighborhood of the base. Since the effects of viscosity are at present ignored and only steady symmetrical flows are considered, the problem is simply that of determining the flow over a two-dimensional, flat, horizontal surface which has a step in it (fig. 2).

FIGURE 1.—Semi-infinite profile.

FIGURE 2.—Example of inviscid flow over a two-dimensional profile.

It is easy to construct a possible flow pattern which satisfies all necessary boundary conditions including the requirement of constant pressure in the dead-air region. For example, suppose the free-stream Mach number is 1.50 and some particular value of the base pressure coefficient, say $P_b = -0.30$ ($p_b/p_{\infty} = 0.53$), is arbitrarily chosen. Since the base pressure is prescribed, the initial angle of turning through the Prandtl-Meyer expansion (fig. 2) is uniquely determined, and in this particular case is equal to 12.4° at B. The pressure, and hence the velocity and Mach number, must be constant along the free streamline BC. For the example under consideration, the Mach number along the free streamline is calculated from the Prandtl-Meyer equations to be 1.92. For a uniform two-dimensional flow over a convex corner, the pressure depends only on the angle of inclination of a streamline, hence it follows that BC is a straight line. The triangle BCE therefore bounds a region of uniform flow having the same pressure as the dead-air

region. As the trailing shock wave (fig. 2) extends outward from E to infinity, interference from the expansion waves gradually decreases its strength until it eventually becomes a Mach wave. That part of the shock wave from C to E must deflect the flow through the same angle as the expansion waves originally turned it (12.4° for the particular example under consideration). This deflection certainly is possible since the Mach number in the triangle BCE is 1.92 which, according to the well-known shock-wave equations, is capable of undergoing any deflection smaller than 21.5° . As the flow proceeds downstream from the trailing shock wave CEF, the pressure approaches the free-stream static pressure, thus satisfying the boundary condition at infinity.

It is evident that a possible flow pattern has been constructed which satisfies all the prescribed requirements as well as the necessary boundary conditions. This flow, however, certainly is not the only possible one for the particular Mach number (1.50) under consideration, since any negative value of P_b algebraically greater than -0.30 also would have permitted a flow pattern to be constructed and still satisfy all boundary conditions. This is not necessarily true, though, if values of P_b algebraically less than -0.30 are chosen, as can be seen by picturing the conditions that would result if the base pressure were gradually decreased. The angle of turning through the Prandtl-Meyer expansion would increase and point C in figure 2 simultaneously would move toward the base. The base pressure can be decreased in this manner only until a condition is reached in which the shock wave at C turns the flow through the greatest angle possible for the particular local Mach number existing along the free streamline. The base pressure cannot be further reduced and still permit steady inviscid flow to exist. The flow pattern corresponding to this condition of a maximum-deflection shock wave can be considered as a "limiting" flow of all those possible. There are obviously an infinite number of possible flows for a given free-stream Mach Number, but only one limiting flow.

The limiting value of the base pressure coefficient can be calculated as a function of the free-stream Mach number by reversing the procedure described above for constructing possible flow patterns. Thus, for a given value of the local Mach number along the free streamline a limiting flow pattern can be constructed by requiring that the angle of turning be equal to the maximum-deflection angle possible for a shock wave at that particular local Mach number. By use of the Prandtl-Meyer relations the appropriate value of the free-stream Mach number is then directly calculated from the angle of turning and the local Mach number along the free streamline. This process can be repeated for different values of the local Mach number along the free streamline and a curve drawn of the limiting base pressure coefficient as a function of Mach number. Such a curve is presented in figure 3. The shaded area represents all the possible values of the base pressure coefficient for two-dimensional inviscid flow. The upper boundary of the shaded area corresponds to the limiting flow condition for various free-stream Mach numbers.

There is no reason a priori to say that for a given M_∞ the limiting flow pattern represents that particular one which most nearly approximates the flow of a real fluid.

FIGURE 3.—Base pressure for two-dimensional inviscid flow.

The curve representing these limiting flow patterns can be considered simply as being the curve of maximum base drag (and hence maximum entropy increase) possible in an inviscid flow. This is the only interpretation that will be given to this curve for the time being. Since it is these limiting solutions which will be singled out later for further use, a special symbol P_{b_i} will be used to designate the base pressure coefficient of such flows. It is evident from figure 3 that in the Mach number region shown the values of P_{b_i} for two-dimensional flow correspond to very high base drags, being almost as high as if a vacuum existed at the base. At Mach numbers greater than or equal to 6.0, the values of P_{b_i} exactly correspond to a vacuum at the base.

AXIALLY SYMMETRIC INVISCID FLOW OVER A SEMI-INFINITE BODY

In principle the same method of procedure can be used for inviscid axially symmetric flow as was used for inviscid two-dimensional flow. The axially symmetric flows, however, are somewhat more involved than the corresponding two-dimensional flows. For example, in axially symmetric flow the expansion wavelets issuing from the corner of the base are not straight lines as they are in Prandtl-Meyer flow. Moreover, additional complications arise since the flow conditions upstream of the trailing shock wave do not depend solely on the inclination of the streamlines at a given point, but depend on the whole history of the flow upstream of the Mach lines passing through that point. As a consequence of these complications, the free streamline of constant pressure cannot be straight.

In order to construct possible flow patterns as was done in the two-dimensional case, the method of characteristics for axially symmetric flow must be used. The details of the particular characteristics method employed are described in reference 6. By employing the characteristics method the inviscid flow field corresponding to a given base pressure can be constructed step by step for any given value of the Mach number. The shape of the free streamline is, of course, determined by the condition that the pressure and the velocity must be constant along it. An example of such a construction for a free-stream Mach number of 1.5 is given in figure 4 (a). In this particular case, the base pressure

FIGURE 4.—Typical Mach nets for inviscid flow over the base of a semi-infinite body of revolution.

coefficient which has been chosen arbitrarily is -0.25 . It is to be noted that there is a striking difference between the axially symmetric flow (fig. 4 (a)) and the two-dimensional flow (fig. 2). The inviscid flow pattern for the axially symmetric case cannot be constructed all the way to the axis of symmetry and still satisfy the prescribed boundary conditions. This is a consequence of the curvature of the free streamline and the fact that the Mach number along the free streamline in the case under consideration is 1.84, which, at the most, is capable of deflecting a streamline only 19.9° by a single shock wave. As is illustrated in figure 4 (a), the angle of inclination of the free streamline for this example is already 19.9° at a value of $r/r_b = 0.552$, where r is the radial distance from the axis and $r_b = h/2$ is the radius of the base. Since the angle of inclination of the constant-pressure free streamline would continue to increase monotonically as the axis is approached, the flow pattern of figure 4 (a) cannot be constructed farther than the point shown ($r/r_b = 0.552$) and still permit the flow to be deflected through a single shock wave and become parallel to the axis of symmetry. This phenomenon is not attributable to the particular combination of Mach number and base pressure selected for figure 4 (a). In figures 4 (b), 4 (c), and 4 (d), other examples are presented which illustrate the flow for different values of Mach number and for different base pressures. In each case the free streamline has been ter-

FIGURE 4.—Concluded.

minated at the point where the local angle of inclination is equal to the angle corresponding to the greatest possible deflection by a single shock wave. It is evident that none of these flow patterns could be constructed down to the axis of symmetry. Altogether, approximately 30 flow patterns were constructed by the characteristics method; in no case could the flow be constructed all the way to the axis.

The flow patterns built up by the method of characteristics should not be regarded as unrealistic simply because the flow cannot be constructed all the way to the axis. In a real fluid the flow outside the boundary layer is similar because the wake behind the body fills the region near the axis and prevents the outer flow from reaching the axis. This fact suggests that the axially symmetric inviscid-flow patterns

should be investigated further as they might bear some relation to actual flows if the displacement effect of the wake were considered.

The flow fields containing a free streamline not meeting the axis of symmetry can be considered as those that would exist in inviscid flow about a body of revolution which has an infinitely long cylindrical rod (or "sting") attached to the base. As an example, the flow of figure 4 (a) would correspond to a body having a rod of diameter $d=0.552h$ attached to the base. (See fig. 5.) With such a model the trailing shock wave turns the free streamline through the greatest deflection possible for the given local Mach number along the free streamline. The flow field is therefore the limiting flow field of all those possible for the given free-stream Mach number and the given ratio of d/h .

FIGURE 5.—Axially symmetric semi-infinite body with rod attached.

Just as in the case of the two-dimensional body, there are also an infinite number of possible flow patterns for the body of revolution with a rod attached. This is true because for a given configuration as many additional flow patterns as desired can be constructed by simply selecting the base pressure to be any pressure between the free-stream pressure and the pressure corresponding to the limiting flow. The limiting flow pattern is to be given the same physical significance for axially symmetric flow as for two-dimensional flow; that is, the corresponding base pressure coefficient P_{b_i} represents the maximum base drag possible for an inviscid flow with a single trailing shock wave and a given ratio of d/h .

By choosing different values of the base pressure coefficient for a fixed Mach number, the inviscid solutions determined by the method of characteristics enable a plot of P_{b_i} against d/h to be made. This procedure has been carried out for Mach numbers of 1.25, 1.5, 2.0, 2.5, 3.0, and 4.0. The results are shown in figure 6. Each point on the curves in this figure represents one flow pattern constructed by the characteristics method. The values for $d/h=0$ correspond to the semi-infinite body without a rod attached. It is to be noted that for each curve in figure 6 the value of P_{b_i} extrapolates to zero as d/h approaches zero. This means that the base pressure is equal to the free-stream static pressure, the free streamline is undeflected, and the base drag is zero. Hence, the limiting flow pattern

FIGURE 6.—Parameter proportional to the maximum base drag possible in an inviscid axially symmetric flow.

and the infinity of possible inviscid flows for $0 < d/h < 1$ degenerate into a single trivial solution corresponding to zero base drag for $d/h=0$. This behaviour appears anomalous on first thought, particularly when one remembers that the coefficient P_{b_i} represents the maximum possible base drag that can exist for an inviscid flow of the type being considered. An explanation can be obtained from a consideration of the equations of motion since they are the basis for the method of characteristics. This explanation, however, is not essential for an understanding of the main conclusions regarding base pressure, and hence is presented as Appendix A.

In figure 6 the limiting values as d/h approaches 1.0 correspond to the previously treated case of two-dimensional flow. It can be seen that this must be the case by visualizing the limiting process as taking place with both d and h approaching infinity, but with the difference $(h-d)$ held constant. The configuration approached in this manner would be a two-dimensional step of height $(h-d)/2$; hence the pressure coefficient approached would be the limiting base pressure coefficient for two-dimensional inviscid flow. On the other hand, if d/h is equal to unity (instead of approaching it from values always less than unity), then the corresponding configuration would be a semi-infinite body of revolution with a cylindrical rod of the same diameter attached to the base. Although no dead-air region exists

in this latter case since the flow is everywhere uniform, the base pressure in the physical sense would be the static pressure at the junction of body and rod, and hence P_{b_i} would be zero.

The occurrence of more than one possible solution in two-dimensional flow and also in axially symmetric flow with a rod attached does not represent a new occurrence in inviscid flow theory. A similar situation occurs, for example, in airfoil theory for an inviscid, incompressible fluid. As is well known, a satisfactory solution in this case has been found in the use of the so-called Kutta condition, which can be readily justified on the basis of qualitative consideration of viscous effects near the trailing edge. Apart from the effects of viscosity several other considerations, such as stability of the flow, also have been of importance in other unrelated problems when selecting a suitable inviscid flow solution from a possible choice of more than one. As an example of this, the inviscid channel flow studied in reference 7 may be cited. For the present problem, however, the preceding analysis of axially symmetric inviscid flows points toward viscous effects (rather than stability of inviscid flow) as being the essential mechanism determining the base pressure. Before considering viscous effects, however, the effect on base pressure of variations in profile shape will be analyzed in detail since experiments have indicated widely different results for various profiles. The method presented later for correlating base pressure data requires that the measurements first be corrected for the effect of profile shape. In the section which follows equations are developed for such a correction.

TWO-DIMENSIONAL AND AXIALLY SYMMETRIC INVISCID FLOW OVER FINITE PROFILES

In this section consideration is given to the flow over a finite two-dimensional profile concurrently with that of a finite body of revolution. For either type of flow, the presence of the profile causes the Mach number and pressure in the flow field ahead of the base (M, p) to be nonuniform and different from free-stream conditions (M_∞, p_∞). This is illustrated in figure 7 (a) for a profile without boattailing. As a result of the disturbance caused by the profile, the base pressure depends on profile shape even in an inviscid flow. In this section, a method is developed for calculating corrected free-stream conditions (M', p') to which the base pressure can be referred and be nearly independent of profile shape. This method does not depend on the magnitude of the base pressure or on the dimension d (fig. 7 (a)), and hence is useful in comparing experimental measurements made on various airfoils and bodies of revolution.

To fix ideas, the Mach lines shown as dotted lines in figure 7 (a) will be thought of as representing weak pressure waves; those with positive tangents (e. g., $D\bar{D}$) being members of the so-called first family, and those with negative tangents (e. g., $\bar{D}A$) being members of the so-called second family. Weak pressure waves issuing from the body can affect the base pressure in several ways. For example, waves of the first family starting between D and E not only affect conditions at A , but also affect conditions between A

(a) Finite profile.
(b) Finite profile with extended afterprofile.
FIGURE 7.—Sketch of inviscid flow over finite profile without boattailing.

and G . Such waves reflect from the bow shock wave between D and $\bar{E}$ and then become members of the second family of waves between $\bar{D}A$ and $\bar{E}G$ which directly interact with the dead-air region. Waves of the second family beyond $\bar{E}G$ would not affect the base pressure in an inviscid flow. The net effect of profile shape on the base pressure of a finite body, therefore, will be determined both by conditions at A and by the variation of conditions between A and G . If a hypothetical afterprofile were extended from the base, as illustrated in figure 7 (b), then such conditions would cause the average pressure (p') and Mach number (M') along AH of the extended afterprofile to differ from the corresponding free-stream conditions. These differences would represent the disturbance field induced near the base by the profile shape, and the base pressure referred to M' and p' (e. g., a curve of P_b' or p_b/p' versus M') could be regarded as corrected for the effects of profile shape in inviscid flow.² By applying the compatibility equations of the method of characteristics for either two-dimensional or axially symmetric flow to the triangle AGH in figure 7 (b), it can be deduced that the magnitude of the velocity averaged at points A and H is approximately equal to the magnitude of the velocity at point G . Thus, M' and p' can be evaluated either from conditions along a hypothetical extended afterprofile, or else from conditions at an appropriate point (G) in the flow over the given profile.

A second case to be considered is that of a profile having a

² It may be noted that M' and p' are analogous in some respects to the corrected free-stream Mach number and pressure used in subsonic wind-tunnel operation: the former represent the average Mach number and pressure induced in the vicinity of the base by the presence of the profile; whereas the latter represent the average Mach number and pressure induced in the vicinity of the test model by the presence of the tunnel walls. Both corrections are accurate only when the induced disturbance field is small and approximately uniform over the region in question.

negative boattail angle (β), as illustrated in figure 8 (a). This flow can be converted to an equivalent flow over a profile without boattailing having the same base pressure as the flow of figure 8 (a) and certain nonuniform conditions ahead of the base. This equivalent flow, illustrated in figure 8 (b), is identical to the type already considered and is such that the flow within $C'O'G'$ coincides with the flow within COG in figure 8 (a). Point G, therefore, is defined by the intersection of the Mach line passing through C, and the particular Mach line passing through O on which the velocity vector at O is parallel to the free-stream direction. Hence, for this second case also, M' and p' can be determined approximately either from conditions on a hypothetical extended afterprofile, or else from conditions in the original flow at point G.

FIGURE 8.—Sketch of inviscid flow in vicinity of base for profiles with boattailing.

A third and last case to be considered is that of a profile having a positive boattail angle, as illustrated in figure 8 (c). This flow also can be converted to an equivalent flow over a profile without boattailing having the same base pressure as the original flow (fig. 8 (c)), and certain nonuniform conditions ahead of the base. As sketched in figure 8 (d), the equivalent flow ahead of the base is such that the conditions downstream of $O'J'$ are identical to conditions downstream of OJ in figure 8 (c).³ Thus for $\beta > 0$, M' and p' can be determined approximately from conditions at G' in the equivalent flow, or else from conditions along a hypothetical profile extended downstream from O' , but M' and p' do not necessarily exist at any easily determined point in the original flow.

For any profile the relationship between the base pressure coefficient $P_b' \equiv (p_b - p')/q'$ which corresponds to the Mach number M' , and the base pressure coefficient $P_b \equiv (p_b - p_\infty)/q_\infty$ which corresponds to the Mach number M_∞ and to the given profile, is given by the equation

$$P_b' = \frac{q_\infty}{q'} (P_b - P') \quad (1)$$

where

$$P' = (p' - p_\infty)/q_\infty \quad (2)$$

and, if the profile disturbance field is small,

$$\frac{q'}{q_\infty} = 1 + \left(\frac{M_\infty^2}{2} - 1 \right) P' - \frac{2}{\gamma M_\infty^2} \left(1 + \frac{\gamma - 1}{2} M_\infty^2 \right) \frac{\Delta p_o}{p_o} \quad (3)$$

In this last equation (derived in appendix C), $\Delta p_o/p_o$ is the fractional loss in total pressure on passing through the bow wave. If the ratio p_b/p_∞ is used instead of the coefficient P_b , the analogous relation between the ratio p_b/p' and p_b/p_∞ obviously is

$$\frac{p_b}{p'} = \frac{1}{(p'/p_\infty)} \frac{p_b}{p_\infty} \quad (4)$$

For a given profile, these equations enable a curve of P_b' (or p_b/p') versus M' to be plotted if a curve of P_b (or p_b/p_∞) versus M_∞ is known.

In order to further clarify the concept of the disturbance field induced by profile shape, and also to illustrate the magnitude of the variations in base pressure that might be expected between different profiles, some representative calculations of M' and p' have been prepared in tables I, II, and III. For simplicity in these calculations, M' and p' have been evaluated along the hypothetical extended afterprofile at a distance h behind the base position, rather than to use in each case a more involved average over the appropriate extent of dead air. Table I applies to two-dimensional flow over the particular profile shown. The computations for $M_\infty = 1$ are based on the pressure distributions calculated by Guderley and Yoshihara in reference 8; the computations for other Mach numbers in this table are based on shock-expansion theory. It is evident that the disturbance field near the base is significant at low supersonic Mach numbers where the bow wave is detached, and also at hypersonic Mach numbers where the bow wave is very strong. At moderate supersonic Mach numbers, however, the profile disturbance field in two-dimensional flow is negligible, and conditions on a thin airfoil depend solely on the local surface inclination. It follows that the base pressure under such circumstances is nearly independent of profile shape and boattail angle. (If the angle of attack is small the base pressure is also nearly independent of angle of attack under these conditions.)

Table II, which is based on the method of characteristics, applies to the cone-cylinder body of revolution shown, and illustrates that the correction for the profile disturbance field is not large if the afterbody comprises a cylinder several diameters long. For example, at a Mach number of 1.5 for which the value of p_b/p_∞ is about 0.7, the value $p'/p_\infty = 0.98$ corresponds to a correction of about 6.7 percent to the base drag (since the base drag is proportional to $(1 - p_b/p_\infty)$).

Table III applies to a cone ($\beta = -10^\circ$), and illustrates that the correction for such profiles can be sizable. At a Mach number of 1.5, for example, the induced pressure field in this case amounts to over one-fourth of the base drag. For larger apex angles, the corresponding correction for cones can be considerably larger. It is to be noted that the induced pressure field usually represents a much more important correction to base drag than the induced Mach number field.

³ Such an equivalent flow can readily be constructed if the Mach number on the surface just ahead of the base in the original flow is sufficiently large, or if β is sufficiently small, to insure supersonic velocities along $O'G'$ in the equivalent flow.

II. A SEMI-EMPIRICAL METHOD FOR CORRELATING BASE PRESSURE MEASUREMENTS AND COMPARISON WITH EXPERIMENTAL RESULTS

QUALITATIVE EFFECTS OF VISCOSITY ON THE BASE-PRESSURE FLOW

A sketch showing the qualitative flow characteristics for the viscous-fluid flow in the region of the base is given in figure 9. The flow along the first expansion wavelet starts with the nonuniform distribution of Mach number M , pressure p , and with a boundary-layer thickness δ . Because the base pressure is lower than the pressure p , a small fan of expansion wavelets originates at point A. The existence

FIGURE 9.—Sketch of the viscous-fluid flow in the neighborhood of the base.

of dead air in a small volume immediately behind the base is a result of the separation at point B. As a consequence of the formation of a dead-air region it might be expected that the pressure along the streamline BC is approximately constant. The qualitative form of the boundary-layer profiles at stations between points B and C must take on the same nature as those existing at the boundary of a supersonic jet issuing into ambient air. Because of the viscosity of the fluid, the dead air is induced into a circulatory motion in the directions indicated by the small arrows in figure 9. The viscous mixing process causes the boundary layer to thicken as it approaches point C. In axially symmetric flow there is an additional reason for further spreading of the streamlines in the boundary layer as the trailing shock wave is approached. Since the mean radius of a streamtube in the boundary layer continually decreases as the trailing shock wave is approached, additional spreading is brought about in order to keep the annular cross-sectional area of the streamtubes approximately constant.

With this qualitative picture of the flow processes in mind, a brief description can be given as to how the base pressure arrives at its steady-state equilibrium value. To fix conditions in mind, suppose a jet of air is pumped from the body into the dead-air region and then is suddenly stopped. At the instant the jet is turned off, point C is far downstream of its equilibrium position. Due to the scavenging effect of the outside flow on the mass of dead air, some of this dead air is removed, thus causing the angle of turning at the corner to be increased and the pressure of the dead-air region to be decreased. The larger angle of turning increases the velocity outside the boundary layer, which in

turn increases the scavenging action, thereby again lowering the pressure and starting the cycle over again. Thus, point C moves rapidly to a position as close to the base as possible. There is, however, at least one important factor which prevents point C from going as far toward the base as that point which would roughly represent the limiting solution for inviscid flow. As C moves toward the base, the pressure ratio of the trailing shock wave increases, making it more difficult for the scavenged air and the low-velocity air in the boundary layer to overcome the pressure rise of the shock wave and flow downstream. The opposition of this effect to the ones mentioned previously would serve to establish equilibrium. It appears, therefore, that a satisfactory theory of base pressure would have to consider the mixing process in conjunction with the inviscid-fluid characteristics of the outer flow.

BASIS FOR CORRELATION OF EXPERIMENTAL DATA

It is assumed that the flow expands over the corner of the base as illustrated in figure 9. The base thickness h would be the trailing-edge thickness in the case of two-dimensional flow, and would be the base diameter in the case of axially symmetric flow. An attempt to correlate the various measurements of base pressure is made on the basis of the relationship

$$P_b' = f\left(M', \frac{\delta}{h}, \beta\right) \quad (5)$$

which assumes that the base pressure coefficient corrected for the profile disturbance field is affected by viscous effects only through the ratio of boundary-layer thickness to base thickness. Actually, even for a fixed value of δ/h the base pressure would be affected by anything that affects the distribution of fluid properties within the boundary layer or within the mixing layer downstream of the base. It will be seen subsequently, though, that in many cases the above relationship yields acceptable results.

If the boundary-layer flow is laminar, then from dimensional analysis and the classical considerations of the terms involved in the boundary-layer equations, it follows that

$$\delta \sqrt{\frac{U_\infty}{\nu_\infty L}} = f(M_\infty, \text{profile shape})$$

Rewriting this equation,

$$\frac{\delta}{h} = \frac{L/h}{\sqrt{\frac{U_\infty L}{\nu_\infty}}} f(M_\infty, \text{profile shape}) = \frac{C}{\sqrt{Re}} \frac{L}{h}$$

where C is a function of the Mach number and profile shape, but independent of viscosity. For a given L/h , variations in profile shape affect the boundary-layer thickness principally through the action of the pressure gradients set up by the particular profile contour. As a first approximation the effects of variations in pressure distribution on the thickness of the boundary layer just ahead of the base will be neglected since these effects in most cases should be small compared to the effects of Reynolds number and L/h ratio. Within the limits of this simplification, the above equation is

applicable to any profile shape or length. Hence in correlating the data for laminar-boundary-layer flow, the parameter $L/(h\sqrt{Re})$ is used in the absence of direct measurements of δ/h .

In the case of turbulent flow a similar parameter can be obtained. By approximating the turbulent boundary-layer profile with a $1/7$ -power law, the ratio δ/h for low-speed flow turns out to be inversely proportional to the $1/5$ power of the Reynolds number. (For example, see reference 9.) Using this result, the appropriate parameter in correlating base-pressure data for turbulent boundary-layer flow would be $L/[h(Re)^{1/5}]$.

EXPERIMENTAL DATA FOR TWO-DIMENSIONAL FLOW

At present the available experimental results on base pressure in two-dimensional flow are rather limited, but they are sufficient to provide a qualitative check on one particular result of the inviscid-flow calculations; this result concerns the essential difference, as indicated by the inviscid-flow calculations, between the base pressure in two-dimensional flow and in axially symmetric flow. The absolute magnitude of the base pressure coefficient for two-dimensional inviscid flow at a given Mach number is represented by the limit of the values for axially symmetric flow as d/h approaches unity in figure 6. For low and moderate supersonic Mach numbers this limiting value is several times the value for a body of revolution, which, as will be seen later, is represented in figure 6 by a d/h ratio somewhere between 0.5 and 0.8. For high supersonic Mach numbers the difference between the two types of flow, according to figure 6, is small. These considerations which indicate that, except at high supersonic Mach numbers, a pronounced difference should exist between the base pressure in two-dimensional and axially symmetric flow, are in agreement with existing data. In reference 10, the wind-tunnel measurements for two-dimensional flow over a wedge airfoil at a Mach number of 1.4 and a Reynolds number of 0.6 million indicate a value of -0.41 for the base pressure coefficient. Measurements presented later for axially symmetric flow at the same Mach number and Reynolds number, however, indicate values around -0.20 . This large difference is in accord qualitatively with the considerations based on the curves of figure 6.

In order to make a preliminary evaluation of the Reynolds number effect on base pressure in two-dimensional flow, some measurements have been made on a constant-chord wing of finite span having a thick trailing edge.⁴ Because the ambient air near the wing tips can flow laterally around the tip and into the low-pressure region behind the base, the data cannot be considered as strictly representing two-dimensional flow. Nevertheless, the ratio of span to base thickness (40) was sufficiently large on the wing employed so that tip effects should not affect conclusions concerning the qualitative influence of Reynolds number on base pressure in two-dimensional flow. The results of base-pressure measurements taken at a Mach number of 2.0 are shown in figure 10 (a). It is apparent that the base drag increases considerably as the Reynolds number increases. Since the surfaces of the wings were smooth, and the highest Reynolds

number attained was 1.8 million, the data are representative of the case of laminar flow in the boundary layer. A plot of these data against the parameter $L/(h\sqrt{Re})$ is shown in figure 10 (b). It is to be noted that in this form a straight line can be faired through the data in the region covered by the tests. For larger values of $L/(h\sqrt{Re})$ the line would be expected to curve and approach the line representing zero base drag.

EXPERIMENTAL DATA FOR AXIALLY SYMMETRIC FLOW

Fortunately, there are sufficient experimental data available for axially symmetric flow to make a fairly extensive correlation of P_b' with the parameters $L/(h\sqrt{Re})$ and $L/[h(Re)^{1/5}]$, where h is now the base diameter. Most of these data have been obtained from wind-tunnel measurements on bodies of revolution mounted from the rear by a cylindrical support. Accordingly, a knowledge of the possible support and wall interference effects is necessary for a satisfactory interpretation of the wind-tunnel measurements. Some experimental data on support interference and reflected bow-wave interference are presented in appendix B. It will suffice for the present purposes to state that the wind-tunnel measurements were taken with a support sting of sufficient unobstructed length so that no interference effect of support length is present in the data. Likewise, no appreciable interference resulting from the

⁴ These data were taken in the Ames 1- by 3-foot supersonic wind tunnel No. 1 employing a wing of 9-inch span with a base-pressure orifice located 1 inch outboard of the plane of symmetry.

reflected bow wave is present in the data. As regards the effects of support diameter, it is known from a relatively complete set of interference measurements made by Perkins (reference 11), part of which is presented later, that the data taken at $M=1.5$ are essentially free of support interference. At the higher Mach numbers, however, a complete set of support-diameter interference measurements was not made. Consequently, some effect may be present in the data taken at $M=2.0$ and $M=2.9$. For consistency, these data which may be affected to a small extent by support-diameter interference have been taken with a fixed value of 0.4 for the ratio of support diameter to base diameter. By comparing the base pressure measured on various bodies tested with the same relative support diameter, the effects of body shape can be deduced if it is assumed that changes in nose shape do not produce significant changes in the support interference. This is believed to be a valid assumption for the body and support dimensions used.

In reducing the experimental data for correlation, the measurements are first corrected for the disturbance field induced by profile shape. All bodies of revolution used in the present experiments consisted of either a cone-cylinder (10° semiangle of cone) or an ogive-cylinder (10-caliber ogival radius) combination. In order to determine the body-shape correction (P') the pressure distribution over such combinations has been calculated using the method of characteristics. Two typical pressure distributions for a Mach

FIGURE 11.—Typical pressure distribution as determined by the method of characteristics; $M_\infty=2.0$.

number of 2.0 are shown in figure 11. For the reasons explained earlier, the correction P' is determined by selecting the value of the pressure coefficient existing on an extension of the cylindrical afterbody at a location approximately one diameter downstream of the base position. The values of P' determined in this manner enable the corresponding values of P_b' to be determined from equations (1) and (3).

The quantity P_b' should not depend on the body shape for a given M' . For all but a few exceptional shapes, such as a simple cone without an afterbody, the Mach number M' in the present tests is sufficiently close to the free-stream Mach number to enable a direct comparison to be made between various body shapes after correcting for the pressure disturbance field only. For these exceptional cases, which represent small values of the length-diameter ratio, an additional correction $\frac{\partial P_b}{\partial M} (M' - M_\infty)$ is added to the right side of equation (1), so that the comparison of various bodies is made on the basis of a constant M' equal to M_∞ . Since even in an extreme case this latter correction is small compared to P' , the derivative $\frac{\partial P_b}{\partial M}$ can be roughly estimated

without affecting the final results appreciably. For the data to be presented subsequently, this correction was made only for those bodies with a length-diameter ratio of 4 or less, since it amounted to only 6 percent of the measured data in the most extreme case ($L/h=0.9$) and was negligible for the bodies with L/h greater than 4.

In attempting to correlate the available experiments it will be convenient to consider first the case of laminar flow in the boundary layer, and then the case of turbulent flow. The experiments representing the case of laminar boundary-layer flow were conducted on bodies of revolution with polished surfaces, and those representing turbulent flow were conducted on the same models with artificial roughness added in the form of a narrow transition strip. (See reference 12.) Although for simplicity the data are referred to simply as representing either laminar or turbulent flow, in a few cases the actual boundary layer may be in the transition state. It is to be noted that with smooth models transition (insofar as it affects base pressure) probably begins at Reynolds numbers of the order of 4 million. Likewise, with roughness added in order to obtain turbulent flow, the artificial roughness may not bring about complete transition ahead of the base at Reynolds numbers less than about 2 million.

Laminar boundary-layer flow approaching base.—Wind-tunnel measurements of the base pressure for various bodies of revolution at a Mach number of 1.53 are shown in figure 12 (a). These data, taken from reference 12, include the effect of variations in Reynolds number and body shape. The large effect of both Reynolds number and body shape is evident. Since the boundary-layer flow is laminar for these data, the extent to which correlation is achieved is most easily determined by plotting P_b' as a function of $L/(h\sqrt{Re})$. Figure 12 (b) shows the data of figure 12 (a) plotted in this form, from which it is evident that the experimental data correlate reasonably well to a single curve. The scatter of the various measurements about the mean line is attributed partly to the fact that the thickness and

(a) Measured data, $M_\infty = 1.53$.

FIGURE 12.—Measured and correlated base pressure data; $M_\infty = 1.53$, laminar boundary-layer flow.

velocity profile of the boundary layer approaching the base, and hence the base pressure, are not strictly a function of the Reynolds number and length-diameter ratio alone.

The results of some measurements of the base pressure for various bodies with laminar boundary-layer flow at a Mach number of 2.0 are shown in figure 13 (a). The data through which curves are drawn were taken in the Ames 1- by 3-foot supersonic wind tunnel No. 1 under conditions similar to the tests at a Mach number of 1.53 reported in reference 12. The remaining data points were obtained from the experiments of Kurzweg (reference 13) by plotting his data for insulated smooth bodies as a function of Mach number, and reading the values of base pressure for $M_\infty = 2.0$ from the faired curves. The same qualitative effects of body shape and Reynolds number as were observed at a Mach number of 1.53 are evident from these data obtained at the higher Mach number. Figure 13 (b) shows the data of figure 13 (a) plotted in the form suitable for correlation according to the theoretical considerations. Considering the wide variety of body shapes tested, it can be seen that these data also correlate reasonably well to a single straight line. If the tests were extended to larger values of L/h , this line presumably would curve and approach the abscissae axis.

Turbulent boundary-layer flow approaching base.—The results of wind-tunnel measurements of base pressure on bodies of revolution at a Mach number of 1.5 with turbulent

(a) Measured data, $M_\infty = 2.0$.
(b) Correlation of measured data, $M_\infty = 2.0$.

FIGURE 13.—Measured and correlated base pressure data; $M_\infty = 2.0$, laminar boundary-layer flow.

boundary-layer flow approaching the base are shown in figure 14 (a). Also shown in this figure are the results of free-flight measurements reported by Charters and Turetsky in reference 5. It is evident from this figure that the effect of Reynolds number on base pressure is small; whereas figure 12 (a) shows that it is large in the case of laminar boundary-layer flow.

The measured data of figure 14 (a) are shown in figure 14 (b) plotted in the form suitable for purposes of correlating experimental data. Since the body-shape correction (P_b') is independent of viscous effects, the same corrections have been used for the case of turbulent flow as were used for laminar flow. It may be seen from figure 14 (b) that the data correlate fairly well to a straight line.

Some experimental data for turbulent boundary-layer flow at a Mach number of 2.0 are shown in figure 15 (a) and the plot of P_b' against $L/[h(Re)^{1/5}]$ is shown in figure 15 (b). The curves in these figures show the same charac-

teristic of relatively constant base pressure as was noted above for turbulent boundary-layer flow at a Mach number of 1.5. Again, there is a reasonably good correlation of these data, as is evident from figure 15 (b).

COMPARISON OF EXPERIMENTAL RESULTS WITH THE INVISCID-FLOW CALCULATIONS

Since the intercept (P_b^*) of a curve of P_b' versus δ/h is independent of the Reynolds number, some correlation (possibly only qualitative) might be expected between the experimental values of P_b^* and the inviscid-flow calculations, provided allowance is made for the displacement effect of the wake near the trailing shock wave. As long as the wake thickness is well defined (reasonably steady wake) a simple and plausible method of estimating P_b^* would be to evaluate the base pressure coefficient for maximum drag in an inviscid flow wherein an equivalent solid object, such as illustrated in figure 5, replaced the wake. Such an object would have no effect in inviscid two-dimensional flow but would have a pronounced effect in axially symmetric flow. If in axially symmetric flow a rod of diameter d is considered to replace the wake of diameter t , the resulting maximum drag in inviscid flow would be the same as calculated in part I where the corresponding base pressure coefficient was designated by P_{b_i} . (See fig. 6.) Thus an estimate for the variation of P_b^* with Mach number in axially symmetric flow would be

(a) Measured data, $M_\infty = 2.0$.
(b) Correlation of measured data, $M' = 2.0$.
FIGURE 15.—Measured and correlated base pressure data; $M_\infty = 2.0$, turbulent boundary-layer flow.

$$P_b^* \approx P_{b_i} \text{ for } \frac{d}{h} = \frac{t}{h} \quad (6)$$

and in two-dimensional flow it would be

$$P_b^* \approx P_{b_i} \quad (7)$$

Since a fluctuating wake presumably cannot be replaced by a rod without essentially altering the flow conditions near the base, the above estimates cannot be expected under such conditions to yield anything more than the right order of magnitude.

Some information on the thickness and steadiness of the wake has been obtained from an examination of numerous spark photographs taken of projectiles in free flight.⁵ Typical spark photographs are shown in figure 16, and the results of measuring the wake thickness on a large number of similar photographs are shown in figure 17. Figure 16 (a) represents the case of laminar flow in the boundary layer at a free-stream Mach number of 1.73. Under these conditions the wake thickness appears to be reasonably well defined, although the trailing shock wave is not well defined near the wake. Figures 16 (b) and 16 (c) indicate that for turbulent boundary-layer flow on bodies of revolution the trailing shock wave and the wake are not very steady at Mach numbers below about 2. Thus it is not surprising

FIGURE 16.—Concluded.

that, as will be seen later, equation (6) is in poor agreement with measurements for turbulent boundary-layer flow at Mach numbers below about 2. At higher Mach numbers the trailing shock wave and the wake become more clearly defined (figs. 16 (d) and 16 (e)), but the accuracy of equation (6) in this region cannot as yet be tested because of insufficient experimental data.

A comparison between inviscid-flow calculations and experimental values of P_b^* is more direct for airfoils than for bodies of revolution since the wake thickness presumably need not be accounted for in two-dimensional flow. The value of P_b^* as determined from the finite-span wing data in figure 10 (b) is -0.30 . This is fairly close to the limiting pressure coefficient (P_{bi}) for two-dimensional flow, which is -0.33 for a Mach number of 2.0. (See fig. 3.) Definite conclusions as to the significance of this agreement, however, will have to await the results of measurements on airfoils at other Mach numbers, and on airfoils with turbulent flow in the boundary layer.

FIGURE 16.—Shadowgraphs of projectiles in flight. (Courtesy Ballistic Research Laboratories, Aberdeen, Md.).

For laminar flow on bodies of revolution at Mach numbers of 1.5 and 2.0, the wake thickness (t/h) from figure 17 is 0.55 and 0.49, respectively. From figure 6, the corresponding values of P_{b_i} are -0.25 and -0.29, respectively. On the other hand, the values of $P_{b_i}^*$ determined from the intercepts of the extrapolated lines in figures 12 (b) and 13 (b) are -0.24 and -0.20, respectively. Hence, although the inviscid-flow calculations may provide a reasonable approximation for two-dimensional flow near $M=2.0$, and for axially symmetric flow near $M=1.5$, there is a serious discrepancy with the experimental results for axially symmetric flow at $M=2.0$. This large discrepancy indicates that the simple relation given by equation (6) which attempts to connect $P_{b_i}^*$ with the inviscid calculations is not always a satisfactory approximation. The good agreement obtained in two of the three cases may be entirely fortuitous. Additional experiments are needed to clarify this point.

FIGURE 17. Wake thickness as a function of Mach number (determined from shadowgraphs of the Ballistic Research Laboratories, Aberdeen, Md.).

The fact that the inviscid-flow calculations agree qualitatively, though not quantitatively, with experimental results can be seen by a comparison with measurements of the base pressure at various Mach numbers but with an essentially constant Reynolds number. Figure 18 shows some experimental free-flight data of Charters (reference 5) together with the corresponding wind-tunnel data of Kurzweg (reference 13), and the present investigation.⁶ These experimental data are for turbulent flow in the boundary layer. In this figure the ordinate of the curve labeled "curve based on equation (6)" is proportional to the value of the limiting pressure coefficient P_{b_i} determined at each Mach number in the manner indicated by equation (6). It is apparent that the curve based on the calculations of P_{b_i} for inviscid flow gives the right order of magnitude for the base pressure coefficient, but does not give good quantitative agreement. As an incidental point, it may be noted that the various wind-tunnel and free-flight measurements shown in this figure agree quite well at all Mach numbers.

VARIATION OF BASE PRESSURE WITH REYNOLDS NUMBER FOR NATURAL TRANSITION

Since the base pressure is different for laminar and turbulent boundary-layer flow approaching the base, it is of interest to examine the results of measurements in the intermediate range of Reynolds number where the transition

FIGURE 18.—Variation of base pressure coefficient with Mach number for turbulent boundary layer flow.

"point" moves from a position downstream of the base to a position upstream of the base. Figure 19 shows the results of some base-pressure measurements at a Mach number of 2.0 on a body of revolution in the Reynolds number range from 0.4 million to 10 million. At Reynolds numbers below about 2 million, where the boundary-layer flow is laminar, the base pressure coefficient depends to a great extent on the Reynolds number, as was noted earlier. In the Reynolds number range from 4 to 6 million, where the transition point moves ahead of the base, the base pressure again is sensitive to changes in the Reynolds number (and presumably also

FIGURE 19.—Variation of base pressure coefficient with Reynolds number for natural transition; $M_\infty=2.0$.

⁶ In the present experiments measurements occasionally were made in more than one facility. For example, the three experimental points in figure 18 representing the wind-tunnel data at Mach numbers near 1.5 represent measurements with three different nozzles.

to other factors affecting transition such as surface roughness, free-stream turbulence, and rate of heat transfer). At the higher Reynolds numbers where a turbulent boundary layer exists for some distance ahead of the base, the base pressure is not sensitive to changes in the Reynolds number.

From the viewpoint of reliably extrapolating small-scale measurements, it is encouraging that the base pressure coefficient for turbulent boundary-layer flow is not sensitive to changes in the Reynolds number. At a Mach number of 2.0 this insensitivity is evident from a comparison of the data for the model with an L/h of 5 in figures 15 (a) and 19. At a Reynolds number of 2×10^6 , where turbulent flow is attained on the models by using artificial roughness, the base pressure coefficient does not differ by more than 3 or 4 percent from the value at a Reynolds number of 1×10^7 , where turbulent flow is attained without such an artifice. At a Mach number of 1.5 the measurements indicate this same characteristic, as can be seen from the data given in figure 20. These data at the somewhat lower Mach number do not show any appreciable dependence on Reynolds number within the range from 2×10^6 to 1.6×10^7 . It is interesting that the free-flight data of Hill and Alpher (reference 14) also show no significant effect of Reynolds number within

the range from 2×10^7 to 1×10^8 . These latter data, however, give a widely different value for the base pressure. It is evident from figure 20 that the base pressures measured in reference 14 differ from the values of references 5 and 13 and the present wind-tunnel tests because of some factor other than differences in Reynolds number. The possible effects of support interference in the present wind-tunnel tests would not appear to contribute any appreciable amount to this discrepancy for two reasons. First, good agreement is obtained at all Mach numbers between the present wind-tunnel tests and the free-flight firings of Charters; and second, the measurements of support interference as described in appendix B indicate that for the support dimensions used ($d/h=0.25$ and $d/h=0.40$ in fig. 20) these effects are an order of magnitude smaller than the observed discrepancies. Since the models of reference 14 were equipped with tail fins of sufficient size so that their presence at moderate supersonic Mach numbers might be expected to lower considerably the pressure in the vicinity of the dead air (algebraically lower the effective P'), it would appear that the observed discrepancy is attributable to the effect of tail fins on base pressure.⁷

FIGURE 20.—Variation of base pressure coefficient with Reynolds number for turbulent boundary-layer flow; $M_\infty = 1.5$.

⁷ Subsequent experiments conducted at the Ames Laboratory by J. R. Spahr and R. R. Dickey have shown that this is the case.

CONCLUDING REMARKS

The simplest approach to an analysis of base pressure for supersonic flow is that of considering the flow of an inviscid fluid. Although such an approach has produced many useful theories when applied to other aerodynamic problems, it produces results of very limited value when applied to the present problem. The inviscid-fluid theory indicates that the only possible base pressure for a body of revolution without a rod attached to the base is the free-stream static pressure. Moreover, this simple theory also indicates that for two-dimensional flows, as well as axially symmetric flows with a rod attached to the base, there are an infinite number of possible solutions for a given body shape and Mach number.

The first of the above-mentioned shortcomings of inviscid theory can be remedied by allowing qualitatively for the existence of a wake, since by so doing the high-velocity streamlines are displaced from the axis of symmetry and a base drag other than zero can be obtained. The second shortcoming, of having an infinite number of possible solutions from which to choose, is not easily remedied. In particular, the comparison between the inviscid-flow calculations and experiment has shown that if the limiting flow pattern (maximum drag possible) at each Mach number is singled out from the infinity of possible inviscid-flow solutions, then the characteristics of base pressure observed thus far can be explained, but only qualitatively. Thus, the experimental finding that an increase in support diameter behind a body of revolution can considerably decrease the base pressure is explained by an interpretation of the behavior in an inviscid-fluid flow. Also, the experimental result of a much lower base pressure in two-dimensional flow (at low and moderate supersonic Mach numbers) than in axially symmetric flow is satisfactorily explained by the inviscid-flow

calculations. As regards quantitative results, though, the calculations based on the maximum drag possible in inviscid flow do not agree with the observed effects for turbulent boundary-layer flow, and agree only in certain cases with the observed effects for laminar boundary-layer flow.

In an attempt to formulate a more accurate quantitative analysis a semi-empirical analysis has been developed. The available experimental data correlate reasonably well when the base pressure coefficient, corrected for the effects of profile shape, is plotted as a function of a parameter which is approximately proportional to the ratio of boundary-layer thickness to base thickness. As a result of this correlation several general conclusions can be drawn. One such conclusion is that the variation of base pressure with Reynolds number is small at high Reynolds numbers where the boundary layer approaching the base is turbulent, but is large at low Reynolds numbers where the boundary layer is laminar. Another conclusion is that the effect on base pressure of the disturbance field induced by profile shape can be adequately explained on the basis of inviscid calculations.

In order to develop a thorough understanding of the behavior of base pressure in supersonic flow, further experimental and theoretical investigations are required. At present, experimental results are especially needed as regards the base pressure in two-dimensional flow, even at low supersonic Mach numbers. Experiments conducted at high supersonic Mach numbers are also needed, both for two-dimensional flow and for axially symmetric flow.

MOFFETT FIELD, CALIF., May 11, 1950.

APPENDIX A

AXIALLY SYMMETRIC FLOWS CONVERGING TOWARD THE AXIS

The rather anomalous result obtained when applying the method of characteristics to base-pressure flows can be clarified by examining the equations of motion on which the method of characteristics is based. The differential equation for the velocity potential ϕ of an inviscid axially symmetric compressible flow is (see reference 6, for example)

$$\left(1 - \frac{\phi_x^2}{a^2}\right) \phi_{xx} - 2 \frac{\phi_x \phi_r}{a^2} \phi_{xr} + \left(1 - \frac{\phi_r^2}{a^2}\right) \phi_{rr} + \frac{\phi_r}{r} = 0 \quad (A1)$$

where a is the local velocity of sound, x is the coordinate measured parallel to the direction of the undisturbed stream, and r is the radial coordinate. If a transformation is made to a new system (ξ, η) of curvilinear coordinates, where ξ and η are distances measured along the two Mach lines issuing from a point, then the equation of motion for the velocity potential becomes simply (the details of the algebra involved in making this transformation may be found in reference 6),

$$\frac{\partial^2 \phi}{\partial \xi \partial \eta} = \frac{\sin^2 \alpha}{r} \frac{\partial \phi}{\partial r} \quad (A2)$$

where α is the local Mach angle. It is to be noted that the new variables have the simple physical significance that lines of constant ξ and η are the Mach lines of the flow. The derivative of the velocity potential in any given direction is the projection of the velocity vector along that direction, and the order of differentiation in equation (A2) can be interchanged. With

$$\frac{\partial \phi}{\partial \xi} = p \quad \frac{\partial \phi}{\partial \eta} = q \quad (A3)$$

and

$$\frac{\partial \phi}{\partial r} = v = w \sin \theta$$

where w is the velocity vector inclined at an angle θ with respect to the axis, it follows from equation (A2) that along Mach lines

$$dp = \frac{\sin^2 \alpha}{r} v d\eta \quad dq = \frac{\sin^2 \alpha}{r} v d\xi \quad (A4)$$

Thus, dp is the increment in the projection of the velocity vector along the ξ direction when passing a distance $d\eta$ in the physical plane along the η direction, and dq is the increment in the projection of the velocity vector in the η direction when passing a distance $d\xi$ along the ξ direction. Equations (A4) are the fundamental equations used in the step-by-step construction of a supersonic flow by Sauer's or Frankl's method of characteristics.

The reasons for the singular behavior as the flow approaches the axis of symmetry can now be explained with the help of equations (A4). Suppose a series of steps were laid off in the physical plane in the manner indicated by the sketch

shown in figure 21 (a). The small increments ($d\xi$ and $d\eta$) along the Mach lines are laid off such that they are always small compared to the distance from the axis r and also such that for all steps $d\xi/r$ and $d\eta/r$ are always very nearly equal to a constant, say $\bar{C}$. It is to be noted that if such a flow converging to the axis is possible, then there would be an infinite number of such steps along the streamline AB in figure 21 (a).

(a) Assumed flow in the physical plane.

(b) Increments in hodograph plane corresponding to figure 21 (a).

FIGURE 21.—Characteristics construction for flows converging to the axis.

Now consider the increments in the hodograph plane corresponding to those laid off in the physical plane (fig. 21 (a)). Figure 21 (b) illustrates the way, according to equations (A3) and (A4), in which the increments must be laid off in the velocity plane. Points having the same number in figures 21 (a) and 21 (b) represent the same point in the flow. Let the smallest average Mach angle along the steps in the physical plane be α_m , and the smallest vertical-velocity component be v_m , then for all steps along AB

$$|dp| > |v_m \bar{C} \sin^2 \alpha_m| = \text{constant}$$

and

$$|dq| > |v_m \bar{C} \sin^2 \alpha_m| = \text{constant}$$

This means that every increment in the hodograph plane is greater than a constant value. This value cannot be zero unless points 1 and 3 are identical, which would represent the exceptional case of a "reversed" conical flow. On passing from point A to point B there are, however, an infinite number of such increments. They must be laid out along the arc of a circle in the hodograph plane since AB is a streamline of constant pressure. Hence, before reaching point B the inclination angle of the velocity vector must be greater than 46° (approximate maximum deflection angle through a single shock wave for $\gamma=1.4$). Because this situation obviously prevents a shock wave from being fitted into the flow, there results a contradiction to the assumption that the over-all flow is possible. It appears, therefore, that these flows are not always possible.

The preceding discussion, though not a mathematically rigorous exposition, points out the reason why the inclination angle θ of a free streamline can increase at an excessive rate as the axis is approached. The source of the trouble is inherently associated with the last term in the equation of motion (A1), since it has r in the denominator and a non-vanishing factor in the numerator. The appearance of r in the denominator of this equation stems entirely from the

continuity equation. This leads to a qualitative explanation of the observed behavior near the axis of the inviscid flows. Consider the changes that must occur on going from point 1 to point 3 in the physical plane (fig. 21 (a)). If the flow were two-dimensional, then the free streamline would be straight and θ_1 would equal θ_3 , thereby preserving the cross-sectional area between two adjacent streamlines on passing from 1 to 3. The term involving $1/r$ does not occur for plane flow and no difficulties arise. In the axially symmetric case, the fundamental condition is again that the cross-sectional area of an annular streamtube must be preserved, since w_1 is equal to w_3 . This means that for purely geometric reasons the streamlines bounding the annular streamtube must spread apart as the axis is approached. In order to have the pressure at point 3 equal to that at point 1, the free streamline curves toward the axis, permitting the bounding streamlines to spread, thereby allowing the continuity equation to be satisfied. Because of the $1/r$ term in the continuity equation, the curvature rapidly increases as the axis is approached. Hence, before the axis is reached, the inclination of the free streamline exceeds the largest value which any oblique shock wave can possibly overcome.

APPENDIX B

WIND-TUNNEL SUPPORT INTERFERENCE AND REFLECTED BOW-WAVE INTERFERENCE

When a body of revolution is tested in a wind tunnel it is usually supported from the rear by a cylindrical rod. As a result the measured values of base pressure may be considerably affected, for one thing, by the presence of the support. Support interference on base pressure is a complicated function of the diameter of support rod, the unobstructed length of support rod, the Mach number, and the Reynolds number. If, as is the case for the experiments referred to herein, the support length is much greater than the base diameter, then the only appreciable interference must arise from the "diameter effect" of the rod. From theoretical considerations certain inferences can be drawn regarding the resulting support-diameter interference on base pressure.

For a fixed Mach and Reynolds number, an increase in the support diameter brings about two different effects. First, the wake thickness is increased, thereby making it possible for lower base pressures to exist. (See fig. 6.) A second effect resulting from an increase in support diameter is that the appropriate dimensionless boundary-layer thickness $\delta/(h-d)$ is increased, thereby tending to increase the base pressure. The two effects, therefore, oppose each other. For values of d/h near unity the second effect must predominate; whereas for small values of d/h the first effect would (on the basis of fig. 6) be expected to predominate, especially at low supersonic Mach numbers.

Before comparing these theoretical considerations with experimental measurements of the effect of variations in d/h it will be advantageous to first consider the effects of having only a finite length of unobstructed support rod. To examine this effect, base-pressure measurements have been taken with a constant value of d/h , but with various lengths of

unobstructed support. In these experiments the model was located at a fixed position in the test section so as to eliminate possible effects of axial pressure gradients along the test section. The results from $M=2.0$ and 2.9 are illustrated by the curves in figure 22, which show, for $d/h=0.3$, no change

FIGURE 22.—Effect of support length on base pressure; $d/h=0.3$.

in base pressure if the support length is greater than about 3 base diameters. Since support lengths of over 4 body diameters have been used in all subsequent tests, it is concluded that any interference in the wind-tunnel measurements of base pressure at $M=2.0$ and 2.9 is not attributable to effects of support length.

The results of base-pressure measurements for various support diameters with laminar boundary-layer flow are shown in figure 23 (a). The data for a Mach number of 1.5 (reported by Perkins in reference 11) show the expected increase, and then eventual decrease in base drag as the support diameter is progressively increased. At a Mach

number of 2.9 the data show a monotonic decrease in base drag as the support diameter is increased. Schlieren photographs show that the wake thickness t/h varies from approximately 0.5 to 1.0 as d/h varies from 0 to 1.0. Consequently, it turns out that the behavior of the three curves in figure 23 (a) is qualitatively the same as would be indicated if equation (6) were used to estimate P_b^* . (It is to be remembered that t/h is the "effective" d/h of fig. 6.)

FIGURE 23.—Effect of support diameter on base pressure.

The corresponding results for turbulent boundary-layer flow are shown in figure 23 (b). At Mach numbers of 1.5 and 2.0 these data show the same trends as for laminar boundary-layer flow, but at a Mach number of 2.9 the trend is not the same. At Mach numbers near 3, and possibly higher, it appears that the relative importance of the two above-mentioned effects of increasing d/h depends on the condition of the boundary-layer flow.

FIGURE 23.—Concluded.

It may be noted from figure 23 (a) that there is one point corresponding to $d/h=0$ on the curve representing laminar flow at a Mach number of 1.5. This point, which was determined from the measurements using a side support, gives the same value for the base pressure as exists for a support with a d/h ratio of about 0.3. At all the other Mach numbers, where special interference measurements were not made, the base pressure was measured with a constant value of 0.4 for the ratio d/h . From the curves in figure 23 (a) it may be inferred that, at least for Reynolds numbers of the order of 4 million, these base-pressure data for laminar flow are not significantly affected by support interference.

Unfortunately, an investigation of support interference for turbulent boundary-layer flow has not been made using a side support. Definite quantitative statements about the possible effects of support interference in the turbulent-flow data (figs. 14, 15, 18, 19, and 20) cannot be made at present. Evidence that the combined effects of support and wall interference are not large, however, is given by the good agreement obtained at all Mach numbers between the free-flight firings of reference 5 and the various wind-tunnel measurements (figs. 14, 15, 18, and 20).

A possible source of wall interference arises from the reflection of a bow wave from the side walls, and the eventual intersection and interaction with the wake at some downstream position. This interaction for $M=2.0$ and $M=2.9$ occurs at a position varying from 7 to 22 base diameters downstream of the base. Since the large disturbance caused by the balance housing has no measurable effect at distance of 3 base diameters from the base (see fig. 22), there is no reason to expect that the base-pressure measurements at $M=2.0$ and $M=2.9$ might be affected by reflections of bow waves from the tunnel side walls. At a Mach number of 1.5, however, the downstream position of interaction is closer; it varies from approximately 2.7 base diameters for the model with an L/h of 7, to 5.4 base diameters for the model with an L/h ratio of 4.3. In view of the possible interference from reflected bow waves at low supersonic Mach numbers, a special investigation was made in 1946 prior to the tests of reference 12 to determine the magnitude of this effect. The results, taken at a Mach number of 1.53,⁸ are presented here as they aid in evaluating the accuracy of the wind-tunnel measurements of base pressure, and they show that the conclusion of Faro (reference 15) regarding the magnitude of the bow-wave interference effect in the present experiments is incorrect.

Figure 24 illustrates the test setup employed in evaluating the effect of a reflected bow wave on base pressure. Because of symmetry the two outer dummy models caused two shock waves, similar to reflected bow waves, to interact with the wake behind the base of the center model (on which the base pressure was measured). By varying the distance between the dummy models of the test setup, the position of interaction was readily changed. The strength of the bow wave on the models employed (6-caliber ogival radius) in this special investigation varied from approximately two to eight times the strength of the bow wave on the various models for which base-pressure data are presented.

⁸ This Mach number differs somewhat from that of more recent tests (at $M=1.50$) since the earlier tests were conducted in 1946 at a time when the 1- by 3-foot supersonic wind tunnel was temporarily equipped with a set of fixed nozzle blocks instead of the flexible plates now employed.

FIGURE 24.—Sketch of test setup used for determining the effect of a reflected bow wave on base pressure.

Schlieren photographs of the flow for two different positions of interaction, and two different Reynolds numbers, are given in figure 25. The distance x , from the base to the position of interaction, is equal to $2.5h$ in both figures 25 (b) and 25 (c). This particular position simulates the closest position to the base of the interaction of reflected waves in the present tests. The corresponding base-pressure measurements⁹ without and with the interference wave present are illustrated in figure 26 by the circle and triangle symbols, respectively. The data show no appreciable effect on base pressure of the shock wave which simulates a reflected bow wave. If a reflected bow wave comes

too close to the base, however, then large interference effects are possible, as illustrated by the square symbols in figure 26, and the corresponding schlieren photographs in figure 25 (d). Except for purposes of illustrating this effect, base-pressure measurements were, of course, not taken under these latter conditions of important interference from reflected waves. Since the simulated reflection waves of the models used in this special investigation were several times stronger than the bow waves on the models for which the base pressure was measured, it is clear that the wind-tunnel measurements presented are not appreciably affected by interference of a reflected bow wave.

⁹ These data fall slightly below other data presented herein because of the very small amount of boattailing on the models used in this special investigation.

APPENDIX C

DERIVATION OF APPROXIMATE EQUATION FOR q'/q_∞

The ratio q'/q_∞ can be written as

$$\frac{q'}{q_\infty} = \frac{\rho' U'^2}{\rho_\infty U_\infty^2} = \frac{\rho'}{\rho_\infty} \frac{\bar{p}_o}{\rho_o} \frac{\rho_o}{\rho_\infty} \left(1 + 2 \frac{\Delta U}{U_\infty} \right) \quad (C1)$$

In this and subsequent equations, powers higher than the first of quantities such as $\frac{\Delta U}{U_\infty} \equiv \frac{U' - U_\infty}{U_\infty}$ are assumed to be small in comparison to unity, and are therefore neglected. In equation (C1), ρ_o and $\bar{p}_o$ represent the stagnation densities corresponding to conditions in the free stream and to conditions just ahead of the base, respectively. Designating $\Delta M \equiv M' - M_\infty$ and again considering only first-order terms, it follows that

$$\begin{aligned} \frac{\rho'}{\rho_o} \frac{\bar{p}_o}{\rho_o} \frac{\rho_o}{\rho_\infty} &= \left[\frac{1 + \frac{\gamma-1}{2} M'^2}{1 + \frac{\gamma-1}{2} M_\infty^2} \right]^{\frac{-1}{\gamma-1}} \left(1 - \frac{\Delta p_o}{p_o} \right) = \\ &= 1 - \frac{M_\infty \Delta M}{1 + \frac{\gamma-1}{2} M_\infty^2} - \frac{\Delta p_o}{p_o} \end{aligned} \quad (C2)$$

where Δp_o is the loss in total pressure on passing through the nose shock wave, and may often be neglected. From the energy equation

$$\frac{\Delta U}{U_\infty} = \frac{U'^2 - U_\infty^2}{2U_\infty^2} = \frac{c_p(T_\infty - T')}{U_\infty^2} = \frac{c_p T_\infty}{U_\infty^2} \left(1 - \frac{T'}{T_\infty} \right)$$

or, using $c_p = \gamma R/(\gamma-1)$ and $M = U/\sqrt{\gamma R T}$

$$\frac{\Delta U}{U_\infty} = \frac{1}{(\gamma-1) M_\infty^2} \left[1 - \left[\frac{1 + \frac{\gamma-1}{2} M_\infty^2}{1 + \frac{\gamma-1}{2} M'^2} \right] \right] =$$

$$\frac{\Delta M}{M_\infty \left(1 + \frac{\gamma-1}{2} M_\infty^2 \right)} \quad (C3)$$

hence the combination of equations (C1), (C2), and (C3) gives

$$\frac{q'}{q_\infty} = 1 + \left(\frac{2}{M_\infty^2} - M_\infty \right) \frac{\Delta M}{1 + \frac{\gamma-1}{2} M_\infty^2} - \frac{\Delta p_o}{p_o} \quad (C4)$$

The pressure coefficient P' is related to ΔM and Δp_o by

$$\begin{aligned} P' &= \frac{p' - p_\infty}{\frac{\gamma}{2} \rho_\infty M_\infty^2} = \frac{2}{\gamma M_\infty^2} \left(\frac{p'}{\bar{p}_o} \frac{\bar{p}_o}{p_o} \frac{p_o}{p_\infty} - 1 \right) = \\ &= \frac{2}{\gamma M_\infty^2} \left[\left[\frac{1 + \frac{\gamma-1}{2} M_\infty^2}{1 + \frac{\gamma-1}{2} M'^2} \right]^{\frac{\gamma}{\gamma-1}} \left(1 - \frac{\Delta p_o}{p_o} \right) - 1 \right] = \\ &= - \frac{2 \Delta M}{M_\infty \left(1 + \frac{\gamma-1}{2} M_\infty^2 \right)} - \frac{2}{\gamma M_\infty^2} \frac{\Delta p_o}{p_o} \end{aligned} \quad (C5)$$

Substitution of equation (C5) into equation (C6) yields the relation

$$\frac{q'}{q_\infty} = 1 + \left(\frac{M_\infty^2}{2} - 1 \right) P' - \frac{2}{\gamma M_\infty^2} \left(1 + \frac{\gamma-1}{2} M_\infty^2 \right) \frac{\Delta p_o}{p_o} \quad (C6)$$

presented earlier as equation (3).

REPORT 1052

A SUMMARY OF LATERAL-STABILITY DERIVATIVES CALCULATED FOR WING PLAN FORMS IN SUPERSONIC FLOW

By ARTHUR L. JONES and ALBERTA ALKSNE

SUMMARY

A compilation of theoretical values of the lateral-stability derivatives for wings at supersonic speeds is presented in the form of design charts. The wing plan forms for which this compilation has been prepared include a rectangular, two trapezoidal, two triangular, a fully-tapered swept-back, a swept-back hexagonal, an unswept hexagonal, and a notched triangular plan form. A full set of results, that is, values for all nine of the lateral-stability derivatives for wings, was available for the first six of these plan forms only. The reasons for the incompleteness of the results available for other plan forms are discussed.

The values of the derivatives presented were obtained directly from tabulated results in the reports referenced or were calculated from expressions presented in these reports. The expressions for the derivatives were derived using linearized theory for compressible flow. The values presented, however, do not represent exact linear-theory solutions in every case due to the fact that approximations and simplifications were sometimes necessary in the derivation of the expressions or in the calculations of the numerical results. The effects of these approximations and simplifications on the accuracy and applicability of the results are considered.

INTRODUCTION

The calculation of the lateral-stability derivative coefficients (hereinafter referred to as the lateral-stability derivatives) for thin wings at supersonic speeds has been accomplished for a number of plan forms and the results are reported in references 1 through 18. These results are necessarily incomplete in view of the fact that there is an unlimited number of plan forms that could be investigated. There appears to be a sufficient quantity of results available, however, to warrant the preparation of a summary. In fact, some summaries, such as references 10 and 17, are already available but the results presented in these reports are restricted to a fairly small number of plan forms or to a small number of derivatives. It is the purpose of this report, therefore, to assemble and present a more extensive set of numerical results than was heretofore available. These results will be limited to the thin-airfoil, inviscid-flow solutions obtained from application of the linearized theory of compressible flow. They will be presented in the form of design charts showing the variations of the derivatives¹ with Mach number, aspect ratio, and other plan-form parameters. The derivatives have been evaluated in a manner that per-

mits their direct application in an analysis using the stability axes system.

A discussion of the limitations in the applicability and availability of the lateral stability derivative results is included. Some of the limitations are inherent in the linearized theory itself, but most of the limitations are due to the approximations and simplifications sometimes found necessary in the application of the theory.

The plan forms for which the results are presented are illustrated in figure 1. Included are a rectangular, two

FIGURE 1.—Types of plan forms for which summarized results are presented.

¹ Although the scale labels show that some of the stability derivatives presented in the figures are divided by angle of attack or angle of attack squared, reference to the variation of this quotient with other variables will be simply referred to as the variation of the derivative. This usage is consistent with the terminology used in previous NACA reports.

triangular, two trapezoidal, a fully-tapered swept-back, a swept-back hexagonal, an unswept hexagonal, and a notched triangular plan form. This group may not cover all the plan forms for which at least partially complete results are available. It is, however, a fairly representative group. In table I the sources of the results for the lateral-stability derivatives of the plan forms surveyed are listed.

SYMBOLS AND COEFFICIENTS

A	aspect ratio
b	span of wing measured normal to plane of symmetry
B	$\sqrt{M^2-1}$
c_r	chord of wing root
$c. g.$	center of gravity
C_l	rolling-moment coefficient $\left(\frac{L}{qSb}\right)$
C_n	yawing-moment coefficient $\left(\frac{N}{qSb}\right)$
C_Y	side-force coefficient $\left(\frac{Y}{qS}\right)$
C_{l_p}	damping-in-roll derivative $\left[\frac{\partial C_l}{\partial(p\dot{b}/2V)}\right]$
C_{l_r}	rolling-moment-due-to-yawing derivative $\left[\frac{\partial C_l}{\partial(r\dot{b}/2V)}\right]$
C_{l_β}	rolling-moment-due-to-sideslip derivative $\left(\frac{\partial C_l}{\partial\beta}\right)$
C_{n_p}	yawing-moment-due-to-rolling derivative $\left[\frac{\partial C_n}{\partial(p\dot{b}/2V)}\right]$
C_{n_r}	yawing-moment-due-to-yawing derivative $\left[\frac{\partial C_n}{\partial(r\dot{b}/2V)}\right]$
C_{n_β}	yawing-moment-due-to-sideslip derivative $\left(\frac{\partial C_n}{\partial\beta}\right)$
C_{Y_p}	side-force-due-to-rolling derivative $\left[\frac{\partial C_Y}{\partial(p\dot{b}/2V)}\right]$
C_{Y_r}	side-force-due-to-yawing derivative $\left[\frac{\partial C_Y}{\partial(r\dot{b}/2V)}\right]$
C_{Y_β}	side-force-due-to-sideslip derivative $\left(\frac{\partial C_Y}{\partial\beta}\right)$
l	over-all longitudinal length of swept-back wing (See fig. 1.)
$l_{c. g.}$	longitudinal location of center of gravity aft of the leading edge of the root chord
L	rolling moment (See fig. 2(b).)
m	slope of right wing tip or leading edge relative to plane of symmetry (Positive for raked-out tip, negative for raked-in tip.)
M	free-stream Mach number
N	yawing moment (See fig. 2(b).)
p	rate of roll, radians per second
q	free-stream dynamic pressure
r	rate of yaw, radians per second
S	area of wing
V	free-stream velocity
x	longitudinal coordinate
$x_{c. g.}$	arbitrary longitudinal location of the center of gravity with respect to the location specified in this report (Positive for locations forward of those specified.)
y	lateral coordinate

Y	side force (See fig. 2 (b).)
z	vertical coordinate
α	angle of attack, radians
β	angle of sideslip (positive when sideslipping to right), degrees
λ	taper ratio

AXES

At least three systems of axes are associated with the development and application of stability derivatives. For instance, the theoretical expressions for the stability derivatives are most easily derived using a set of three orthogonal axes, known as the wind axes, that are oriented as shown in figure 2 (a). The origin of these axes is at the leading edge of the root chord. The x axis is an extension of the free-stream vector through the origin and is positive rearward. The y axis lies in the plane of the wing perpendicular to the x axis and is positive toward the right tip. The z axis stands perpendicular to the x and y axes and is positive upward. These axes are commonly used in wing-theory calculations.

Body-axes systems (see fig. 2 (b)) are sometimes used in the calculations of the motion of an aircraft. These calculations are commonly referred to as dynamic-stability calculations. The origin of the axes for such calculations is usually the center of gravity rather than the leading edge of the root chord. Thus the expressions initially derived for the derivatives should be corrected for the change in moment-center location accompanying the change in location of the origin of the body axes.

A third system of axes known as the stability axes (fig. 2 (c)) is often preferred for dynamic-stability calculations. The basic difference between the orientations of a stability-axes system and a body-axes system is the location of the x axis. In a stability-axes system the x axis is assumed to lie along the intersection of the plane of symmetry and a plane perpendicular to the plane of symmetry which contains the free-stream velocity vector (or the velocity vector of the center of gravity). Thus the stability axes, in general, correspond to the body axes rotated through an angle of $-\alpha$ and, in order to transform expressions for stability derivatives that are applicable to a body-axes system to expressions applicable to a stability-axes system, it is necessary to correct for the angle of attack. If the origins of the body and stability axes are coincident, this correction can be made by using the transformation formulas in reference 19. If the origins are not coincident, the correction must also include the effects of the chordwise distance between the origins. Most of the reports used as sources for the material presented, references 1 through 17, provide either formulas for both systems of axes or means for converting from one system to the other. It is interesting to note that the definitions of the positive directions for the velocities, forces, and moments of the wing conform to the right hand screw-rule for a set of body or stability axes.

For the calculation of the stability derivatives presented herein, the location of the center of gravity was selected as $c_r/2$ for the rectangular, trapezoidal, and unswept hexagonal wings, $(2/3) c_r$ for the triangular wings, and $(2/3) l$ for the swept-back wings. The values of the derivatives pertain to a stability-axes system so located. For arbitrary locations

of the center of gravity the derivatives that are affected by changes in the location can be evaluated using the following formulas:

$$(C_{l_r})_{x_{c.g.}} = C_{l_r} - \frac{2x_{c.g.}}{b} C_{l_\beta}$$

$$(C_{n_p})_{x_{c.g.}} = C_{n_p} - \frac{x_{c.g.}}{b} C_{Y_p}$$

$$(C_{n_\beta})_{x_{c.g.}} = C_{n_\beta} - \frac{x_{c.g.}}{b} C_{Y_\beta}$$

$$(C_{n_r})_{x_{c.g.}} = C_{n_r} - \frac{x_{c.g.}}{b} \left(C_{Y_r} + 2C_{n_\beta} - 2 \frac{x_{c.g.}}{b} C_{Y_\beta} \right)$$

$$(C_{Y_r})_{x_{c.g.}} = C_{Y_r} - \frac{2x_{c.g.}}{b} C_{Y_\beta}$$

DERIVATION OF RESULTS

The derivation of theoretical results involves both the formulation of expressions for the derivatives and the calculation of the numerical values of the derivatives for specific plan forms and conditions. In some of the reports referenced, the analytical expressions for the derivatives were derived and presented but no numerical results were included. In other reports, both the analytical expressions and a few numerical results were given. The following discussion, therefore, will be concerned with the general method of analysis used in obtaining the analytical expressions and the way in which the numerical results presented were compiled.

GENERAL METHOD OF ANALYSIS

A stability derivative is an expression of the rate of change of a force or moment with respect to the motion producing it. Once the shape of the object for which a stability derivative is desired has been decided upon and its motion prescribed, an analysis to determine the resulting force or moment can be started. The first step in the analysis is the formulation of the boundary conditions and at this point an idealization is usually made. For a wing of finite dimensions it is convenient to assume that the effects of wing thickness and of the viscosity of the flow can be ignored or at least estimated independently. On the basis of this assumption, the wing and its flow field can be represented by a thin plate operating in an inviscid flow. This idealization permits the linearized theory for compressible flow to be used for the analysis, provided the angle of attack of the wing is kept small.

The first step in the calculation of the lateral-stability derivatives for a wing, therefore, is the specification of boundary conditions for a thin wing in sideslip, roll, or yaw. This specification can be made readily for two of these three lateral motions. For instance, a wing in sideslip at a small angle of attack can be represented by a flat plate in the same position and the plate can be simulated by use of a uniform distribution of the vertical perturbation velocity over the plan form. A rolling wing can be represented by a twisted thin plate and simulated by a linear spanwise variation of the downwash perturbation velocity over the plan-form area. This representation of the rolling wing is an illustration of the manner in which quasi-steady flow conditions

can be substituted for conditions that are, in fact, unsteady. Such a substitution permits the use of a simple steady-state analysis which yields results of sufficient accuracy for the motions considered in stability theory if not for the more rapid motions involved in flutter theory. A yawing wing, however, cannot be suitably represented by a flat or twisted thin plate in steady flow. In fact, no quasi-steady flow conditions have been developed at the present time which would permit the straightforward application of a steady-state analysis. Thus it appears that the most desirable procedure in the case of the yawing wing would be to undertake the analysis as a problem in unsteady flow. Such analyses are quite complex, however, and have not as

(a) Wind-axes system used in derivations of expressions for stability derivatives;
(b) Body-axes system and definition of positive moments and velocities;
(c) Stability-axes system usually preferred for dynamic-stability calculations.

FIGURE 2.—Three systems of axes associated with the development and application of stability derivatives.

yet been carried out extensively. Consequently, the results presented herein for the derivatives due to yawing are approximations based on strip theory. In the case of the rectangular plan form of infinite span or the trapezoidal plan form with raked-in supersonic tips, the validity of these results has been confirmed by an unsteady-flow solution presented in reference 20.

Having specified the boundary conditions, the next step in the analysis is to apply the linearized theory for compressible flow to the calculation of the pressure distributions. The details of this step may be found in a number of reports dealing with supersonic wing theory. (See, for example, references 21, 22, and 23.) Unfortunately, only pressures acting normal to the surface of the flat plate are calculated directly from the application of the linearized theory. These pressures are not a complete representation of the pressures acting on a wing of finite thickness, and in order to obtain a better representation the theory of edge suction must be applied and the pressures acting on the edges of the thin plate determined. Then by using both the normal and edge pressures, the moments and forces acting on the wing can be determined for the motion prescribed and the stability derivative can be calculated.

The foregoing general description of the method of calculating stability derivatives for wings, using the linearized theory of compressible flow, is merely a brief summarization of the procedure. For a more detailed description of the steps involved, the reports referenced should be consulted.

LIMITATIONS OF BASIC THEORY

The idealization of the flow field discussed above and the resulting simplifications in the theoretical analysis are reflected as limitations in the applicability of the results obtained in this manner. An obvious limitation, for instance, is that the results should be applicable only at the small angles of attack to which the wing was restricted for the analysis. Comparisons of experimental and theoretical results, however, have shown that this particular limitation usually can be exceeded in practical applications without incurring excessive inaccuracy. The less obvious limitations can be deduced from considerations of the effects of neglecting thickness and viscosity. For instance, the two basic reasons for differences between the experimental and theoretical results are: (1) the difference in pressure distributions caused by neglecting the effects of thickness, camber, and viscosity in the calculations; and (2) the existence of a skin-friction force caused by viscosity. In general, it does not seem likely that the pressure distributions due to thickness or camber will vary appreciably with any of these lateral motions. Consequently the linearized-theory results should not be greatly limited in application due to the effects of thickness or camber. On the other hand, the effect of viscosity on the pressure distribution, which is principally the effect of the boundary layer, is of consequence. It is very difficult, however, to determine the nature of the boundary-layer flow and its effect on the pressure distribution in steady straight flight and even more difficult in the case of flight involving the lateral motions. Thus the contribution of the pressure-distribution effects of viscosity to the values of the

lateral-stability derivatives is a relatively unknown factor and probably the greatest source of discrepancy between the theoretical and actual values of the lateral derivatives. The skin-friction force, which is also due to viscosity, will vary appreciably with yawing velocity but not significantly with rolling velocity or sideslip. The effects of this force can be estimated and added to the linearized-theory value of C_n to reduce the limitations of applicability of this derivative. The contribution of the skin-friction force to C_l , however, is not significant since it is mainly a drag force and has only a very small component in the direction that would produce a rolling moment.

Another assumption which is inherent in the analysis applied is that the wing be completely rigid. The applicability of the theoretical results obtained on the basis of complete rigidity is limited, of course, by the effects of the deflection or distortion of the actual wing. However, only wings that have exceptionally long and slender panel lengths are subject to much distortion or deflection. Furthermore, current studies of the effect of aeroelasticity on stability derivatives are directed toward the determination of deviations from rigid-body results and it can be anticipated that the possibility of making appropriate changes in the values of the derivatives given herein may result from such analyses.

COMPILATION OF NUMERICAL RESULTS

The numerical results presented were obtained directly from the results tabulated in references 1 through 17 or were calculated using expressions presented in these reports. Wherever possible, both the numerical values of the derivatives and the expressions from which they were obtained were checked against identical results available from duplicate analyses. The plotting and cross plotting of the results in the construction of the figures presented also provided an effective check against errors.

Use was made of the reversability theorem (see reference 24) in the calculation and checking of the results for the damping-in-roll derivative C_{l_p} . No evidence or proof exists, however, that would permit the reversability theorem to be applied to the calculation or checking of the results for the other lateral derivatives.

RESULTS AND DISCUSSION

PRESENTATION OF RESULTS

As mentioned previously, the plan forms covered in this summary include a rectangular, two triangular, two trapezoidal, a fully-tapered swept-back, a swept-back hexagonal, an unswept hexagonal, and a notched triangular plan form. Estimates of all the lateral stability derivatives are available for the first six of these plan forms. Only partially complete results are available for the other plan forms.

The values of the derivatives plotted against aspect ratio and against Mach number parameter B are shown in figures 3 through 19. The results are grouped by derivatives rather than by plan forms. The values of the damping-in-roll parameter BC_{l_p} for all the plan forms surveyed are presented in figures 3 and 4, which show the variation of this derivative with the aspect-ratio parameter BA . A similar presentation,

figure 7, was used for the side-force derivative C_{Y_p} . The other derivatives required separate plots to show the aspect-ratio and Mach number variations for each type of plan form. In table II, a convenient cross reference of the figure numbers, plan forms, and derivatives is presented.

For these general results, the aspect-ratio range investigated extended from 0 to 9 and values of the derivatives were calculated for constant values of B of 1, 2, and 4. The Mach number parameter range investigated extended from 0 to 4, corresponding to Mach numbers of 1 and 4.13, respectively, and the derivatives were calculated for aspect ratios of 2, 4, and 6. More extensive ranges and additional intermediate values of these variables could have been investigated, but the complexity of the calculations made it impractical to do so. It is felt, however, that included within these limits of aspect ratio and Mach number are most of the plan forms and speeds currently of interest. Furthermore, by interpolation and, in some instances, by careful extrapolation of the results presented, it is possible to obtain theoretical values of the derivatives for plan forms of the type covered, but not specifically investigated, that should be useful as preliminary design estimates.

For the trapezoidal plan forms, the tip rake was selected to correspond to an angle of sweep of approximately 63° ($m = \pm 0.5$) and the aspect ratio was varied by changing the span. Supplementary plots showing the variation of the derivatives with tip rake for a constant aspect ratio are presented in figures 20 through 28. For the fully-tapered swept-back plan forms, the value of the ratio of the root chord to over-all length c_r/l was set at 0.5 and the aspect ratio was varied by changing the sweep of the leading edge. Supplementary plots were used in this case to show the variation of the derivatives with the ratio of root chord to the over-all length for a constant value of leading-edge sweep. These variations are presented in figures 29 through 37.

In figures 38 through 67 the variations with taper ratio and with leading-edge slope of the derivatives available for the swept-back and unswept hexagonal and the notched triangular plan forms are presented.

ASPECT RATIO AND MACH NUMBER RANGES COVERED

In many instances, the results previously described were available only within small portions of the ranges of aspect ratio and Mach number mentioned. The reasons for these limitations are discussed in the following paragraphs of this section.

For the lateral motions of rolling and sideslip, the linearized theory is directly applicable and the results available are limited only by the complexity of the calculations involved in determining the load distributions for certain plan forms and certain conditions. For the yawing motions, however, the difficulty in specifying quasi-steady boundary conditions precludes the direct application of steady-state linearized theory. Approximate solutions based on strip theory can be used, however, wherever suitable solutions of this type can be developed. Rigorous unsteady-flow solutions would of course be preferable for the yawing derivatives but only one such solution has been reported at this time. Thus it is apparent that the derivatives due to yawing

are neither as available nor as generally applicable as the derivatives due to rolling or sideslip.

The cause of the calculation complexities that limit the determination of the load distribution to certain plan forms and certain conditions is the existence of regions on a wing which are affected by the interaction of flows past two or more subsonic edges² lying within the Mach forecones of points contained within the region. Such regions exist on any wing having interacting subsonic edges, that is, on any wing having one subsonic edge lying within the region of influence of another. These regions also exist on a wing having mutually interacting subsonic edges. The determination of the load distribution for such regions is extremely difficult using the basic integral-equation methods (references 21 and 22) developed for supersonic wing theory. This is especially true for the regions influenced by mutually interacting subsonic edges. As a consequence, special cancellation-of-load techniques have been used (references 11, 15, and 18) to handle plan forms having interacting or mutually interacting subsonic edges. The application of these cancellation techniques, however, usually involves rather lengthy calculations and, consequently, numerical results are available for only relatively few of the plan forms that require such methods. Thus most of the results presented herein are for plan forms that do not have interacting subsonic edges.

The actual ranges of the aspect-ratio parameter for which results are presented are given in table III. The limits of these ranges are explained in the discussion that follows.

Rectangular plan form.—For values of BA less than 1 the Mach lines from the tip of the rectangular plan form would intersect the opposite edges and thereby change them from noninteracting to interacting subsonic edges. Thus a lower limit is set on the aspect-ratio parameter BA for which C_{l_p} , C_{n_p} , C_{Y_p} , C_{l_β} , C_{n_β} , and C_{Y_β} are presented. The derivatives due to yawing, C_{l_r} , C_{n_r} , and C_{Y_r} , were calculated using the analysis presented in reference 6. This analysis indicated that reasonably accurate approximate values of C_{l_r} , C_{n_r} , and C_{Y_r} could be obtained as a fraction $\frac{\alpha(1-B^2)}{B^2}$

of the C_{l_p} , C_{n_p} , and C_{Y_p} results. Thus the limitations of the aspect-ratio parameter for C_{l_r} , C_{n_r} , and C_{Y_r} are the same as those for C_{l_p} , C_{n_p} , and C_{Y_p} .

Trapezoidal plan form.—The lower limits on the aspect-ratio parameter for both types of trapezoidal plan form (tips raked in and tips raked out) are to prevent the plan-form tips from becoming interacting subsonic edges. If the plan form has supersonic tips, however, the lower limit is the aspect ratio for which the trapezoid becomes a triangle.

The derivatives due to yawing were obtained from the application of the factor $\frac{\alpha(1-B^2)}{B^2}$ developed for the rectangular plan form. The justification of this step is given in a later section of the report wherein the sources and development of the results are discussed.

² In the terminology that has become associated with supersonic flow analysis, the term "subsonic edge" refers to an edge swept behind its Mach line (because the component of flow normal to the edge is subsonic) and the term "supersonic edge" refers to an edge swept ahead of its Mach line.

Triangular plan form with apex forward.—There is no aspect-ratio-parameter limitation necessary for the derivatives due to rolling or sideslip. The derivatives due to yawing, however, have been obtained only for plan forms having a BA of 4 or less because no solution, approximate or otherwise, has been developed for the yawing triangular wing with supersonic leading edges.

Triangular plan form with base forward.—For values of BA less than 4, the edges of this plan form become mutually interacting subsonic trailing edges and the reflections of the Mach lines establish an infinite number of regions which would have to be analyzed independently. This limit applies to the derivatives due to sideslip and yawing and would apply to the derivatives due to rolling if it were not for the fact that the reversability theorem (see reference 24) permits these derivatives to be calculated for the same plan-form range as obtained for the triangular plan forms with apex forward.

The derivatives due to yawing were obtained by applying the factor $\frac{\alpha(1-B^2)}{B^2}$ developed in the rectangular-wing analysis to the derivatives due to rolling. The justification of using this factor for a base-forward triangular plan form is given in a later section of this report. Inasmuch as the reversability theorem does not apply to the derivatives due to yawing, the lower limit for BA is 4 rather than zero.

Fully-tapered swept-back plan form.—The lower limit of BA , $4\frac{l}{c_r}\left(1-\frac{c_r}{l}\right)$, is common to all the derivatives in order to assure that the trailing edge of this plan form does not become subsonic. The upper limit of BA for the derivatives due to sideslip and yawing, $4l/c_r$, assures that the leading edge will not become supersonic. Values of the derivatives C_{l_p} , C_{n_p} , and C_{Y_p} , however, have been obtained from references 13 and 16 for plan forms having supersonic leading edges.

Swept-back hexagonal plan form.—The plan forms considered to fall in this classification have streamwise tips and range from the constant-chord swept-back, $\lambda=1$, to the swept-back plan form having a straight trailing edge, $A=4m(1-\lambda)/(1+\lambda)$. The aspect-ratio parameter range for this wing, given in table III, indicates that results are presented for plan forms having either subsonic or supersonic leading edges and having supersonic trailing edges. An added restriction provided by the limits on the aspect-ratio parameter range is that the Mach lines from the leading edges of the tips must not cross on the wing.

Unsweppt hexagonal plan form.—These plan forms have streamwise tips and range from the swept back with a straight trailing edge to the hexagonal plan form having fore-and-aft symmetry, which can be expressed as an aspect ratio range of

$$\frac{2m(1-\lambda)}{(1+\lambda)} \leq A \leq \frac{4m(1-\lambda)}{(1+\lambda)}$$

The results presented for the derivatives due to rolling and yawing are subject to the same aspect-ratio-parameter limitations that were given for the derivatives due to rolling for the swept-back hexagonal plan form.

Notched triangular plan form.—The derivatives due to rolling are presented for both subsonic and supersonic leading edges. It should be pointed out that for the damping-in-roll derivative the plan forms having subsonic leading edges differ from those having supersonic leading edges in that the trailing edges of the former always lie along the Mach line from the trailing end of the root chord; whereas the trailing edges of the latter are parallel to the leading edges. (See reference 2.) The derivatives due to sideslip are presented only for the plan form having supersonic leading edges.

SOURCES AND DEVELOPMENT OF RESULTS

The sources of the results for the lateral-stability derivatives of the various plan forms surveyed are listed in table I. An indication of the rigor which has been maintained in the individual developments of these results is given in the following discussion. Sources of some of the results available for plan forms other than those surveyed are also mentioned.

Derivative C_{l_p} . The rolling wing lends itself to readily specified boundary conditions and a rigorous application of the linearized-theory analysis. The damping moment obtained varies linearly with the rolling velocity p and, accordingly, the expression obtained for the derivative C_{l_p} is usually a relatively simple one. Furthermore, the numerical results are readily computed and can be presented in one figure showing both the variation with Mach number and aspect ratio. Consequently, there are more results available for the damping-in-roll derivative than for any of the other lateral derivatives, particularly in regard to the number of plan forms investigated.

In addition to the results presented in this summary, more extensive damping-in-roll results are available in the referenced reports for plan forms having arbitrary sweep and taper. In references 9 and 10, C_{l_p} is determined for such plan forms having subsonic leading edges and supersonic trailing edges. In reference 13, these results are extended to include such plan forms having supersonic leading and trailing edges. The effect of subsonic trailing edges has been investigated in references 11 and 15 using the cancellation-of-pressure technique, but the numerical results are limited to one or two plan forms. Values of C_{l_p} described as the upper limits for swept-back plan forms having subsonic trailing edges are presented in reference 9. These values were obtained by extending the expressions developed for C_{l_p} beyond the limits of applicability for which they were derived. The damping-in-roll derivative for swept-back tapered wings having raked-in or cross-stream tips and subsonic leading edges has been investigated and the results are presented in reference 12. Thus, it is possible to calculate the damping-in-roll derivative for a large number of plan forms of arbitrary sweep, taper, and tip rake. In some cases the numerical values of the derivative have been calculated and presented. In other cases the calculations must be carried out, a step which involves rather lengthy calculations when the trailing edges are subsonic and the cancellation techniques must be used.

It should be mentioned, however, that in many instances values for the damping-in-roll derivative can be determined

for plan forms and Mach angle configurations that would be extremely tedious if at all possible to calculate, by application of the plan form reversibility theorem presented in reference 24.

Derivative C_{n_p} : The contribution of the normal force to this derivative is $-\alpha C_{l_p}$ which can be evaluated from the damping-in-roll results previously discussed. The effects of edge suction on this derivative are also readily calculated. Thus it is possible to calculate C_{n_p} for the same extensive range of plan forms for which it was possible to calculate C_{l_p} . The results actually available for C_{n_p} , however, cover only the plan forms considered in this summary.

For the trapezoidal plan forms having raked-out tips, the expression for C_{n_p} applicable to the stability-axes system has not been published previously. For subsonic tips, and with the center of gravity located at $c_r/2$, the expression is,

$$C_{n_p} = \frac{-256\alpha\sqrt{1-B^2m^2}}{9\pi B^3 A^3(1+Bm)\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)^3} \left\{ B \left[\frac{3(1+Bm)(m^2-1)-2m^2}{\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)} \right] - (BA)[3B(m^2-1)+m] + \frac{9B^2A^2}{8} m \left(1+\sqrt{1-\frac{4Bm}{BA}}\right) - \frac{B}{4} \left[9BA - \frac{12Bm}{\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)} - \frac{8}{\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)} \right] \right\}$$

and for supersonic tips the expression is

$$C_{n_p} = -\alpha C_{l_p}$$

Derivative C_{Y_p} : The derivative C_{Y_p} exists only when edge suction forces are present. The results available for C_{Y_p} cover only the plan forms considered in this summary and some swept-back tapered wings with streamwise tips having either supersonic or subsonic leading edges. (See references 14 and 16, respectively.)

The expressions for C_{Y_p} for the trapezoidal plan forms having raked-out or raked-in tips have not been published previously. For the subsonic raked-out-tip plan forms the expression applicable to the stability axes system is

$$C_{Y_p} = \frac{64\alpha\sqrt{1-B^2m^2}}{\pi B^2 A^2(1+Bm)\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)^2} \left[BA - \frac{4Bm}{3\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)} - \frac{8}{9\left(1+\sqrt{1-\frac{4Bm}{BA}}\right)} \right]$$

For the supersonic raked-out-tip plan forms and for the raked-in-tip plan forms there is no suction effect and C_{Y_p} is, consequently, zero.

Derivative C_{l_p} : For wings in sideslip, the boundary conditions are easily specified and the linearized-theory analysis to obtain the normal force is easily carried out. Unfortun-

nately, however, the rolling moment cannot be generally expressed as a linear function of sideslip angle. (See reference 5.) To obtain the derivative C_{l_p} , therefore, it is necessary to plot C_l against the sideslip angle β and to measure the slope or, if the sideslip is restricted to very small angles (reference 4), it is possible to linearize the expression for C_l and obtain an explicit expression for C_{l_p} . Although no derivatives due to sideslip are presented for the unswept and swept-back hexagonal plan forms, these derivatives can be calculated for these plan forms using references 21, 22, or 23, or if a cancellation technique is needed, reference 18 gives a demonstration that is directly applicable to these cases.

It should be pointed out that for the trapezoidal plan forms with a tip slope m of $\pm \frac{1}{2}$ the Mach cones and tips coincide at

$B=2$. Double values of the derivatives due to sideslip, C_{l_p} , C_{n_p} , and C_{Y_p} , occur at this value of B and in order to avoid any ambiguity the limiting values of the derivatives obtained by approaching $B=2$ from the lower values of B (tips subsonic) were labeled $B=2(-)$ and the limiting values of the derivatives obtained by approaching from higher values of B (tips supersonic) were labeled $B=2(+)$.

For plan forms having streamwise tips, such as rectangular plan forms, there is some doubt as to the validity of the results obtained by applying the Kutta condition to the trailing tip at small angles of sideslip. In reference 6 it is assumed that the Kutta condition does not apply, whereas in reference 5 it is assumed that the Kutta condition applies to the trailing tip at small angles of sideslip as well as large. This difference in basic assumptions leads to two entirely different values for C_{l_p} . From physical considerations of what the flow must be past a sharp trailing edge, such as the tip of a thin airfoil, the theoretical analysis based on the latter assumption is the correct one. From physical considerations of the flow about a wing tip of finite thickness, the correctness of either assumption depends upon the ability of the boundary layer on the tip to resist separation. If the suction force caused by the high velocity flow of air from the bottom surface to the top surface is strong enough to cause the boundary layer to separate, then a flow corresponding to the Kutta condition will result and the edge suction force will no longer exist. The angle of sideslip at which separation of the flow around the tip will take place is, at present, undetermined. It will depend on the angle of attack and on the shape of the tip to a large extent. It is definitely possible, however, for separation to occur on tips raked at a slight angle into the stream, such as the advancing tip of the rectangular wing in sideslip, as well as on a trailing tip. If this were the case, the Kutta condition would have to be applied to both tips at small angles of sideslip rather than to one or neither as assumed in the previously mentioned analyses. Until experimental results are obtained that will provide definite quantitative evidence to the contrary, therefore, it seems most reasonable to assume that the solution based on the flow over a thin trailing edge is valid. In other words, it seems most reasonable to assume that the Kutta condition holds for all trailing edges and the edge suction exists on all leading edges no matter what the angle of inclination is

between the edge and the stream. Accordingly, the results presented in this survey correspond to those reported in reference 5.

Derivative $C_{n\beta}$: The contribution of the edge suction effects to this derivative is easily estimated but the resulting expression for the yawing moment is nonlinear with sideslip. The normal force contribution $-\alpha C_{l\beta}$ is also nonlinear with sideslip as described in the discussion of $C_{l\beta}$. Both of these nonlinearities can be handled, however, in the manner mentioned in that discussion.

For the plan forms having streamwise tips the application of the Kutta condition to the trailing tip at small angles of sideslip causes a jump in the yawing-moment curve at zero sideslip. (See references 8 and 17.) This jump makes it difficult to establish a rational value for $C_{n\beta}$ especially in view of the fact that in actuality the jump will, undoubtedly, be rounded off and the curve will have no discontinuity in slope at zero sideslip. The value of the derivative selected for the curve with the jump was based on the slope of the yawing-moment curve as it approached zero sideslip. This value is questionable in magnitude. It has the proper sign, however, and should be an underestimation of the actual value of $C_{n\beta}$.

Derivative $C_{Y\beta}$: Inasmuch as the edge-suction force is the only source of side force for wing plan forms, the derivative $C_{Y\beta}$ is zero (at zero sideslip) for plan forms having supersonic raked-out tips or raked-in tips. For trapezoidal plan forms having subsonic tips, the expression for the side force is

$$C_{Y\beta} = \frac{-32\alpha^2}{\pi A \left(1 + \sqrt{1 - \frac{4Bm}{BA}}\right)^2} \frac{(1+B^2)}{B^2(1+Bm)\sqrt{1-B^2m^2}}$$

The jump that appears in the yawing moment versus sideslip curve at zero sideslip for plan forms having streamwise tips occurs also in the side force versus sideslip curve. The evaluation of the derivatives under these conditions was handled in the manner described in the discussion of $C_{n\beta}$.

Derivative C_{l_r} : As mentioned in a preceding section of this report, the yawing wing cannot be fitted satisfactorily to quasi-steady boundary conditions that would permit the use of an exact linearized-theory analysis based on a steady-state flow. For rectangular and triangular wings, however, modified strip-theory analyses have been applied in references 6 and 4, respectively, and approximate values for the rolling-moment-due-to-yawing derivative have been obtained. The analysis for the triangular wing takes into account the spanwise variation of speed but not the spanwise variation of Mach number. A chordwise variation of the effective sideslip angle for a yawing wing is also included in the triangular-wing analysis. The contribution of this latter factor is predominant for triangular wings of low aspect ratio (that is, triangular wings having small vertex angles). Both the spanwise variations of Mach number and of speed were taken into account in a somewhat similar analysis for the rectangular wing. From this latter analysis a factor of

$\frac{\alpha(1-B^2)}{B^2}$ was found to exist between the loading due to rolling and the loading due to yawing over the portion of the rectangular wing where the flow was two dimensional, and it was assumed that this factor could also be applied in the vicinity of the tips. An analysis of a rectangular wing of infinite span based on unsteady flow, made in reference 20, provided verification of the existence of the factor $\frac{\alpha(1-B^2)}{B^2}$

for the region of two-dimensional flow. In view of this verification, it seems that the rectangular-wing values for C_{l_r} obtained from reference 6 should be a good approximation, at least for plan forms having high aspect ratios. Furthermore, application of the factor $\frac{\alpha(1-B^2)}{B^2}$ to the rolling-moment results for a trapezoidal plan form having supersonic raked-in tips should provide exact theoretical values for C_{l_r} (using the unsteady-flow-analysis results as a norm) because of the lack of tip effects. Inasmuch as any plan form having relatively large regions of two-dimensional flow should be suited to this approximate analysis, it was decided to use this factor to obtain approximate values of C_{l_r} for the trapezoidal plan forms, the base-forward triangular plan form with supersonic tips, and the unswept hexagonal plan form. By this step, theoretical estimates of C_{l_r} were made available for all but the apex-forward triangular plan form with supersonic leading edges, the base-forward triangular plan form with subsonic trailing edges, the swept-back hexagonal plan form, and the notched triangular plan form.

Derivative C_{n_r} : Application of the factor $\frac{\alpha(1-B^2)}{B^2}$ to the calculation of the edge-suction-force contribution to C_{n_r} from the edge-suction force due to rolling will yield an admittedly rougher approximation than the application of this factor to the determination of the normal force due to yawing. However, in view of the fact that it was the only method available for estimating the edge-suction force in yawing, it was used to obtain the C_{n_r} results for all the plan forms similarly analyzed for C_{l_r} .

Derivative C_{Y_r} : The application of the factor $\frac{\alpha(1-B^2)}{B^2}$ to calculate C_{l_r} and C_{n_r} from C_{l_p} and C_{n_p} , respectively, for certain plan forms was extended to the side-force calculations in order to obtain values for the derivative C_{Y_r} . The apex-forward triangular plan form having subsonic leading edges was excepted inasmuch as the derivative C_{Y_r} was available from reference 4.

CONCLUDING REMARKS

Values of the lateral-stability derivatives for wings at supersonic speeds, calculated using the linearized theory for compressible flow, have been presented in the form of design charts showing the variations of the derivatives with Mach number and aspect ratio for nine plan forms. These plan forms were: (1) rectangular; (2) trapezoidal with raked-out tips; (3) trapezoidal with raked-in tips; (4) triangular with apex forward; (5) triangular with base forward; (6) fully

apered swept-back; (7) swept-back hexagonal; (8) unswept hexagonal; and (9) notched triangular.

Limitations in the applicability and availability of the lateral-stability derivatives are discussed.

REPORT 1053

INVESTIGATION OF TURBULENT FLOW IN A TWO-DIMENSIONAL CHANNEL¹

By John Laufer

SUMMARY

A detailed exploration of the field of mean and fluctuating quantities in a two-dimensional turbulent channel flow is presented. The measurements were repeated at three Reynolds numbers, 12,300, 30,800, and 61,600, based on the half width of the channel and the maximum mean velocity. A channel of 5-inch width and 12:1 aspect ratio was used for the investigation.

Mean-speed and axial-fluctuation measurements were made well within the laminar sublayer. The semitheoretical predictions concerning the extent of the laminar sublayer were confirmed. The distribution of the velocity fluctuations in the direction of mean flow u' shows that the influence of the viscosity extends farther from the wall than indicated by the mean velocity profile, the region of influence being approximately four times as wide.

Fluctuations perpendicular to the flow in the lateral and vertical directions v' and w' , respectively, and the correlation coefficient $k = \frac{\overline{u'v'}}{\sqrt{\overline{u'^2}}\sqrt{\overline{v'^2}}}$ were also measured. The turbulent

shearing stress was computed by three different methods. The results show satisfactory agreement for the two lower Reynolds numbers. In the case of the highest Reynolds number, however, the total shearing stress τ obtained from the fluctuation measurements was approximately 20 percent lower than that computed from the mean-velocity and mean-pressure measurements. All dimensionless mean fluctuating quantities were found to decrease with increasing Reynolds number. Measurements of the scales of turbulence L_v and L_z and microscales of turbulence λ_v and λ_z across the channel are presented and their variation with Reynolds number is discussed. Using a new technique, values for the microscale λ_z were obtained; a new method for estimating the scale L_z is also given.

The energy balance in the turbulent flow field was calculated from the measured quantities. From this calculation it is possible to give a descriptive picture of turbulent-energy diffusion in the center portion of the channel cross section.

For the flow corresponding to a Reynolds number of 30,800 the energy spectrum of the u'^2 -fluctuations at various points across the channel, including one in the laminar sublayer, was obtained.

At station $y/d=0.4$, where y is lateral distance and d is half width of the channel, the contribution to the turbulent shear stress from various frequency bands was measured and it was found that the contribution corresponding to frequencies above 1500 cycles per second is negligible. Since the spectrum of u'^2

at this point extends to about 5000 cycles per second it is evident that the high frequencies are nearly isotropic in agreement with Kolmogoroff's hypothesis.

INTRODUCTION

In recent years a considerable step forward was made in the theory of turbulence. Kolmogoroff (reference 1), Heisenberg (reference 2), and Onsager (reference 3) obtained independently an energy-spectrum law that holds in rather restricted types of turbulent flows. This progress gave a new impetus to both theoretical and experimental investigations. The experimental worker may follow two principal methods of approach to the problem. First, he may establish flow fields which satisfy sufficiently the assumptions of the new theory, namely, that the flow is isotropic and of high Reynolds number so that the influence of viscosity is a minimum and the effect of the turbulence-producing mechanism is small. Under these conditions he may measure quantities such as correlation functions, scales, and microscales that are defined exactly in the flow field and may compare his results with those predicted by the theory. The main difficulty with this method is to predict how closely one has to approximate in the actual flow the conditions assumed in the theory. In other words, the sensitivity of the theory to deviations from true isotropic conditions is not known and in case the measurements do not agree with the theory one does not know whether to attribute the disagreement to faulty assumptions in the theory or to the incomplete isotropic conditions of the flow. Furthermore, the imposition of the condition of isotropy to fluctuating fields may be a very strong restriction and the study of such fields may not yield the complete picture of the turbulence mechanism.

The second method of approach is to establish a simple nonisotropic turbulent flow field with well-defined boundary conditions and, in the light of the existing theories, to try to obtain information on the mechanism of energy transfer from the low frequencies of the energy spectrum to the high ones. The present investigation of a turbulent channel flow has this purpose in mind in its long-range program.

The difficulties of this method are immediately realized. Because of the nonisotropic nature of the flow, characteristic quantities such as scale and microscale are no longer well-defined and it is very possible that in the first stages of the investigation certain quantities will be measured that later will prove to be trivial. On the other hand, the main advantage of a fully developed channel flow is the fact that, in contrast with the flow behind grids, flow conditions are

¹Supersedes NACA TN 2123 "Investigation of Turbulent Flow in a Two-Dimensional Channel" by John Laufer, 1950.

steady; no decay of mean or fluctuating quantities exists in the direction of the flow. Consequently, the turbulent energy goes through all of its stages of transformation across the channel section—turbulent-energy production from the mean flow, energy diffusion, and turbulent and laminar dissipation—and one may study these transformations in detail.

It has become clear that the phenomenological theories of turbulence, such as the mixing-length theories, have lost most of their importance. These theories, developed in the late twenties and early thirties, were aimed specifically at an evaluation of the mean-velocity distribution in turbulent flow. The existing experimental evidence shows clearly that the mean-velocity distribution is very insensitive to the essential assumptions introduced into the phenomenological theories. In fact, purely dimensional arguments generally suffice to give the shape of the mean velocity profile with sufficient accuracy. For the further development of an understanding of turbulence, detailed measurements of the field of fluctuating rather than of mean velocities are necessary. The program of experimental research of which this work is one part is based on this reasoning. It is quite apparent and natural that the same conclusions have been drawn by workers in the turbulent field elsewhere and that, in general, the main emphasis of current experimental investigation is the exploration of the field of the fluctuating-velocity components.

The present set of experiments deals with flow in a two-dimensional channel, that is, with pressure flow between two flat walls. Channel flow of this type is the simplest type of turbulent flow near solid boundaries which can be produced experimentally. The simpler Couette type flow requires that one wall move with constant velocity, a condition which is difficult to realize experimentally. It can be approximated by the flow between concentric cylinders, but complications due to centrifugal forces arise here. The simple geometry of a two-dimensional channel allows an integration of the Reynolds equations, and the turbulent shearing stress can then be related directly to the shearing stress on the surfaces which, in turn, can be determined from the mean-pressure gradient or the slope of mean velocity profile at the wall.

The relation between the apparent stresses and the wall shearing stress can be used to advantage in two fashions. It is here possible to obtain the magnitude of the correlation coefficient responsible for the apparent shear by measuring only the intensities of the turbulent fluctuations. The turbulent shearing stress can also be measured directly by means of the hot-wire anemometer. A comparison with the shear distribution obtained from mean-pressure-gradient or mean-velocity-profile measurements serves then as a very useful check on the underlying assumptions, on the one hand, and specifically as a check on the reliability and accuracy of the direct measurements, on the other.

Measurements of channel flow have previously been made by Dönch (reference 4), Nikuradse (reference 5), Watten-

dorf and Kuethe (references 6 and 7), and Reichardt (references 8 and 9). A few unpublished measurements have been made recently at the Polytechnic Institute of Brooklyn.

Dönch's and Nikuradse's measurements were concerned only with the mean-velocity distribution and are thus of not too much interest for a comparison with the present set of measurements. Wattendorf measured the intensity of the fluctuating-velocity components and then deduced the correlation coefficient from the mean-pressure measurements. The technique for measuring the axial component of the velocity fluctuation was well-developed at the time, but the cross component was only tentatively measured.

The most complete set of measurements is due to the work of Reichardt, who measured velocity fluctuations in the direction of the flow and normal to the wall as well as the turbulent shear directly. Reichardt found very good agreement between the shearing stress determined in these two ways; his paper comes closest to the present investigation and his results will be used for comparison. The Reynolds number in Reichardt's measurements was 8000, which is lower than the range covered by the present measurements. A criticism which can be made of Reichardt's investigation is his use of a tunnel of only 1:4 aspect ratio. The two-dimensional character of the flow is thus somewhat doubtful. Wattendorf's experiments were made in a channel of very large aspect ratio (18:1) and are thus free of this criticism.

In a preliminary investigation a channel 1 inch wide and 60 inches high was chosen. The measurements, however, have shown that in this case the scale of turbulence is so small that great care must be taken to correct the hot-wire readings for the effect of wire length. Measurements of the microscales were, in fact, impossible in the 1-inch channel. The microscales were about 0.1 centimeter and thus smaller than the length of the wire. The corrections for the case of measurements of v' and w' were about 30 percent. Since the method of correction becomes very inaccurate for such large ratios of wire length to microscale, the measurements were repeated in a 5-inch channel with a 12:1 aspect ratio. This ratio was still large enough to insure two-dimensional flow and the length corrections were greatly reduced.

This investigation was conducted at the Guggenheim Aeronautical Laboratory, California Institute of Technology, under the sponsorship and with the financial assistance of the National Advisory Committee for Aeronautics.

The author wishes to acknowledge the constant advice and help in both experimental methods and interpretation of results of Dr. H. W. Liepmann during this investigation. He also wishes to thank Dr. C. B. Millikan for his continuous interest in this research. The cooperation of Dr. F. E. Marble and Mr. F. K. Chuang is much appreciated.

SYMBOLS

x longitudinal coordinate in direction of flow;
 $x=0$ corresponds to channel exit

y	lateral coordinate; $y=0$ corresponds to channel wall
z	vertical coordinate
d	half width of channel (2.5 in.)
δ	thickness of laminar sublayer
u	mean velocity at any point in channel
U_o	maximum value of mean velocity
u'	instantaneous value of velocity fluctuations in direction of mean flow x
v', w'	instantaneous values of velocity fluctuations normal to mean flow in directions y and z , respectively
$\tilde{u}'$	root-mean-square value of velocity fluctuations in direction of mean flow x
$\tilde{v}', \tilde{w}'$	root-mean-square values of velocity fluctuations normal to mean flow in directions y and z , respectively
p	pressure at any point in channel
ρ	air density
τ	total shearing stress
τ_o	shearing stress at wall
U_τ	friction velocity ($\sqrt{\tau_o/\rho}$)
μ	absolute viscosity of air
ν	kinematic viscosity
R	Reynolds number based on half width of channel and maximum mean velocity
k	correlation coefficient responsible for apparent shear $\left(\frac{\overline{u'v'}}{\sqrt{\overline{u'^2}}\sqrt{\overline{v'^2}}}\right)$
R_x, R_y, R_z	correlation coefficients as functions of X, Y , and Z , respectively
$\lambda_x, \lambda_y, \lambda_z$	microscales of turbulence $\left(\frac{\overline{u'^2}}{\lambda_x^2} = \overline{\left(\frac{\partial u'}{\partial x}\right)^2}, \frac{\overline{u'^2}}{\lambda_y^2} = \frac{1}{2} \overline{\left(\frac{\partial u'}{\partial y}\right)^2}, \frac{\overline{u'^2}}{\lambda_z^2} = \frac{1}{2} \overline{\left(\frac{\partial u'}{\partial z}\right)^2}\right)$

L_x, L_y, L_z	scales of turbulence $\left(L_x \equiv \int_0^\infty R_x dX, L_y \equiv \int_0^\infty R_y dY, L_z \equiv \int_0^\infty R_z dZ\right)$
X, Y, Z	distances (in the x -, y -, and z -direction, respectively) between points at which correlation fluctuations are measured
σ	ratio of square of compensated and uncompensated fluctuations
M	time constant expressing thermal lag of hot-wire
n	frequency, cycles per second
$F_{u'^2}(n)$	fraction of turbulent energy $\overline{u'^2}$ associated with band width dn
$F_{u'v'}(n)$	fraction of turbulent shear $\overline{u'v'}$ associated with band width dn
W	dissipation of turbulent energy
t	time
e_1, e_2	voltage fluctuations

ANALYTICAL CONSIDERATIONS

EQUATIONS OF MOTION FOR TWO-DIMENSIONAL CHANNEL FLOW

The mean- and fluctuating-velocity components are denoted by u_i and u'_i , respectively; Cartesian coordinates are designated by x_i ; and p_{ik} denotes the components of the stress tensor which includes both the viscous and apparent (Reynolds) stresses. The Reynolds equation and the continuity equation for steady flow can thus be written, using Cartesian tensor notation,

$$\rho u_k \frac{\partial u_i}{\partial x_k} = \frac{\partial p_{ik}}{\partial x_k} \quad (1a)$$

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (1b)$$

where

$$p_{ik} = \begin{vmatrix} -p + 2\mu \frac{\partial u_1}{\partial x_1} - \rho \overline{u_1'^2} & \mu \left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right) - \rho \overline{u_1' u_2'} & \mu \left(\frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1} \right) - \rho \overline{u_1' u_3'} \\ \mu \left(\frac{\partial u_1}{\partial x_2} + \frac{\partial u_2}{\partial x_1} \right) - \rho \overline{u_1' u_2'} & -p + 2\mu \frac{\partial u_2}{\partial x_2} - \rho \overline{u_2'^2} & \mu \left(\frac{\partial u_2}{\partial x_3} + \frac{\partial u_3}{\partial x_2} \right) - \rho \overline{u_2' u_3'} \\ \mu \left(\frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1} \right) - \rho \overline{u_1' u_3'} & \mu \left(\frac{\partial u_2}{\partial x_3} + \frac{\partial u_3}{\partial x_2} \right) - \rho \overline{u_2' u_3'} & -p + 2\mu \frac{\partial u_3}{\partial x_3} - \rho \overline{u_3'^2} \end{vmatrix}$$

For channel flow between two parallel flat walls,

$$\begin{matrix} u_1 = u(y) \\ u_2 = 0 \\ u_3 = 0 \end{matrix} \quad p_{ik} = \begin{vmatrix} -p - \rho \overline{u'^2} & \mu \frac{du}{dy} - \rho \overline{u'v'} & 0 \\ \mu \frac{du}{dy} - \rho \overline{u'v'} & -p - \rho \overline{v'^2} & 0 \\ 0 & 0 & -p - \rho \overline{w'^2} \end{vmatrix}$$

where x , y , and z replace x_i , and u' , v' , and w' replace u_i' for convenience in writing equations (1a) and (1b) in simpler form. Equation (1b) is automatically satisfied and equation (1a) becomes:

$$\left. \begin{aligned} 0 &= \frac{\partial}{\partial x} (-p - \rho \overline{u'^2}) + \frac{\partial}{\partial y} \left(\mu \frac{du}{dy} - \rho \overline{u'v'} \right) \\ 0 &= \frac{\partial}{\partial y} (-p - \rho \overline{v'^2}) + \frac{\partial}{\partial x} \left(\mu \frac{du}{dy} - \rho \overline{u'v'} \right) \end{aligned} \right\} \quad (2)$$

In fully developed turbulent flow the variation of mean values of the fluctuating quantities with x should be zero; that is, the flow pattern is independent of the streamwise direction. Hence, equations (2) become:

$$\frac{1}{\rho} \frac{\partial p}{\partial x} = \nu \frac{d^2 u}{dy^2} - \frac{d \overline{u'v'}}{dy}$$

or

$$\frac{1}{\rho} \frac{\partial p}{\partial x} = \frac{1}{\rho} \frac{d\tau}{dy} \quad (3a)$$

$$\frac{1}{\rho} \frac{\partial p}{\partial y} = - \frac{\partial \overline{v'^2}}{\partial y} \quad (3b)$$

Differentiating equation (3b) with respect to x gives $\frac{1}{\rho} \frac{\partial^2 p}{\partial x \partial y} = 0$; consequently $\partial p / \partial x$ is independent of y and equation (3a) is immediately integrable. Thus

$$\frac{y}{\rho} \frac{\partial p}{\partial x} = \nu \frac{du}{dy} - \overline{u'v'} + \text{Constant}$$

In the center of the channel the shear vanishes; hence if the channel has the width $2d$

$$\text{Constant} = \frac{d}{\rho} \frac{\partial p}{\partial x}$$

and hence

$$\frac{1}{\rho} \frac{\partial p}{\partial x} (y-d) = \nu \frac{du}{dy} - \overline{u'v'}$$

Or in nondimensional form:

$$\frac{y-d}{\rho U_o^2} \frac{\partial p}{\partial x} = \frac{\nu}{U_o^2} \frac{du}{dy} - \frac{\overline{u'v'}}{U_o^2} \quad (4)$$

In terms of the shearing stress at the wall,

$$- \frac{\tau_o}{\rho U_o^2} \frac{y-d}{d} = \frac{\nu}{U_o^2} \frac{du}{dy} - \frac{\overline{u'v'}}{U_o^2} \quad (5)$$

It is evident from equations (4) and (5) that τ_o can be determined in three different ways:

(a) From the mean-pressure gradient

$$\tau_o = -d \frac{\partial p}{\partial x}$$

(b) From the slope of the mean velocity profile near the wall

$$\tau_o = \mu \left(\frac{du}{dy} \right)_{y=0}$$

(c) From a direct measurement of $\overline{u'v'}$

$$\tau_o = \left(\rho \overline{u'v'} - \mu \frac{du}{dy} \right)_{y=d}$$

If y/d is not too small,

$$\mu \frac{du}{dy} < \rho \overline{u'v'}$$

and then

$$\tau_o = \rho \overline{u'v'} \frac{d}{y-d}$$

The technically simplest way to determine τ_o , and thus in fact the complete shear distribution, is a measurement of $\partial p / \partial x$. This is the method applied in most investigations.

To determine the slope of the velocity profile near the wall, the profile has to be known up to points very close to the wall, that is, at least to distances $y/d = 10^{-2}$. This in general requires the use of the hot-wire anemometer and very precise measurements.

The third method requires a direct measurement of the correlation between the axial and lateral velocity fluctuations. The technique of this type of measurement is known and was first applied by Reichardt and by Skramstad and, in somewhat different form, in recent investigations at the National Bureau of Standards, Polytechnic Institute of Brooklyn, and California Institute of Technology.

In the present investigation all three methods have been applied and the results compared, with the exception of the flow at the lowest Reynolds number. In this case the pressure gradient is extremely small (approx. 0.0003 mm of alcohol/cm) and reasonably accurate measurements were not possible. This comparison of the three methods has the advantage that it gives a good indication of the absolute accuracy of measurements of the fluctuating quantities and the correlation coefficient k .

ENERGY EQUATION

Writing equation (1a) in the form

$$\rho u_k \frac{\partial u_i}{\partial x_k} = - \frac{\partial p}{\partial x_i} + \mu \nabla^2 u_i \quad (6)$$

and multiplying it by u_i , the following relation is obtained:

$$\frac{1}{2} \rho \frac{\partial u_i u_i u_k}{\partial x_k} = - \frac{\partial p u_i}{\partial x_i} + \mu u_i \frac{\partial^2 u_j}{\partial x_j \partial x_j}$$

Transforming the last term by partial integration the energy equation of the mean flow becomes

$$\frac{1}{2} \rho \frac{\partial u_i u_i u_k}{\partial x_k} = -\frac{\partial p u_i}{\partial x_i} + \frac{1}{2} \mu \frac{\partial^2 u_i u_i}{\partial x_j \partial x_j} - \mu \left(\frac{\partial u_i}{\partial x_j} \right) \left(\frac{\partial u_i}{\partial x_j} \right) \quad (7)$$

The velocity perturbations can now be introduced:

$$u_1 = u + u'$$

$$u_2 = v'$$

$$u_3 = w'$$

Since the velocities are independent of the coordinates x and z the following equation is obtained after averaging:

$$\rho \overline{u'v'} \frac{du}{dy} + \rho u \frac{d\overline{u'v'}}{dy} + \frac{1}{2} \rho \frac{d}{dy} \overline{v'(u'^2 + v'^2 + w'^2)} = -u \frac{\partial p}{\partial x} - \frac{\partial \overline{v'p}}{\partial y} + \mu \frac{d^2 u}{dy^2} + \frac{1}{2} \mu \frac{d^2}{dy^2} \overline{(u'^2 + v'^2 + w'^2)} - \mu \left(\frac{\partial u_i'}{\partial x_j} \right) \left(\frac{\partial u_i'}{\partial x_j} \right)$$

Making use of equation (3a) this simplifies to

$$\tau \frac{du}{dy} = \frac{d}{dy} \left[\rho v' \left(\frac{u'^2 + v'^2 + w'^2}{2} \right) + v' p \right] + \mu \left(\frac{du}{dy} \right)^2 - \frac{1}{2} \mu \frac{d^2}{dy^2} \overline{(u'^2 + v'^2 + w'^2)} + \mu \left(\frac{\partial u_i'}{\partial x_j} \right) \left(\frac{\partial u_i'}{\partial x_j} \right)$$

This form was obtained by Von Kármán (reference 10) while discussing a nonisotropic flow in terms of the statistical theory of turbulence. In order to see the relative orders of magnitudes of the different terms in the equation, Von Kármán expresses them in terms of a single velocity $q = \sqrt{u'^2 + v'^2 + w'^2}$ and a characteristic length D corresponding to the width of the channel. Since

$$\frac{\tau}{\rho} \approx -\overline{u'v'} = 0(q^2)$$

and

$$\frac{du}{dy} = 0 \left(\frac{\sqrt{\frac{\tau}{\rho}}}{D} \right) = 0 \left(\frac{q}{D} \right)$$

the above equation may be written as

$$A_1 \frac{q^3}{D} = A_2 \frac{q^3}{D} + A_3 \frac{\nu q^2}{D^2} + A_4 \frac{\nu q^2}{D^2} + A_5 \frac{\nu q^2}{\lambda^2}$$

where the coefficients have the characteristics of correlation functions and λ is the microscale of turbulence. For a high Reynolds number flow $qD/\nu \gg 1$, it follows that $\nu q^2/D^2 \ll q^3/D$. Thus the second and third terms on the right side of the equation may be neglected. Since the pertinent quantities have been measured during the present work, the order of magnitude of these terms can be directly evaluated and the omission of the terms is found to be justified. The above equation thus contains only terms of the forms q^3/D and $\nu q^2/\lambda^2$; these terms should be of the same order of magnitude and therefore $q\lambda^2/\nu D = 0(1)$. It is of considerable interest to

see whether experimental results confirm this relation. Taking as an example results from the measurements at $R=30,800$ and $y/d=0.5$ (where $q^3/D \approx 11 \times 10^3$ and $\nu q^2/\lambda^2 \approx 1.7 \times 10^3$)

$$q = 52 \text{ centimeters per second}$$

$$\lambda_y = 0.5 \text{ centimeter}$$

therefore

$$\frac{q\lambda^2}{\nu D} = \frac{52 \times 0.25}{0.155 \times 12.7} = 6.6$$

This ratio seems to be fairly constant for different Reynolds numbers and across the channel cross section.

In view of the above dimensional considerations, the energy equation may be written

$$\tau \frac{du}{dy} = \frac{d}{dy} \left(\rho v' \frac{u'^2 + v'^2 + w'^2}{2} + v' p \right) + \mu \left(\frac{\partial u_i'}{\partial x_j} \right) \left(\frac{\partial u_i'}{\partial x_j} \right) \quad (8)$$

The equation expresses the fact that the energy produced by the turbulent shear forces at a certain point is partly diffused and partly dissipated. This equation has been used in estimating the energy diffusion across the channel, since from the measured quantities the production term and dissipation can be calculated.

EQUIPMENT AND PROCEDURE

WIND TUNNEL

The investigation was carried out in the wind tunnel shown in figure 1. The turbulence level is controlled by a honeycomb and seamless precision screens, followed by an approximately 29:1 contraction. The screens have 18 meshes per inch and a wire diameter of 0.018 inch. The honeycomb consists of paper mailing tubes, 6 inches long and 1 inch in diameter.

FIGURE 1.—Diagram of two-dimensional tunnel.

The over-all length of the channel is 23 feet. At the entrance section it is 3 inches wide and has an aspect ratio of 20:1. In a distance of 7 feet it expands to a width of 5 inches and the aspect ratio is reduced to 12:1. The walls of the exit portion of the channel (about 6 ft) are made of 3/4-inch-

thick plywood with a $\frac{1}{4}$ -inch birch inside cover. They were specially treated in order to acquire a smooth finish and were reinforced in order to avoid warping (fig. 2); in spite of this a few percent of width variation existed.

FIGURE 2.—Exit of channel.

The tunnel is operated by a 62-horsepower stationary natural-gas engine—normally operating at a fraction of its rating—which drives two eight-bladed fans. The speed is remotely controlled by means of a small electric motor which drives the throttle through a gear and lead-screw system.

The experiments were carried out at speeds of 3, 7.5, and 15 meters per second.

TRAVERSING MECHANISM

Figure 3 shows the type of traversing mechanism used during the experiments. It consists simply of a micrometer screw on which the hot-wire support is fastened. The support can rotate freely in a plane perpendicular to the air flow; thus, the hot-wire may be adjusted exactly parallel to the wall.

FIGURE 3.—Traversing mechanism.

The zero reading of the traversing mechanism ($y=0$) was carefully found using the following method: The hot-wire was placed close to the wall (approx. 0.025 cm away); the distance between the wire and its image in the polished wall was measured by means of an ocular micrometer. The position of the wire is, of course, one-half of the observed distance and could be determined with an accuracy of ± 0.0005 centimeter.

In order to obtain the pressure distribution along the middle of the channel a 6-inch-long thin-walled tube $\frac{3}{8}$ -inch in diameter was used with a small static-pressure hole drilled close to its end. The tube was free to slide in a support at the entrance of the channel so that the position of the pressure hole relative to the channel exit could be changed. The tube was kept straight and under tension by means of weights.

HOT-WIRE EQUIPMENT

All velocity measurements were made with hot-wire anemometers. The frequency response of the amplifier-compensator unit of the hot-wire equipment, using a 0.00024-inch wire at standard operating conditions, is flat from approximately 2 to 10,000 cycles per second.

The compensation of the hot-wire for thermal lag is accomplished by a capacity network. The range of time constants was chosen from 0 to 1 millisecond corresponding to the characteristics of 0.00005- to 0.00024-inch wires at the operating conditions employed in general at GALCIT. No attempt was made to extend the range of compensation to larger values of M , since in this case the noise level soon becomes appreciable.

The correct setting of the compensating unit was found using the square-wave method described by Kovátszay (reference 11). The time constants of the wires used for turbulence measurements fell between 0.1 and 0.9 millisecond.

The output readings were taken with a thermocouple and precision potentiometer.

Mean-speed measurements.—A 1/2-mil (0.0005-in.) platinum wire of 1-centimeter length was used to measure the mean speed. The measurements were made by the constant-resistance method. This method has the advantage of keeping the wire temperature constant through the velocity field.

Turbulence measurements.—For the investigation of turbulent fluctuations, 0.00024-inch Wollaston wire was used. The wire was soft-soldered to the tips of fine sewing needles after the silver coating had been etched off. The two lateral components v' and w' and the correlation coefficient $R_y = \frac{\overline{u'v'}}{\sqrt{\overline{u'^2}}\sqrt{\overline{v'^2}}}$ were measured using the X-wire technique. The

method was essentially the same as described in detail in previous reports from this laboratory. (See, for example, reference 12.)

The X-meters for shear measurements had angles between the wires of approximately 90° . The angles of the v', w' -meter were of the order of 30° . The wire length of the u' -meter was about 1.5 millimeters and that of the v' -meter was 3 millimeters.

The parallel-wire technique used recently at the Polytechnic Institute of Brooklyn was also tried in order to obtain the lateral component of the velocity fluctuation and the shear close to the wall. The parallel-wire instrument is superior to the X-meter since it allows an exploration of the turbulent field up to distances of a few thousandths of an inch from the wall. However, it was found impossible to obtain reliable values with this instrument. The corrections due to u' -fluctuations and to unequal heating of the wires were pronounced and not easily accountable. The method was therefore temporarily abandoned after considerable time and labor had been spent on it.

Measurements of correlations between two points.—The correlation functions between values of u' at points along the y - and z -axis, that is,

$$R_y = \frac{\overline{u'(0)u'(Y)}}{\sqrt{\overline{u'(0)^2}}\sqrt{\overline{u'(Y)^2}}}$$

$$R_z = \frac{\overline{u'(0)u'(Z)}}{\overline{u'^2}}$$

were measured using the standard technique (reference 12). The scales of turbulence L_y and L_z and the microscales λ_y and λ_z at different points across the channel were obtained from these measurements.

Measurements of λ_z .—A method suggested by Townsend (reference 13) was applied to measure λ_z . Using an electronic differentiation circuit the amplifier output signal was differentiated and λ_z computed from the following relation:

$$\left(\frac{\partial u'}{\partial t}\right)^2 = u^2 \left(\frac{\partial u'}{\partial x}\right)^2 = u^2 \frac{\overline{u'^2}}{\lambda_z^2}$$

The error involved in the approximation $\frac{\partial}{\partial t} \rightarrow u \frac{\partial}{\partial x}$ can be estimated and it may be seen that the above relation holds with reasonable accuracy over the large center portion of the channel.

A new technique for the measurement of λ_z has also been applied. The method is described in detail in reference 14 and consists in counting the zeros of an oscillograph trace

of the u' -fluctuations. From these counts λ_z may be calculated directly by assuming a normal and independent distribution for both u' and $\partial u'/\partial x$:

$$\frac{1}{\lambda_z} = \frac{\pi}{U_o} \times \text{Average number of zeros of } u' \text{ per second}$$

It is known that the distribution of u' is closely a Gaussian one even in nonisotropic turbulence (see, for instance, reference 15); however, for the case of $\partial u'/\partial x$ a small deviation from the normal distribution was found (reference 13). For the preliminary measurements of λ_z reported presently, no corrections were applied as yet for this effect. Figure 4 shows an oscillograph trace of the u' -fluctuation in the middle of the channel at $R=30,800$. The trace represents an interval of approximately 1/20 second.

FIGURE 4.—Typical oscillogram of u' -fluctuation at $R=30,800$ and $y/d=1.0$. Horizontal line corresponds to $u'(t)=0$; interval is approximately 1/20 second.

Measurement of L_z .—The following simple procedure² was applied to obtain a rough estimate of scale of turbulence corresponding to correlations between points along the x -axis: Denote by $F_{u'^2}(n)$ the fraction of turbulent intensity which is contributed by frequencies between n and $n+dn$; that is,

$$\overline{u'^2}(n) dn = \overline{u'^2} F_{u'^2}(n) dn$$

and thus

$$\int_0^\infty F_{u'^2}(n) dn = 1$$

Consider now an uncompensated hot-wire. If the time constant of this uncompensated wire is M , the response will be

$$[u'(n)^2]_{uncomp.}$$

where

$$[u'(n)^2]_{uncomp.} = \frac{\overline{u'(n)^2}}{1 + M^2 n^2}$$

The total intensity for the uncompensated wire will then be given by³

$$(\overline{u'^2})_{uncomp.} = \overline{u'^2} \int_0^\infty \frac{F_{u'^2}(n)}{1 + M^2 n^2} dn$$

² This method was suggested by Dr. H. W. Liepmann.

³ Formulas of this general type have been proposed by Kampé de Fériet and by Frenkiel for determining the spectrum of turbulence from uncompensated hot-wire measurements by varying M (reference 16).

Thus, if the ratio of the response of the same wire compensated and uncompensated is denoted by σ ,

$$\frac{1}{\sigma} = \int_0^\infty \frac{F_{u'^2}(n)}{1 + M^2 n^2} dn \quad (9)$$

In order to estimate L_x , $F_{u'^2}(n)$ is assumed to have the simple form

$$F_{u'^2}(n) = \frac{2}{\pi} \frac{L_x/U_o}{1 + n^2 \frac{L_x^2}{U_o^2}}$$

which was given by Dryden (reference 17) and corresponds to an exponential correlation curve.

Then

$$\frac{1}{\sigma} = \frac{2}{\pi} \int_0^\infty \frac{L_x/U_o}{\left(1 + n^2 \frac{L_x^2}{U_o^2}\right)(1 + M^2 n^2)} dn$$

or with

$$\eta = L_x n / U_o$$

$$\alpha = M U_o / L_x$$

then

$$\frac{1}{\sigma} = \frac{2}{\pi} \int_0^\infty \frac{d\eta}{(1 + \eta^2)(1 + \alpha^2 \eta^2)} = \frac{1}{1 + \alpha}$$

Hence

$$L_x = \frac{M U_o}{\sigma - 1}$$

Thus by measuring the ratio of the mean squares of the fluctuating velocities with and without compensation, L_x can be estimated.

The procedure was checked in the flow behind a $\frac{1}{2}$ -inch grid where the lateral scale was measured and where because of isotropy the relation $L_x = 2L_y$ should hold fairly well.

The results were:

$$\sigma = 1.85$$

$$M = 7 \times 10^{-4} \text{ second}$$

$$U_o = 1.5 \times 10^3 \text{ centimeters per second}$$

therefore

$$L_x = 1.24 \text{ centimeters}$$

Direct measurements gave $L_y = 0.553$ centimeter. Hence $L_x = 1.11$ centimeters which shows that this method of estimating the value of L_x is satisfactory.

Measurement of turbulent-energy spectrum.—In order to be able to measure accurately the energy distribution over a wide frequency band, it was found necessary to use extremely thin wires with small time constants and thus to increase the signal-to-noise ratio. Wires of 0.00005-inch diameter, operating with time constants of approximately 2×10^{-4} second, were used. In this way it was possible to detect

energy values in the high-frequency bands that were 10^{-7} times the value corresponding to zero frequency.

The hot-wire signal was fed into a Hewlett-Packard wave analyzer, the output circuit of which was somewhat altered in order to be able to feed the output signal into a root-mean-square voltmeter. The averaging characteristics of the root-mean-square meter were checked and, for a narrow-band-width signal, were found to give the same mean values as those calculated from thermocouple readings.

With this method the energy of the $\overline{u'^2}$ -fluctuation was measured at different points across the channel. At $y/d = 0.4$ the spectrum of the turbulent shear $\overline{u'v'}$ was also obtained.⁴ An X-type meter was used, both wires making an angle of 45° with the free-stream direction. If $\overline{e_1^2}$ and $\overline{e_2^2}$ are the mean-square voltage fluctuations (corrected for time lag) across the two wires it may be shown (reference 12) that

$$\overline{e_1^2} - \overline{e_2^2} = \text{Constant} \times \overline{u'v'}$$

If e_1 and e_2 are fed into the wave analyzer then the above relation holds for all band widths dn ; that is,

$$\overline{e_1(n)^2} - \overline{e_2(n)^2} = \text{Constant} \times \overline{u'v'(n)}$$

PRELIMINARY MEASUREMENTS IN A 1-INCH CHANNEL

In the initial stages of the turbulent-channel-flow investigation a two-dimensional channel of 1-inch width was used. Measurements of mean and fluctuating velocities and of the correlation coefficient k were completed. The scales L_y and L_z were also measured at the channel center and were found to be about 0.2 to 0.3 centimeter. This small-scale turbulence existing in the channel imposed a definite limitation on the accuracy of the fluctuating measurements. Wire-length corrections as high as 30 percent had to be applied to the measurements of v' and w' . Furthermore, no microscales could be measured accurately; thus one of the objectives of the investigation, the calculation of the energy dissipation across the channel, could not be obtained. Nevertheless, results show good consistency; the three independent measurements of the turbulent shear indicate satisfactory agreement.

It is of interest to present these preliminary measurements, the Reynolds number of which was 12,200, and to compare them with those obtained in the 5-inch channel. Figure 5 shows the distribution of all the measured quantities in the 1-inch channel and it may be directly compared with figure 16 which shows the quantities measured in the 5-inch channel at nearly the same Reynolds number.

Although the slopes of the mean velocities at the wall are almost the same in each case (for the 1-in. channel $\tau_o/\rho U_o^2 = 0.0019$; for the 5-in. channel $\tau_o/\rho U_o^2 = 0.0018$), the velocity ratios u/U_o in the 5-inch channel seem to be lower across most of the channel. This indicates that a more intense

⁴ This method appears to have been first used by Dr. Stanley Corrsin in a turbulent jet (private communication).

 FIGURE 5.—Distribution of measured quantities across two-dimensional channel of 1-inch width. $R=12,200$.

turbulent-energy production $\tau \frac{du}{dy}$ takes place in the 5-inch channel. Indeed, the turbulent-velocity fluctuations $\tilde{u}'/U_0$, $\tilde{v}'/U_0$, and $\tilde{w}'/U_0$ (especially $\tilde{u}'/U_0$) increase at a faster rate toward the wall in the wider channel, although their values at the channel center check very well in the two cases. The shear distribution $\tau/\rho U_0^2$ is almost the same for the two channels; it follows, therefore, from the relation

$$\frac{\overline{u'v'}}{U_0^2} = k \frac{\tilde{u}'}{U_0} \frac{\tilde{v}'}{U_0}$$

that k must have a higher absolute value in the 1-inch channel since both $\tilde{u}'/U_0$ and $\tilde{v}'/U_0$ are smaller there. Indeed the maximum value of k in this case is -0.6 , while in the 5-inch channel it is -0.5 .

As a matter of interest it could be mentioned that if the basis of comparison is not Reynolds number but maximum mean speed (for the 1-in. channel $U_0=15$ m/sec) then figure 5 shows a distribution of $\tilde{u}'$, $\tilde{v}'$, and $\tilde{w}'$ very similar to that of figure 18, the absolute values being somewhat lower in the 5-inch channel.

RESULTS AND DISCUSSION

MEAN-VELOCITY DISTRIBUTION

A careful study of the two-dimensional nature of the channel flow was first made. Mean-velocity measurements were carried out at approximately $x=-2$ inches at different

heights in the channel: At positions 6 inches from the bottom, 6 inches from the top, and at the middle. Agreement among the three sets of measurements confirmed the two-dimensionality. A further check was made on possible end effects that might influence the results. The length of the channel was extended by 6 inches and the mean-velocity measurements were repeated at $x=-8$ inches. No change in the profile was noticed. Figure 6 shows the mean-velocity distributions at three Reynolds numbers, $R=61,600$, $R=30,800$, and $R=12,300$. The distributions follow Von Kármán's logarithmic law very well, except, of course, near the wall and at the center of the channel (fig. 7). The values of U_τ were obtained from the velocity gradients at the wall.

FIGURE 6.—Mean-velocity distribution. Measured points close to wall are not shown.

FIGURE 7.—Logarithmic representation of mean-velocity distribution.

Measurements were made with special care close to the wall. Velocities at a large number of points were recorded within the laminar sublayer in order to establish with reasonable accuracy the shape of the velocity profile at the wall (fig. 8). The thickness of the laminar sublayer (the point where the velocity distribution deviates from the logarithmic law) was found to be $\delta \approx 30\nu/U_\tau$ (fig. 7).

FIGURE 8.—Mean-velocity distribution near wall.

In figure 8 it can be seen that for the case of the lowest Reynolds number a few points near the wall indicate very low velocities. Since the point at which $y/d=0$ has been determined with great accuracy and since the equations of motion of the channel flow require a negative curvature for the velocity profile, it was concluded that the hot-wire indicated too low velocities near the wall for the lowest Reynolds number. (The dashed curve for this case in fig. 8 shows the interpolated velocity distribution for $0 < y/d < 0.01$.) It can be shown that very high local-velocity fluctuations cause the hot-wire to read velocities lower than the true

mean value. Since the mean current of the wire varies with the fourth root of the velocity,

$$\sqrt{u} = \sqrt{\bar{u}} \left[\left(1 + \frac{u'}{\bar{u}} \right)^2 + \left(\frac{v'}{\bar{u}} \right)^2 + \left(\frac{w'}{\bar{u}} \right)^2 \right]^{1/8}$$

where u is the velocity to which the hot-wire responds and $\bar{u}$ is the true mean velocity. Near the wall $\left(\frac{v'}{\bar{u}} \right)^2 \ll 1$ and can therefore be neglected. Because of the cosine-type directional characteristics of the hot-wire the effect of the w' -fluctuation can also be neglected. The velocity measured by the wire can be written, after expanding the above expression, as

$$u = \bar{u} \left[1 - \frac{3}{16} \left(\frac{u'}{\bar{u}} \right)^2 + \dots \right]$$

Since the average of the odd terms is zero the series converges rapidly. In the region in question, the velocity fluctuations obtained were very high indeed ($\bar{u}'/\bar{u} > 0.30$). Their absolute values, however, are probably even larger, since the nonlinearity effect of the large fluctuations on the hot-wire response still further amplified by the very low mean velocities is not taken into account because the wire-length corrections are neglected. The mean-velocity correction therefore given by the above relation is too small to give the required negative curvature of the profile.

TURBULENCE LEVELS

Figures 9 to 14 represent the results of measurements of the three components $\tilde{u}'$, $\tilde{v}'$, and $\tilde{w}'$ of the turbulent-velocity-fluctuation distribution in the channel for the three Reynolds numbers.

FIGURE 9.—Velocity fluctuations u' relative to local speeds.

 FIGURE 10.—Velocity fluctuations u' relative to local speeds near wall.

 FIGURE 11.—Velocity fluctuations $\tilde{u}'$.

 FIGURE 12.—Velocity fluctuations $\tilde{u}'$ near wall.

 FIGURE 13.—Distribution of velocity fluctuations $\tilde{v}'$.

 FIGURE 14.—Distribution of velocity fluctuations $\tilde{w}'$.

The velocity fluctuations $\tilde{u}'$ relative to local speeds increase very rapidly near the wall as is shown in figures 9 and 10. Measurements very close to the wall indicate that $\tilde{u}'/u$ reaches a maximum within the laminar boundary layer ($yU_0/\nu \approx 17$) and it tends toward a constant value at the wall which is independent of the Reynolds number. This point will be discussed in detail under "Reynolds Number Effect."

The absolute values of the distribution of $\tilde{u}'$ show the same general shape as that obtained by Reichardt (reference 9), having the characteristic maximum near the wall and thus showing the strong action of viscosity even for values of $y \approx 4\delta$.

Using the X-type hot-wire technique for obtaining the velocity-fluctuation components v' and w' , no measurements could be obtained near the wall. Figures 13 and 14 show that, while in the center of the channel the magnitudes of $\tilde{v}'$ and $\tilde{w}'$ are the same, $\tilde{w}'$ increases faster toward the wall. This agrees with the ultramicroscope measurements in a pipe by Fage and Townend (reference 18).

No length corrections were necessary to the measurements of u' except near the wall; however, no corrections were applied in this region since no measurements of λ_z could be made. In this region, furthermore, the fluctuations are very large and the values given in figure 10 must be accepted with reserve. The hot-wire response for large velocity fluctuations is not well-understood yet and no correction was attempted. Length corrections were applied to the measurements of v' and w' .

CORRELATION COEFFICIENT AND SHEAR DISTRIBUTION

The correlation coefficient is fairly constant across most of the channel (fig. 15) as indicated already by Wattendorf

FIGURE 15.—Correlation-coefficient distribution.

and Kueth (reference 6). The maximum values of k obtained decrease slowly with increasing Reynolds number and thus show a definite Reynolds number dependence. Existing results indicate, however, that parameters other than Reynolds numbers also influence the value of k . The following table shows magnitudes of the maximum correlation coefficient as obtained by different investigators working with channels of various widths and with various Reynolds numbers:

Experiments by—	Channel width (cm)	R	k_{max}
Reichardt (reference 9) ----	24.6	8,000	-.45
Laufer (present paper) ----	2.5 (1 in.)	12,200	-.63
Laufer (present paper) ----	12.7 (5 in.)	12,300	-.50
Wattendorf (reference 7) ---	5.0	15,500	-.52
Laufer (present paper) ----	12.7 (5 in.)	30,800	-.45
Laufer (present paper) ----	12.7 (5 in.)	61,600	-.40

Wattendorf obtained his value of k from his measurements of the quantities $\tilde{u}'/U_o$, $\tilde{v}'/U_o$, and $\overline{u'v'}/U_o^2$. Unfortunately his preliminary measurements of $\tilde{v}'$ are incorrect; their magnitude is larger than that of $\tilde{u}'$ at all values of y across the channel contrary to results obtained by Reichardt and by the present writer. Wattendorf himself points out the inaccuracy of the values of $\tilde{v}'$ in his paper. Because of the large values of $\tilde{v}'$ his computed correlation coefficients are too low. The value $k_{max} = -0.52$ listed in the above table was obtained by using Wattendorf's values $\overline{u'v'}/U_o^2 = 0.001$ and $\tilde{u}/U_o = 0.055$ and the value $\tilde{v}'/U_o = 0.035$ ($y/d = 0.5$) obtained by the author for both the 1-inch (2.5-cm) and 5-inch (12.7-cm) channel at $R = 12,200$ and $R = 12,300$, respectively.

The variation of k indicates that for the same Reynolds number the correlation coefficient tends to increase with increasing maximum mean velocity (i. e., in a channel of decreasing width).

Figures 16 to 18 show the distribution of all the measured quantities including the shear distribution. For the case of the two higher Reynolds numbers, three independent measurements were made for the determination of the shear distribution by methods indicated in "Equations of Motion for Two-Dimensional Channel Flow." Figure 19 indicates that consistent results are obtained for the value of τ whether calculated from the pressure gradient along the channel or from the velocity gradient at the wall. The turbulent-shear distributions obtained from hot-wire measurements and those calculated from figure 17 show satisfactory agreement. However, for the flow at the highest Reynolds number, the

hot-wire measurements gave a 20-percent-lower value for the shear coefficient, as may be seen in figure 18.⁵ At present, the writer can give no satisfactory explanation for this discrepancy. In the flow at the lowest Reynolds number, no pressure measurements were made because the very low pressure gradient (approx. 0.0003 mm of alcohol/cm) did not permit accurate measurements. However, in this case the wall shear computed from the measured mean fluctuating quantities $\tilde{u}'$, $\tilde{v}'$, and k and the mean-velocity measurements may be compared with that obtained in the 1-inch-channel flow having nearly the same Reynolds number. The comparison shows satisfactory agreement: For the 1-inch channel $\tau_o/\rho U_o^2 = 0.0019$; for the 5-inch channel $\tau_o/\rho U_o^2 = 0.0018$.

SCALE AND MICROSCALE MEASUREMENTS

For a further understanding of the structure of the turbulent field, correlations of u' -fluctuations at two different points were carried out. Since the field is not isotropic, the scale and microscale measurements were repeated both in the y - and z -direction for different values of y/d .

R_z -correlation.—Figure 20 shows typical R_z -correlation distributions at different values of y/d corresponding to $R = 30,800$. For larger values of z , inaccuracies in the measurements did not permit the exploration of the negative region of the correlation distribution. From the measured distributions of R_z at four stations across the channel and for different values of R , the values of L_z and λ_z were calculated (figs. 21 and 22). In these figures L_z is seen to be decreasing uniformly toward the wall, while λ_z reaches a definite maximum at about $y/d = 0.7$ and then decreases with decreasing y/d .

R_y -correlation.—Distributions of the R_y -correlation at a given value of y/d were obtained by fixing the stationary hot-wire at the given value of y/d and traversing with the moving hot-wire away from the fixed one toward the channel center. Values of L_y and λ_y were then calculated from these distributions of R_y . In the region $1.0 > y/d > 0.1$ the gradients of the various quantities are slight; no significant asymmetry in the function R_y is therefore expected. Measurements of the top part of the R_y -correlation distribution ($1.0 > R_y > 0.8$) by Prandtl and Reichardt (reference 19) justify this belief fairly well.

By comparing figure 20 with figure 23, the strong effect of the existing nonisotropy can immediately be seen. Although both R_y and R_z correspond to Von Kármán's g -function (reference 10) they exhibit different behaviors across the channel. The R_z -correlation function falls more and more rapidly to zero with decreasing y/d . Traversing from $y/d = 1.0$ to $y/d = 0.70$ the distribution of R_y is found to behave similarly; however, the dashed curve measured at $y/d = 0.4$ (fig. 23) indicates considerably increased correlations for larger values of Y . It is thus seen that around $y/d = 0.7$ there is a definite decrease in energy content of the fluctuations having low frequencies. Further consideration of this fact is given later in the discussion of the energy balance in the channel.

⁵ This result was accepted after the absolute values were carefully checked; the v' -wire response was compared with u' -fluctuations in an isotropic field and the two-dimensional character of the flow was checked.

 FIGURE 16.—Distribution of mean and fluctuating quantities. $R=12,300$.

 FIGURE 17.—Distribution of mean and fluctuating quantities. $R=30,800$.

FIGURE 18.—Distribution of mean and fluctuating quantities. $R=61,600$.FIGURE 19.—Pressure distribution along channel. Solid lines indicate pressure gradient obtained from measured du/dy .FIGURE 20.— R_z -correlation. $R=30,800$. At $y/d=1.0$, $L_z=1.65$ centimeters, $\lambda_z=0.70$ centimeter; at $y/d=0.7$, $L_z=1.55$ centimeters, $\lambda_z=0.81$ centimeter.

The values of $L_y = \int_0^\infty R_y dY$ (fig. 21) are not so reliable as those of L_z since R_y could not be measured at sufficiently large values of Y because of the limitation of the traversing mechanism used.

The distribution of λ_y across the channel is similar to that of λ_z (fig. 22). From $y/d=1.0$ to $y/d \approx 0.7$ both λ_y and λ_z increase almost proportionally to u' , indicating that the turbulent-energy dissipation $W \propto u'^2/\lambda^2$ is approximately constant in this region. It should be noticed, however, that λ_z is consistently larger than λ_y throughout the channel cross section. Some measurements of λ_y close to the wall are also indicated in figure 23. No length correction was found to be necessary for the measured values of λ_y and λ_z .

A rough estimate of L_x by the method already described gave a value approximately twice that of L_z at the center of the channel (fig. 21). Its value increases to a maximum at $y/d \approx 0.5$ and then decreases rapidly. No values for L_x are given for the lowest Reynolds number; in this case the value of σ is very close to unity and, since L_x is proportional to $\frac{1}{\sigma-1}$, σ should be known within an accuracy of 1 percent to give consistent results for L_x . Unfortunately measurements of L_x cannot be made with this accuracy, particularly when the u' -fluctuations are of rather low frequencies as is the case for $R=12,300$. It should be mentioned that the accuracy of the determination of L_x is more limited by the inaccurately measured value of σ than by the fact that an approximate spectrum function $F_{u'^2}(n)$ is used in equation (9).

FIGURE 21.—Scale of turbulence distribution.

The distribution of λ_z obtained by the differentiation method shows the same behavior as that of λ_y and λ_x (fig. 22). It has the characteristic maximum at $y/d \approx 0.7$. No measurements were made for $R=12,300$ because of the inaccuracy due to the large noise-to-signal ratios.

As a matter of interest the results of some measurements of λ_z obtained with the zero-counting method are compared with those described above. (See fig. 22.) Since the validity of the assumptions involved in this method is not clarified yet, these measurements should be regarded as preliminary.

SPECTRUM MEASUREMENTS

The spectra of the velocity fluctuations $\overline{u'^2}$ have been obtained at various values of y/d across the channel. With

improved instrumentation it was possible to reduce experimental scatter by a considerable amount. The accuracy of the present measurements is believed to be within ± 10 percent with the exception of values corresponding to low frequencies ($n < 100$ cps) because of the large-amplitude fluctuations and with the exception of values corresponding to high frequencies ($n > 4000$ cps) because of noise and of possible wire-length effect. A typical spectrum distribution taken at $y/d=1.00$ is shown in figure 24. (The measured spectra at various positions of y/d are given in table I.) No attempt is made to compare the measured distributions with existing theories since the restrictive assumptions of these theories (isotropy and flows at high Reynolds numbers) are not satisfied in the present experiments. The only frequency range where comparison is possibly justified is the viscous region, that is, the high-frequency part of the spectrum where viscosity plays a dominant role. Unfortunately here the accuracy of the measurements is not good enough to afford any definite conclusions. Therefore, the rather close agreement of the measured spectrum (for all values of y/d except in the laminar sublayer) with the n^{-7} -law predicted by Heisenberg (reference 2) should be accepted with reserve (fig. 24).

FIGURE 22.—Microscale measurements.

 FIGURE 23.— R_y -correlation. $R=30,800$. At $y/d=1.0$, $L_y=1.3$ centimeters, $\lambda_y=0.50$ centimeter; at $y/d=0.7$, $L_y=1.2$ centimeters, $\lambda_y=0.56$ centimeter.

FIGURE 24.—Frequency spectrum of $\bar{u}'^2$ at channel center. Scale values within parentheses correspond to curve on left.

FIGURE 25.—Spectrum distributions across channel. $R=30,800$.

For a comparison of the energy spectra at different points in the channel, figure 25 shows the distribution of $n^2 F_{u'^2}(n)$ instead of that of $F_{u'^2}(n)$ as a function of the frequency. This method of presentation emphasizes energies corresponding to the higher frequencies but gives a clearer over-all comparison of the different sets of measurements. The characteristic maximum of the distribution of λ_x immediately becomes apparent in this figure. From the fact that the

correlation coefficient is a Fourier transform of the spectrum function it follows that

$$-\left(\frac{\partial^2 R_x}{\partial X^2}\right)_{x=0} = \frac{1}{\lambda_x} = \frac{4\pi^2}{u^2} \int_0^\infty n^2 F_{u'^2}(n) dn$$

Thus λ_x can be computed from the distributions of $n^2 F_{u'^2}(n)$. The calculated values check within a few per cent with direct measurements (fig. 22).

REYNOLDS NUMBER EFFECT

Figure 7 shows the distribution of mean velocities plotted in the form of "friction velocity" u/U_τ against "friction-distance parameter" yU_τ/ν . In this form the profiles are independent of the Reynolds number $U_\tau d/\nu$ and follow Von Kármán's logarithmic law:

$$\frac{u}{U_\tau} = A \log \frac{yU_\tau}{\nu} + B$$

The constants A and B are 6.9 and 5.5, respectively. Comparing the present measurements with previous ones it is to be noted that because of the very smooth wall surfaces used, the value B is larger than that of other investigators. Making allowances for this effect, measurements are in fairly good agreement with those of Dönch (reference 4) and Reichardt (reference 9). Nikuradse's channel results (reference 5) differ from all other existing experiments. It is pertinent to mention that for the Reynolds number range in question ($R < 100,000$) the slope of the logarithmic mean-

velocity distribution (the constant A) both in pipes and channels is larger than that established by Nikuradse's pipe measurements ($A=5.75$).

The Reynolds number has a definite influence on the velocity fluctuations also. Along most of the cross section where the influence of the viscosity is negligible the fluctuations $\tilde{u}'$, $\tilde{v}'$, and $\tilde{w}'$ decrease slowly with increasing Reynolds number.

Very close to the wall, according to Prandtl's hypothesis, all velocities of the form $\text{Velocity}/U_\tau$ must be a function of the friction-distance parameter only. It has already been pointed out that the mean velocity obeys this similarity law. Figure 26 shows the distribution of $\tilde{u}'/U_\tau$ as a function

FIGURE 26.—Logarithmic representation of velocity fluctuations u' .

of yU_τ/ν for the different flow conditions investigated. The following remarks can be made with reference to this figure:

(1) For values of $yU_\tau/\nu < 100$, values of $\tilde{u}'/U_\tau$ corresponding to the various cases indicate similar behavior. They reach a maximum at about $yU_\tau/\nu \approx 17$.

(2) It is believed that the similarity is actually more complete than indicated in figure 26. Because the microscale is not known in regions very close to the wall no length corrections could be applied. These corrections would of course be appreciably higher for the two high-velocity flows ($R=61,600$, $2d=5$ in. and $R=12,200$, $2d=1$ in.) and would therefore bring the various distributions of $\tilde{u}'/U_\tau$ closer together in the region in question.

(3) The effect of viscosity is more pronounced on the fluctuating quantities than on the mean velocity.

(4) Taylor pointed out in 1932 (supporting his arguments by Fage and Townend's ultramicroscope measurements) that $\tilde{u}'/u$ and $\tilde{w}'/u$ approach a finite value at the wall (reference 18). It follows from the similarity law that this value should be an absolute constant independent of the Reynolds number. Figure 10 indicates this to be true, the constant being $(\tilde{u}'/u)_{y=0} \approx 0.18$.

It is of considerable interest to discuss the variation of the scale and microscale with Reynolds number. For flows behind grids where the turbulence is isotropic the scale is independent of the mean velocity and depends on the mesh size of the grid. Similar behavior was found for the channel flow. Figure 21 shows the distributions of L_y and L_z for different velocities. These distributions indicate no con-

sistent variation with velocity. Furthermore, measurements in a 1-inch channel give a value for L_z five times lower and a ratio for L_y somewhat larger than the values obtained in the present investigation.

The variation of λ depends, of course, on the velocity and channel width. The values of λ decrease with increasing velocity; however, the variation of λ with channel width is less than that of L .

FULLY DEVELOPED CHARACTER OF TURBULENCE

The flow in the channel is called fully developed if the variations of the mean values of the velocity and the mean squares of the velocity fluctuations with x are very small. That the mean velocity profile does not vary downstream is evident from the pressure-gradient measurements (fig. 19). The gradient in x of $\overline{u'^2}$ was measured on the axis of the channel. It was found that $\overline{u'^2}$ was indeed decreasing with x . The gradient, however, was very small as compared with $\frac{1}{\rho} \frac{\partial p}{\partial x}$:

$$\frac{\partial \overline{u'^2}}{\partial x} \approx 0.01 \frac{1}{\rho} \frac{\partial p}{\partial x}$$

Hence for all practical purposes $\partial \overline{u'^2}/\partial x$ can be neglected. No measurements have been made concerning $\partial \overline{u'v'}/\partial x$, since the scatter in the values would cover any effect. However, there is little doubt that $\partial \overline{u'v'}/\partial x$ is of the same order as $\partial \overline{u'^2}/\partial x$ and that the use of equations (3a) and (3b) is therefore justified here.

ENERGY BALANCE IN FLUCTUATING FIELD

The energy equation for a two-dimensional channel has the form given by equation (8) and is valid throughout the cross section of the channel with the exception of a small region near the wall. The term $\tau \frac{du}{dy}$ on the left side of equation (8) corresponds to the energy produced by the shearing stresses and it can be obtained directly from the measurements of τ and from the mean velocity profile. The second term on the right $\mu \left(\frac{\partial u_i'}{\partial x_j} \right) \left(\frac{\partial u_i'}{\partial x_j} \right)$ expresses the amount of energy that is being dissipated because of the breaking down of the larger eddies to smaller ones. The term may be written explicitly

$$W = \mu \left[\left(\frac{\partial u'}{\partial x} \right)^2 + \left(\frac{\partial u'}{\partial y} \right)^2 + \left(\frac{\partial u'}{\partial z} \right)^2 + \left(\frac{\partial v'}{\partial x} \right)^2 + \left(\frac{\partial v'}{\partial y} \right)^2 + \left(\frac{\partial v'}{\partial z} \right)^2 + \left(\frac{\partial w'}{\partial x} \right)^2 + \left(\frac{\partial w'}{\partial y} \right)^2 + \left(\frac{\partial w'}{\partial z} \right)^2 \right]$$

The problem is to express these functions in terms of easily measurable quantities. In the case of isotropic turbulence Taylor solved the problem by introducing the microscale of turbulence λ and obtained for the dissipation

$$W = 15\mu \frac{\overline{u'^2}}{\lambda^2} \quad (10)$$

It is attempted here to carry over his analysis to the case of channel flow. The following assumptions have to be made in this connection:

(a) The gradient of the velocity fluctuations is small in all three directions. With the exception of the region near the wall this is justifiable from the measurements.

(b) Since only correlations of u' have been measured, it is assumed that the correlations of w' as functions of Z (Von Kármán's f -function) have the same curvature at the origin ($Y=Z=0$) as the correlation of u' has as a function of X ; that is,

$$\left(\frac{\partial^2 R_z^{w'}}{\partial Z^2}\right)_0 = \left(\frac{\partial^2 R_x^{u'}}{\partial X^2}\right)_0 = -\frac{1}{\lambda_x^2}$$

Furthermore the correlations of v' as functions of X and Z and the correlations of w' as functions of X (Von Kármán's g -functions) have the same curvature at the origin as the correlation of u' has as a function of Z ; that is,

$$\left(\frac{\partial^2 R_x^{v'}}{\partial X^2}\right)_0 = \left(\frac{\partial^2 R_z^{v'}}{\partial Z^2}\right)_0 = \left(\frac{\partial^2 R_x^{w'}}{\partial X^2}\right)_0 = \left(\frac{\partial^2 R_z^{u'}}{\partial Z^2}\right)_0 = -\frac{2}{\lambda_z^2}$$

Finally,

$$\left(\frac{\partial^2 R_y^{v'}}{\partial Y^2}\right)_0 = \left(\frac{\partial^2 R_y^{w'}}{\partial Y^2}\right)_0 = \left(\frac{\partial^2 R_y^{u'}}{\partial Y^2}\right)_0 = -\frac{2}{\lambda_y^2}$$

With these assumptions the derivatives of the fluctuations could be expressed in terms of the measured values of λ_x , λ_y , and λ_z :

$$W = \mu \left[\frac{\overline{u'^2}}{\lambda_x^2} + \frac{2\overline{u'^2}}{\lambda_y^2} + \frac{2\overline{u'^2}}{\lambda_z^2} + \frac{2\overline{v'^2}}{\lambda_x^2} + \frac{2\overline{v'^2}}{\lambda_y^2} + \frac{2\overline{v'^2}}{\lambda_z^2} + \frac{2\overline{w'^2}}{\lambda_x^2} + \frac{2\overline{w'^2}}{\lambda_y^2} + \frac{\overline{w'^2}}{\lambda_z^2} \right]$$

At the middle of the channel W turned out to be 2.62 ergs per cubic centimeter per second for $R=30,800$. Using the isotropic relation

$$W = 15\mu \frac{\overline{u'^2}}{\lambda_y^2} = 15\mu \frac{\overline{u'^2}}{\lambda_x^2} = 15\mu \frac{\overline{u'^2}}{\lambda_z^2}$$

the values 2.88, 4.38, and 2.24 ergs per cubic centimeter per second were obtained depending upon whether λ_x , λ_y , or λ_z was used. (For the value of $\overline{u'^2}$ the algebraic mean of the squares of the fluctuations was used.)

Figure 27 shows the distribution of W in the center region

FIGURE 27.—Turbulent-energy balance in center region of channel. $R=30,800$.

of the channel. Taylor obtained a similar distribution of the dissipated energy across the channel (reference 20); however, his numerical magnitudes are too high since he substituted in the isotropic relation, in equation (10), the values of λ_y , which turn out to be less than those of λ_x and λ_z .

From the known distributions of the energy production and dissipation the diffusion of energy is easily calculated from equation (8). It should be pointed out that because of the approximations involved in the calculation of the dissipation and diffusion terms, the conclusions derived from them are more or less of a qualitative nature. It is seen from figure 27 that at $y/d \approx 0.7$ the diffusion term is zero. It was also pointed out earlier that in this region the R_y -correlations show a considerable change in shape indicating a shift in energy from the lower to higher frequencies of the velocity fluctuations. These two facts suggest that the energy diffusion is associated mainly with the low frequencies of the fluctuations.

The equation expressing the balance of the three forms of energy furnishes the following picture of the turbulent flow field in the channel where viscous dissipation is still negligible: Two planes passing through points where the diffusion of energy vanishes divide the channel flow into three parts. The middle region, the width of which is of the order of L_x , receives most of its energy by diffusive action and this energy is dissipated here at a constant rate. In the two outside regions all three energy terms increase rapidly, the production term being the dominant one, and their interaction is more involved.

This picture of the flow field is only of a descriptive nature. The purpose of further investigations should be to obtain information on the development and mechanism of such an energy balance.

LOCALLY ISOTROPIC CHARACTER OF TURBULENT CHANNEL FLOW

The concept of locally isotropic turbulence obtained by Kolmogoroff requires the smaller eddies in turbulent flow to approach isotropy. Smaller eddies are the ones with length dimension l small compared with the scale of turbulence L . The smallest characteristic length in turbulent motion is Kolmogoroff's η defined as

$$\eta = \left(\frac{\nu^3}{\epsilon} \right)^{1/4}$$

where ϵ is the total dissipated energy. Clearly, to approach locally isotropic conditions it is necessary that

$$L \gg \eta$$

It follows from this hypothesis that beyond sufficiently high frequencies (of the order of $\tilde{u}'/\eta$, say) no correlations exist between the components of the velocity fluctuations. Figure 28 shows the measured spectrum of $\overline{u'^2}$ as compared with the spectrum of $\overline{u'v'}$ at $y/d=0.4$. It is seen that the shear spectrum tends to zero at a frequency of about 1500 cycles per second while $\overline{u'^2}(n)$ still has a detectable value at 5000 cycles per second. This result verifies Kolmogoroff's assumption. It should be mentioned that the

 FIGURE 28.—Comparison of spectra of $\overline{u'^2}$ and $\overline{u'v'}$ at $y/d=0.4$.

absolute values of $F_{u'v'}(n)$ are not so accurate as those of $F_{u'^2}(n)$ since they represent the small difference between two large values of hot-wire signal.

It is to be noted that even though local isotropy was shown to exist in the channel flow, the values of the various vorticity terms $(\overline{u_i^2}/\lambda_j^2)$ differ appreciably, indicating that the relative magnitudes of these terms do not constitute a sensitive test for the existence of local isotropy. This is evident from the comparison of the distributions $n^2 F_{u'^2}(n)$ and $n^2 F_{u'v'}(n)$ (fig. 28). It is apparent from the figures that a large part of the contribution to $\int_0^\infty n^2 F_{u'^2}(n) dn$ comes from a frequency well below 1500 cycles per second. Local isotropy, according to the shear spectrum, exists only above a frequency of 1500 cycles per second.

CONCLUDING REMARKS

The measurements presented here confirm the general conceptions concerning the mean velocity profile in a turbulent channel. The extent of the laminar sublayer, the velocity profile in the sublayer, and the over-all velocity

distribution as measured here are in good agreement with general theoretical expectations.

Measurements of the turbulent field show that the hot-wire technique is well enough developed to give consistent results for the intensities and correlation functions.

Detailed measurements of the velocity fluctuations in the direction of the flow u' were carried out well within the laminar sublayer. It was found that the similarity law for $\tilde{u}'/U_\tau$, where U_τ is friction velocity, holds fairly well in the vicinity of the wall and as a consequence the magnitude of $\tilde{u}'/u$, where u is local mean velocity, approaches an absolute constant at the wall (approx. 0.18), the value being independent of the Reynolds number. The magnitudes of the velocity fluctuations normal to the flow in the lateral and vertical directions $\tilde{v}'$ and $\tilde{w}'$ are nearly the same in the middle region of the channel, $\tilde{w}'$ increasing more rapidly toward the wall.

The measured microscales of turbulence λ_x , λ_y , and λ_z consistently show a maximum at $y/d \approx 0.7$, where y is lateral distance and d is half width of the channel; they increase proportionally with $\tilde{u}'$, indicating a constant rate of energy dissipation W in the center portion of the channel since $W \propto \overline{u'^2}/\lambda^2$.

The scales of turbulence L_y and L_z in the center region are independent of Reynolds number and depend only on the channel width. The microscales, however, show a dependency on the Reynolds number.

From the calculated magnitudes of the energy produced by the shearing stresses and of the dissipated energy a descriptive picture of the energy diffusion in the center region of the channel is obtained.

The spectrum measurements of the $\overline{u'^2}$ -fluctuations tend to indicate that $F_{u'^2}(n)$ behaves as n^{-7} over a large band in the high-frequency region (where $F_{u'^2}(n)$ is fraction of turbulent energy associated with band width dn and n is frequency). From the comparison of the spectra of $\overline{u'^2}$ and of the turbulent shear the existence of local isotropy in the channel flow is verified.

REPORT 1054

INTEGRALS AND INTEGRAL EQUATIONS IN LINEARIZED WING THEORY¹

By HARVARD LOMAX, MAX. A. HEASLET, and FRANKLYN B. FULLER

SUMMARY

The formulas of subsonic and supersonic wing theory for source, doublet, and vortex distributions are reviewed, and a systematic presentation is provided which relates these distributions to the pressure and to the vertical induced velocity in the plane of the wing. It is shown that care must be used in treating the singularities involved in the analysis and that the order of integration is not always reversible. Concepts suggested by the irreversibility of order of integration are shown to be useful in the inversion of singular integral equations when operational techniques are used. A number of examples are given to illustrate the methods presented, attention being directed to supersonic flight speeds.

INTRODUCTION

One of the most fundamental approaches to the analytical investigation of linearized wing theory, throughout the subsonic and supersonic ranges, stems from the use of certain elementary mathematical expressions that are identified with the physical properties of sources, doublets, and elementary horseshoe vortices. By means of these expressions boundary-value problems involving wings with thickness, camber, and angle of attack can be solved. These problems naturally fall into two categories: one, involving bodies with symmetrical thickness and no lift, is analyzed by means of source distributions; and the other, involving lifting plates without thickness, is analyzed by means of doublet and vortex distributions.

All these distributions require the treatment of singularities in the mathematical analysis. Thus; for subsonic Mach numbers, the concept of the generalized principal part plays an important role in the calculation of the induced velocities in the plane of a vortex sheet. In supersonic wing theory, the generalized principal part is again used in the analysis of vortex distributions, and it has further application in the treatment of conical-flow problems. However, the existence in supersonic flow of pressure discontinuities (due to Mach, or linearized shock, waves) brings about another type of singularity the mathematical analysis of which leads to the introduction of the finite-part concept. The integrals in both subsonic and supersonic wing theory thus require careful attention to the discontinuities in the integrand and, as an illustration, indiscriminate use of such standard devices as inversion of the order of integration can lead to incorrect results.

When direct problems are involved, that is, when prescribed functions are to be integrated (as in the problem of finding the pressure on a wing with symmetrical thickness), a guide to the proper method of calculation is often furnished by physical intuition. However, when inverse problems arise, that is, when integral equations are to be inverted (as for the flat plate of arbitrary plan form), the mathematical methods are more abstract. Nevertheless, the solutions to several types of inverse aerodynamic problems have been obtained by reasoning that required an understanding of the physical nature of the flow field. This method of solution may be sufficient for the particular problem involved but it is difficult to generalize. By using the aerodynamic data to construct mathematical boundary-value problems requiring the inversion of singular integral equations and by obtaining these inversions from a purely mathematical (operational) basis, a technique evolves whereby the existing solutions for two-dimensional subsonic, and three-dimensional supersonic wing problems (e. g., thin airfoil, conical flow, and Esvard solutions) are synthesized. Furthermore, the solution to the general supersonic wing problem is suggested.

The purpose of the present report is: First, to review the formulas of linearized wing theory in which source, doublet, and elementary horseshoe vortex distributions are introduced and to relate these distributions to the pressure and vertical induced velocity in the plane of the wing; second, to present an operational technique that can be used to invert the singular integral equations appearing in the application of the above formulas; and finally, to present certain special examples which will illustrate the basic concepts.

LIST OF IMPORTANT SYMBOLS

B_n	$\frac{1}{k_n^2} (E_n - k_n'^2 K_n)$
c	chord of a wing
C_D	drag coefficient $\left(\frac{\text{drag}}{\frac{1}{2} \rho_\infty V_\infty^2 S} \right)$
C_p	pressure coefficient $\left(-2 \frac{u}{V_\infty} \right)$
E	complete elliptic integral of second kind, modulus k
K	complete elliptic integral of first kind, modulus k
K_n, E_n	complete elliptic integrals of first and second kinds, respectively, with moduli k_n
k, k_n	moduli of elliptic integrals

PART I—THE THREE FUNDAMENTAL FORMULAS

[SOME BASIC MATHEMATICAL FORMULAS]

[FIELD EQUATION FOR SUBSONIC FLOW]

The basic linearized partial differential equation governing a subsonic flow field is derived under the assumption that perturbation velocity components are small relative to the free-stream velocity V_o . Written in terms of the perturbation velocity potential $\varphi(x, y, z)$ the equation is

$$(1-M_o^2)\varphi_{xx} + \varphi_{yy} + \varphi_{zz} = 0 \quad (1)$$

where M_o is the free-stream Mach number and the x axis is parallel to the free-stream direction. Equation (1) is, in its

normalized form, Laplace's equation in three dimensions. If a sufficiently thin wing at a small angle of attack is situated on or in the immediate vicinity of the xy plane, the boundary conditions in the resulting linearized theory may be assumed specified at $z=0$ and, by means of Green's theorem (see, e. g., reference 1), a solution to equation (1) can be written in the form

$$\varphi(x, y, z) = -\frac{1}{4\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[\Delta w(x_1, y_1) \frac{1}{r_c} - \Delta \varphi(x_1, y_1) \frac{\beta^2 z}{r_c^3} \right] dx_1 dy_1 \quad (2)$$

where

$$\beta^2 = 1 - M_o^2$$

and

$$r_c = \{(x-x_1)^2 + (1-M_o^2)[(y-y_1)^2 + z^2]\}^{1/2}$$

Equation (2) relates the perturbation velocity potential at a point (x, y, z) in space to the discontinuities in the potential and vertical induced velocity at the "plane of the wing." Thus, $\Delta \varphi = \varphi_u - \varphi_l$ and $\Delta w = w_u - w_l$, where the subscripts u and l denote conditions on the upper and lower side of the xy plane.

In a later section, equation (2) will be used to obtain expressions for source, vortex, and doublet distributions in subsonic flow.

FIELD EQUATION FOR SUPERSONIC FLOW

The form of the basic linearized partial differential equation governing supersonic flow fields can be written in terms of the perturbation velocity potential as

$$(M_o^2 - 1)\varphi_{xx} - \varphi_{yy} - \varphi_{zz} = 0 \quad (3)$$

Since M_o is now greater than one, equation (3) is, in its normalized form, the wave equation. A solution to equation (3) that relates the potential in space to its jump $\Delta \varphi$ and the jump of the vertical velocity Δw across the $z=0$ plane has also been derived by means of Green's theorem. A form of such a solution, due to Volterra (reference 2), can be written

$$\varphi(x, y, z) = -\frac{1}{2\pi} \frac{\partial}{\partial x} \int_{\tau} \int \left\{ \Delta w(x_1, y_1) \operatorname{arc} \cosh \frac{x-x_1}{\beta\sqrt{(y-y_1)^2 + z^2}} - \Delta \varphi(x_1, y_1) \frac{z(x-x_1)}{[y-y_1)^2 + z^2]r_c} \right\} dx_1 dy_1 \quad (4)$$

where

$$\beta^2 = M_o^2 - 1$$

and

$$r_c = \{(x-x_1)^2 - (M_o^2 - 1)[(y-y_1)^2 + z^2]\}^{1/2}$$

The area τ is that part of the $z=0$ plane contained within the Mach forecone from the point (x, y, z) ; that is, the area bounded by the line $x_1 = -\infty$ and the hyperbola $(x-x_1)^2 - \beta^2(y-y_1)^2 - \beta^2 z^2 = 0$.

Obviously equations (2) and (4) are not similar although the basic equations to which they apply are. A formal similarity can be obtained, however, through the introduction of an integral operator, originated by Hadamard (reference 3), and referred to as the "finite part." The use of the finite part and certain other techniques necessary to reduce equation (4) to a form similar to equation (2) requires some attention and a discussion of the mathematical

difficulties involved will be given in the following section. Then an application of these techniques in subsequent sections will make it possible to obtain expressions for source, vortex, and doublet distributions in supersonic flow.

THE FINITE PART OF AN INTEGRAL

In the study of linearized supersonic flow problems, one is continually confronted with expressions of the form

$$\frac{\partial}{\partial x} \int_a^x \frac{f(x, y) dy}{\sqrt{x-y}}, \quad a < x \quad (5)$$

The integrals are of this form in the sense that the integrand is infinite at one (or both) of the limits and this limit is a function of the variable by which the partial derivative is to be taken. Such an expression is annoying because the derivative cannot be "moved" through the integral sign according to the usual rule, namely,

$$\frac{\partial}{\partial x} \int_a^x F(x, y) dy = F(x, x) + \int_a^x \frac{\partial F(x, y)}{\partial x} dy \quad (6)$$

Direct application of equation (6) to equation (5) obviously yields an unacceptable indeterminate form since the term corresponding to $F(x, x)$ is infinite. One way of avoiding the difficulty is to integrate equation (5) by parts so that the radical appears in the numerator of the integral and then to apply equation (6) to the resulting expression. Such a procedure can be carried out without the introduction of any new mathematical symbol or concept. However, this involves unnecessary restrictions on the integrand and often leads to unwieldy forms since the derivative of the function $f(x, y)$ with respect to y can be cumbersome.

Definition.—A more direct way of taking the derivative through the integral sign in equation (5) is accomplished by using the integral operator known as the finite part. Consider the simple equality

$$\frac{\partial}{\partial x} \int_a^x \frac{dy}{\sqrt{x-y}} = \frac{1}{\sqrt{x-a}}$$

The finite-part sign can be introduced by the definition

$$\int_a^x \frac{\partial}{\partial x} \frac{dy}{\sqrt{x-y}} = \frac{\partial}{\partial x} \int_a^x \frac{dy}{\sqrt{x-y}} \quad (7)$$

from which it follows

$$\int_a^x \frac{dy}{(x-y)^{3/2}} = \frac{-2}{\sqrt{x-a}} \quad (8)$$

The natural extension of this idea is to consider

$$J = \int_a^x \frac{\partial}{\partial x} \frac{A(y) dy}{\sqrt{x-y}} = \frac{\partial}{\partial x} \int_a^x \frac{A(y) dy}{\sqrt{x-y}} \quad (9)$$

where $A(y)$ is continuous at $x=y$ and is integrable elsewhere in the range of integration. The evaluation of J can be reduced to a form that requires only the definition introduced by equation (7). Thus, by adding and subtracting the same term, J can be written

$$J = \frac{\partial}{\partial x} \left[\int_a^x \frac{A(y) - A(x)}{\sqrt{x-y}} dy + A(x) \int_a^x \frac{dy}{\sqrt{x-y}} \right]$$

and it follows that

$$\int_a^x \frac{A(y) dy}{(x-y)^{3/2}} = \int_a^x \frac{A(x) - A(y)}{(x-y)^{3/2}} dy + A(x) \int_a^x \frac{dy}{(x-y)^{3/2}} \quad (10)$$

The final generalization of the definitions given by equations (7) and (9) is accomplished by considering the n^{th} derivative of the integrals and, furthermore, by allowing a functional dependence on x of the integrand A . First consider the definition

$$\begin{aligned} \int_a^x \left(\frac{\partial}{\partial x} \right)^n \frac{A(y) dy}{\sqrt{x-y}} &= (-1)^n \frac{1 \cdot 3 \cdots (2n-1)}{2^n} \int_a^x \frac{A(y) dy}{(x-y)^{n+1/2}} \\ &= \left(\frac{\partial}{\partial x} \right)^n \int_a^x \frac{A(y) dy}{\sqrt{x-y}} \end{aligned} \quad (11)$$

The second integral can be expressed in the form

$$\int_a^x \frac{A(y) dy}{(x-y)^{n+1/2}} = \int_a^x \frac{A(y) - B(x, y)}{(x-y)^{n+1/2}} dy + \int_a^x \frac{B(x, y) dy}{(x-y)^{n+1/2}} \quad (12)$$

where

$$B(x, y) = A(x) - A'(x)(x-y) + \dots + \frac{(-1)^{n-1} A^{(n-1)}(x)}{(n-1)!} (x-y)^{n-1}$$

and

$$\begin{aligned} \int_a^x \frac{dy}{(x-y)^{i+1/2}} &= \frac{(-1)^i 2^i}{1 \cdot 3 \cdots (2i-1)} \left(\frac{\partial}{\partial x} \right)^i \int_a^x \frac{dy}{\sqrt{x-y}} \\ &= \frac{-2}{(2i-1)(x-a)^{i-1/2}} \end{aligned}$$

Finally replacing $A(y)$ by $A(x, y)$, equation (11) again defines uniquely a finite-part integral provided that

$$\lim_{y \rightarrow x} \left[\sqrt{x-y} \left(\frac{\partial}{\partial x} \right)^n A(x, y) \right] = 0$$

Methods of evaluation.—If expressions of the type presented in equation (5) appear in an analytical development, it is now possible, by using the finite-part symbol, to take the partial derivative operation through the integral sign. Such a process needs no further amplification. In applying the results of such an analysis to the solution of some specific problem, however, one is confronted with the inverse operation, that is, the problem of evaluating the finite-part integrals. This can always be done, of course, by means of the definitions already given. Often, though, such evaluations can be simplified by using one of the two following processes.

The first process is readily outlined. Rewrite equations (8) and (10) in the form

$$\int_a^x \frac{f(x, y) dy}{(x-y)^{3/2}} = \lim_{\epsilon \rightarrow x} \int_a^\epsilon \frac{f(x, y) - f(x, x)}{(x-y)^{3/2}} dy - \frac{2f(x, x)}{\sqrt{x-a}}$$

and set the indefinite integral of

$$\int \frac{f(x, y) dy}{(x-y)^{3/2}}$$

equal to $F(x, y) + C$. It follows that

$$\int_a^x \frac{f(x, y) dy}{(x-y)^{3/2}} = -[F(x, a) + C] \quad (13)$$

where

$$C = \lim_{y \rightarrow x} \left[\frac{2f(x, y)}{\sqrt{x-y}} - F(x, y) \right] \quad (14)$$

The second technique avoids the necessity of evaluating the constant C . It depends on the use of the complex variable and is valid only when $f(x, y)$ is real in the interval $a \leq y \leq b$ where b is some number greater than x . Again set the indefinite integral of

$$\int \frac{f(x, y) dy}{(x-y)^{3/2}}$$

equal to $F(x, y) + C$. Now if r. p. stands for the real part of a function, the evaluation of the finite-part integral is provided by the equality

$$\int_a^x \frac{f(x, y) dy}{(x-y)^{3/2}} = \text{r. p.} \int_a^b \frac{f(x, y) dy}{(x-y)^{3/2}} = \text{r. p.} [F(x, b) - F(x, a)], \quad a < x < b \quad (15)$$

As an example of the second technique, consider the integral

$$I = \int_0^x \frac{y^2 dy}{(x^2 - y^2)^{3/2}} = \text{r. p.} \int_0^b \frac{y^2 dy}{(x^2 - y^2)^{3/2}}$$

where $x < b$. From the relation

$$\int \frac{y^2 dy}{(x^2 - y^2)^{3/2}} = \frac{y}{\sqrt{x^2 - y^2}} - \arcsin \frac{y}{x}$$

together with equation (15), it follows that

$$I = \text{r. p.} \left(\frac{b}{\sqrt{x^2 - b^2}} - \arcsin \frac{b}{x} \right) = -\frac{\pi}{2}$$

A simple extension of this result yields

$$\int_{-x}^x \frac{y^2 dy}{(x^2 - y^2)^{3/2}} = \text{r. p.} \int_{-b}^b \frac{y^2 dy}{(x^2 - y^2)^{3/2}} = -\pi$$

An application.—The above methods can be applied to give the following simple but useful result. Let $Y = a + by + cy^2 = (\lambda_2 - y)(y - \lambda_1)(-c)$ and $q = 4ac - b^2$, then

$$\int_t^{\lambda_2} \frac{(c_0 + c_1 y) dy}{Y^{3/2}} = - \int_{\lambda_1}^t \frac{(c_0 + c_1 y) dy}{Y^{3/2}} = \frac{-2}{q \sqrt{a + bt + ct^2}} [c_0(2ct + b) - c_1(bt + 2a)] \quad (16)$$

Included in this result is the equality

$$\int_{\lambda_1}^{\lambda_2} \frac{c_0 + c_1 y}{Y^{3/2}} dy = 0 \quad (17)$$

which contains the very important identity

$$\int_{\lambda_1}^{\lambda_2} \frac{dy}{(\lambda_2 - y)^{3/2} \sqrt{y - \lambda_1}} = \int_{\lambda_1}^{\lambda_2} \frac{dy}{(y - \lambda_1)^{3/2} \sqrt{\lambda_2 - y}} = 0 \quad (18)$$

The case of multiple integrals.—When applied to the analysis of single integrals, the above definitions of the finite part coincide with, or are a re-expression of, those given originally by Hadamard (reference 3). Hence,

$$\int_a^x \frac{f(x, y) dy}{(x-y)^{3/2}} = \int_a^x \frac{f(x, y) dy}{(x-y)^{3/2}}$$

where $\int$ was the symbol used by Hadamard to denote evaluation by finite-part methods. When applied to double integrals, however, the signs $\int$ and $\int$ are no longer equivalent. Hadamard, as well as A. Robinson (reference 4), maintains the convention that the order of integration in the operation $\int$ is reversible; that is,²

$$\int dy \int dx f(x, y) = \int dx \int dy f(x, y)$$

Such a convention requires that all singularities for which the order of integration is irreversible must be excluded from the area of integration. These singular regions are then treated separately. This convention has the disadvantage that, in evaluating multiple integrals, the value of a given integral is not independent of succeeding integrals. The operator $\int$ avoids difficulties of this kind and each definite integral is independent of succeeding operations. For example,

$$\int_0^x \frac{d\eta}{(\xi - \eta)^{3/2} \sqrt{\eta}} = \int_0^x d\xi \int_0^x \frac{d\eta}{(\xi - \eta)^{3/2} \sqrt{\eta}} = 0$$

but, according to reference 3,

$$\int_0^x \frac{d\eta}{(\xi - \eta)^{3/2} \sqrt{\eta}} = 0$$

whereas, according to the same reference,

$$\int_0^x d\xi \int_0^x \frac{d\eta}{(\xi - \eta)^{3/2} \sqrt{\eta}} = -2\pi$$

Although the use of the symbol $\int$ makes each integration independent of subsequent integrations, the order of integration for operations involving the sign $\int$ cannot be reversed. Hence,

$$\int dy \int dx f(x, y) \neq \int dx \int dy f(x, y)$$

For example, the relation

$$\int_0^x d\xi \int_0^x \frac{d\eta}{(\xi - \eta)^{3/2} \sqrt{\eta}} = 0$$

holds while the same integral taken over the same area but in reversed order is

²Since the order of integration plays an important role in the following development, integration first with respect to x and then with respect to y will be denoted $\int dy \int dx f(x, y)$ while integration first with respect to y and then with respect to x will be denoted $\int dx \int dy f(x, y)$. When the notation $\int \int f(x, y) dy dx$ is used, the order of integration is immaterial.

$$\int_0^x d\eta \int_{\eta}^x \frac{d\xi}{(\xi-\eta)^{3/2}\sqrt{\eta}} = -2\pi$$

The operation defined by the symbol $\oint$ will be used consistently throughout the present report. Hence attention must always be paid to the order but not to the multiplicity of integrations. It can be seen that the finite part of a conventional-type integral coincides with the value found by standard methods.

THE GENERALIZED PRINCIPAL PART OF AN INTEGRAL

Another type of important operation appearing in the development of both subsonic and supersonic wing theory appears implicitly in the expression

$$I_0 = \lim_{z \rightarrow 0+} \int_a^b \frac{\partial}{\partial z} \left[\frac{zf(y_1, z)}{z^2 + (y - y_1)^2} \right] dy_1 \quad (19)$$

where $f(y, z)$ and its derivatives are bounded and continuous in the interval $a \leq y \leq b$. In the attempt to simplify I_0 by letting z approach zero before performing the integration, a second special integral operator will be introduced.

To simplify I_0 , first integrate by parts

$$I_0 = \lim_{z \rightarrow 0+} \frac{\partial}{\partial z} \left[f(a, z) \arctan \frac{y-a}{z} - f(b, z) \arctan \frac{y-b}{z} + \int_a^b \frac{\partial f(y_1, z)}{\partial y_1} \arctan \frac{y-y_1}{z} dy_1 \right]$$

Then since

$$\lim_{z \rightarrow 0+} \int_a^b \frac{\partial f_z(y_1, z)}{\partial y_1} \arctan \frac{y-y_1}{z} dy_1 = \pi f_z(y, 0) - \frac{\pi}{2} [f_z(a, 0) + f_z(b, 0)]$$

I_0 becomes

$$I_0 = \frac{f(b, 0)}{y-b} - \frac{f(a, 0)}{y-a} - \int_a^b \frac{f_{y_1}(y_1, 0) dy_1}{y-y_1} + \pi f_z(y, 0) \quad (20)$$

Definition of the generalized principal part.—The expression of I_0 given in equation (20) contains the integral of the function $f'(y_1)/(y-y_1)$. Such an integration is not, in general, convergent; however, when the integral is so written without further qualification it is generally accepted that the singularity occurring in the integrand is to be treated using Cauchy's principal part. Evaluation by such a method is often indicated by the symbol $\oint$ and is defined by the equation

$$\oint_a^b \frac{A(y_1) dy_1}{y_1 - y} = \lim_{\epsilon \rightarrow 0} \left[\int_a^{y-\epsilon} \frac{A(y_1) dy_1}{y_1 - y} + \int_{y+\epsilon}^b \frac{A(y_1) dy_1}{y_1 - y} \right] \quad (21)$$

or, alternatively,

$$\oint_a^b \frac{A(y_1) dy_1}{y_1 - y} = -\frac{\partial}{\partial y} \int_a^b A(y_1) \ln|y_1 - y| dy_1 \quad (22)$$

To assure the convergence of the right-hand side of equations (21) and (22) it is sufficient but not necessary to assume that $A(y_1)$ is differentiable at the point $y_1 = y$ and that

elsewhere within the region of integration $A(y_1)$ is either continuous or possesses integrable singularities. The concept of the Cauchy principal part is so well known that the symbol on this integral is often omitted, as shall be done here.

The differential operator in equation (22) lends itself readily to a generalization of the principal-part concept. Thus, for the next higher order, the definition (see also, in this connection, reference 5)

$$\oint_a^b \frac{A(y_1) dy_1}{(y_1 - y)^2} = -\frac{\partial^2}{\partial y^2} \int_a^b A(y_1) \ln|y - y_1| dy_1 = \frac{\partial}{\partial y} \int_a^b \frac{A(y_1) dy_1}{y_1 - y} \quad (23)$$

applies and, in general,

$$n! \oint_a^b \frac{A(y_1) dy_1}{(y_1 - y)^{n+1}} = -\frac{\partial^{n+1}}{\partial y^{n+1}} \int_a^b A(y_1) \ln|y - y_1| dy_1 = \frac{\partial^n}{\partial y^n} \int_a^b \frac{A(y_1) dy_1}{y_1 - y} \quad (24)$$

The generalized principal part can also be expressed in the form

$$\oint_a^b \frac{A(y_1) dy_1}{(y_1 - y)^{n+1}} = \int_a^b \frac{A(y_1) - B(y, y_1)}{(y_1 - y)^{n+1}} dy_1 + \oint_a^b \frac{B(y, y_1) dy_1}{(y_1 - y)^{n+1}}$$

where

$$B(y, y_1) = A(y) + \frac{A'(y)}{1} (y_1 - y) + \dots + \frac{A^{(n-1)}(y)}{(n-1)!} (y_1 - y)^{n-1}$$

and

$$\oint_a^b \frac{dy_1}{(y_1 - y)^{i+1}} = \frac{1}{i!} \left(\frac{\partial}{\partial y} \right)^i \int_a^b \frac{dy_1}{y_1 - y} = \frac{-1}{i} \left[\frac{1}{(b-y)^i} - \frac{1}{(a-y)^i} \right], \quad i \geq 1.$$

The first n derivatives of $A(y_1)$ are assumed to exist and be single valued at $y_1 = y$ while elsewhere in the range of integration $A(y_1)$ may possess integrable singularities. This definition is in a form that involves no extension beyond the concept of Cauchy's principal part.

It is possible to extend the definition contained in equation (24) to include a functional dependency on y in the numerator of the integrands. Thus, replacing $A(y_1)$ by $A(y, y_1)$, equation (24) again defines uniquely a principal-part integral provided the first n derivatives of $A(y, y_1)$ with respect to y and y_1 exist at $y_1 = y$.

Method of evaluation.—Operations involving the symbol $\oint$ can always be performed by means of the definitions just given. However, another method can be used, which is often simpler to apply. If the indefinite integral of $A(y_1)/(y_1 - y)^{n+1}$ exists such that

$$\int \frac{A(y_1) dy_1}{(y_1 - y)^{n+1}} = G(y_1, y) + C \quad (25)$$

then the value of the generalized principal part can be found by following the conventional rules for substitution of limits; thus

$$\frac{f_a^b A(y_1) dy_1}{(y_1 - y)^{n+1}} = G(b, y) - G(a, y), \quad y \neq a, b \quad (26)$$

The proof of this result can be obtained by mathematical induction.

An application.—Returning to equation (20), since an integration by parts yields the relation

$$\frac{f_a^b f(y_1, 0) dy_1}{(y_1 - y)^2} = \frac{f(b, 0)}{y - b} - \frac{f(a, 0)}{y - a} - \int_a^b \frac{f_{y_1}(y_1, 0) dy_1}{y - y_1}$$

the limiting process symbolized by I_0 can be expressed as an integral that contains only the function evaluated at $z=0$ and not its derivative. Thus, finally

$$\lim_{z \rightarrow 0+} \int_a^b \frac{\partial}{\partial z} \left[\frac{zf(y_1, z)}{z_2 + (y - y_1)^2} \right] dy_1 = \frac{f_a^b f(y_1, 0) dy_1}{(y_1 - y)^2} + \pi f_z(y, 0) \quad (27)$$

THE OBLIQUE COORDINATE SYSTEM

Equations (1) through (4) gave the basic partial differential equations of wing theory, together with their solutions, in terms of the usual Cartesian coordinate system, the x axis extending in the direction of the undisturbed flow and the y and z axes oriented normal to this direction in such a way that boundary conditions for the wing can be specified in the $z=0$ plane. In the study of supersonic flow fields it is at times mathematically convenient to introduce in the $z=0$ plane new coordinate axes making arbitrary angles with the x and y axes.

The general case. Consider the ξ, η, z coordinate system (fig. 1) such that the z axis is normal to the plane supporting

FIGURE 1.—Coordinate systems.

the boundary conditions while ξ and η are normal to z and coincident with the lines $x = -m_2 y$ and $x = m_1 y$. If

$$\mu_1 = \sqrt{1 + m_1^2}, \quad \mu_2 = \sqrt{1 + m_2^2} \quad (28)$$

the equations relating the two systems of coordinates are

$$\left. \begin{aligned} x &= \frac{\eta m_1}{\mu_1} + \frac{\xi m_2}{\mu_2}, & \xi &= \frac{\mu_2(x - m_1 y)}{m_1 + m_2} \\ y &= \frac{\eta}{\mu_1} - \frac{\xi}{\mu_2}, & \eta &= \frac{\mu_1(x + m_2 y)}{m_1 + m_2} \\ z &= z, & z &= z \end{aligned} \right\} \quad (29)$$

while the relation between the differential areas, as determined from the Jacobian of the transformations, is

$$dx_1 dy_1 = \frac{m_1 + m_2}{\mu_1 \mu_2} d\xi_1 d\eta_1 \quad (30)$$

The value of r_c , as defined under equation (4), becomes

$$r_c = \left[\frac{(\eta - \eta_1)^2 (m_1^2 - \beta^2)}{\mu_1^2} + \frac{2(\eta - \eta_1)(\xi - \xi_1)(m_1 m_2 + \beta^2)}{\mu_1 \mu_2} + \frac{(\xi - \xi_1)^2 (m_2^2 - \beta^2)}{\mu_2^2} - \beta^2 z^2 \right]^{1/2} \quad (31a)$$

where $\beta^2 = M_0^2 - 1$. If the variable ν_c is introduced such that

$$\nu_c = \frac{x - x_1}{(y - y_1)^2 + z^2} \quad (31b)$$

it follows that in the transformed coordinates this variable becomes

$$\nu_c = \frac{(\eta - \eta_1) \frac{m_1}{\mu_1} + (\xi - \xi_1) \frac{m_2}{\mu_2}}{\left[(\eta - \eta_1) \frac{1}{\mu_1} - (\xi - \xi_1) \frac{1}{\mu_2} \right]^2 + z^2} \quad (31c)$$

Finally, the differential operator $\partial/\partial x$ transforms to

$$\frac{\partial}{\partial x} = \frac{1}{m_1 + m_2} \left(\mu_2 \frac{\partial}{\partial \xi} + \mu_1 \frac{\partial}{\partial \eta} \right) \quad (31d)$$

The area τ over which the integration of equation (4) is to be taken is still, of course, bounded by the hyperbola $r_c^2 = 0$ and the line $x_1 = -\infty$. The asymptotes to the hyperbola become, however,

$$\left. \begin{aligned} \eta - \eta_1 &= -\frac{\mu_1}{\mu_2} (\xi - \xi_1) \frac{m_2 + \beta}{m_1 - \beta} \\ \eta - \eta_1 &= -\frac{\mu_1}{\mu_2} (\xi - \xi_1) \frac{m_2 - \beta}{m_1 + \beta} \end{aligned} \right\} \quad (32)$$

Figure 2 shows how the area τ in the xy plane transforms to the $\xi\eta$ plane.

(Although the ξ and η axes are oblique with respect to the original axial system, no inconsistency results if the equations in the transformed variables are plotted relative to orthogonal axes.) In case both m_1 and m_2 are less than β (the case for which the sketch was drawn), the asymptotes are straight lines with positive slopes, and the area is bounded in both the ξ and η directions by the maximum points ξ_a, η_a and ξ_b, η_b , respectively. These maximum points are shown in the figure and their analytical expressions are

$$\left. \begin{aligned} \xi_a &= \xi - \frac{z \mu_2 \sqrt{\beta^2 - m_1^2}}{m_1 + m_2}, & \eta_a &= \eta - \frac{z \mu_1 (m_1 m_2 + \beta^2)}{(m_1 + m_2) \sqrt{\beta^2 - m_1^2}} \\ \xi_b &= \xi - \frac{z \mu_2 (m_1 m_2 + \beta^2)}{(m_1 + m_2) \sqrt{\beta^2 - m_2^2}}, & \eta_b &= \eta - \frac{z \mu_1 \sqrt{\beta^2 - m_2^2}}{m_1 + m_2} \end{aligned} \right\} \quad (33)$$

If the oblique coordinate system is chosen such that m_1 is less than and m_2 is greater than β , one of the asymptotes in equation (32) has a slope of opposite sign and the area τ is unbounded in the η_1 direction although ξ_a, η_a is still the point which determines the farthest extent of τ in the ξ_1 direction.

 FIGURE 2.—Area of integration τ .

On the other hand, if m_2 is less than and m_1 is greater than β , τ extends infinitely in the ξ_1 direction and ξ_b, η_b represents its upper bound in terms of η_1 . Finally, if both m_1 and m_2 are greater than β , the area τ is not bounded for either negative or positive ξ_1 or η_1 .

The characteristic coordinate system.—Another special case of the ξ, η, z system (the x, y, z system is, of course, a special case obtained when $m_1=0$ and $m_2=\infty$) that is important enough to receive a particular notation is the one obtained when the ξ and η axes are parallel to the Mach lines (i. e., the traces of the characteristic cones) in the $z=0$ plane. These axes are shown in figure 3, will be designated r and s , and are given by equations (29) when $m_1=m_2=\beta$ and $\mu_1=\mu_2=M_0$; thus

$$\left. \begin{aligned} x &= \frac{\beta}{M_0} (s+r), & r &= \frac{M_0}{2\beta} (x-\beta y) \\ y &= \frac{1}{M_0} (s-r), & s &= \frac{M_0}{2\beta} (x+\beta y) \\ z &= z, & z &= z \end{aligned} \right\} \quad (34)$$

FIGURE 3.—Characteristic coordinate system.

When z is set equal to zero, the equation for r_c and the form of the area τ become especially simple. Thus

$$(r_c)_{z=0} = r_0 = \frac{2\beta}{M_0} \sqrt{(r-r_1)(s-s_1)} \quad (35)$$

and the area τ , shown in figure 4, is bounded by the straight lines $r_1=r$, $s_1=s$ and $r_1=s_1=-\infty$.

 FIGURE 4.—Integration area in characteristic system for $z=0$.

THE THREE FUNDAMENTAL FORMULAS IN SUBSONIC FLOW

The parallelism between the basic formulas in subsonic and supersonic wing theory is so obvious that it is advantageous to present first the somewhat more classical results applying to the purely subsonic regime. The immediate objective is therefore to present as briefly as possible the expressions for the perturbation velocity potential due to a distribution of sources, doublets, or elementary horseshoe vortices and then, by means of these expressions, to relate the pressure and vertical induced velocity in the $z=0$ plane to the weight of these distributions.

THE PERTURBATION POTENTIAL AT A POINT IN SPACE

The linearized form of the perturbation velocity potential due to a unit source, elementary horseshoe vortex, or doublet situated in a free stream moving at a uniform subsonic velocity V_∞ is given as follows:

$$\begin{aligned} \text{Unit source} & \dots\dots\dots \varphi = -1/4\pi r_c \\ \text{Unit elementary horseshoe vortex} & \dots\dots\dots \varphi = -z v_c / 4\pi r_c \\ \text{Unit doublet} & \dots\dots\dots \varphi = -z\beta^2 / 4\pi r_c^3 \end{aligned}$$

where r_c is defined in equation (31b) and $\beta^2 = 1 - M_\infty^2$.

It is well known that a distribution of sources in the $z=0$ plane splits the streamlines and forms a field symmetrical in u , v , and φ above and below the source plane. Hence, the strength of the sources is related to the term Δw (which, in turn, is related to the gradient of thickness of the simulated body) while the variables u , v , and φ are continuous. On the other hand, a distribution of elementary vortices or doublets causes a discontinuity in the streamwise induced velocity (or, what amounts to the same thing, the perturbation potential) across the reference plane but, at the same time, causes no division of the streamlines. The strengths of the vortices and doublets are therefore related to the terms Δu and $\Delta\varphi$, respectively, (which, in turn, are related to the wing loading), and produce no discontinuities in w . The exact analytical form of these distributions can be obtained readily from equation (2).

The source distribution.—The velocity potential induced by a distribution of sources over the $z=0$ plane follows immediately from equation (2) since, by symmetry, $\Delta\varphi$ must be zero. In practice, the area over which the sources are distributed is limited to the area S defined by the plan form. Hence,

$$\varphi(x, y, z) = \frac{-1}{4\pi} \iint_S \frac{\Delta w}{r_c} dx_1 dy_1 \quad (36)$$

The elementary-vortex distribution.—Equation (1) was written in terms of the perturbation potential φ . It could, however, after differentiation have been expressed in terms of any one of the induced velocity components and the solution in equation (2) would then also be expressed in terms of the particular velocity component chosen. Consider such a case, taking for the dependent variable the streamwise perturbation velocity instead of φ . Equation (2) then becomes

$$u(x, y, z) = \frac{-1}{4\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left(\frac{\partial \Delta u}{\partial z} \frac{1}{r_c} - \Delta u \frac{\beta^2 z}{r_c^3} \right) dx_1 dy_1$$

If the field is to be without sources, both Δw and $\partial \Delta w / \partial z$ vanish. But for an irrotational field the equality $\partial \Delta w / \partial x = \partial \Delta u / \partial z$ holds and the first term in the integrand of the above equation is zero. By definition

$$\int_{-\infty}^x u(x_1, y, z) dx_1 = \varphi(x, y, z)$$

from which it follows that if the operator $\int_{-\infty}^x dx$ is applied to both sides of the resulting equation, the relation

$$\varphi(x, y, z) = \frac{-1}{4\pi} \iint_S \frac{z(x-x_1)\Delta u}{[(y-y_1)^2 + z^2]^{3/2}} dx_1 dy_1 \quad (37)$$

follows where the area of integration is limited to the wing plan form. This result expresses the perturbation velocity potential due to a distribution of elementary horseshoe vortices over a wing plan form in the $z=0$ plane.

The doublet distribution.—The solution for a doublet distribution, just as in the case of the sources, follows immediately from equation (2). Since the streamlines are not divided by the doublets the term containing Δw vanishes. The doublet distribution exists, however, not only over the wing area but also over the vortex wake streaming downstream behind the wing since the discontinuity in the potential persists in this region. Designating the wake area by W , the final expression for the perturbation potential associated with the doublet sheet becomes

$$\varphi(x, y, z) = \frac{\beta^2 z}{4\pi} \iint_{S+W} \frac{\Delta\varphi}{r_c^3} dx_1 dy_1 \quad (38)$$

REDUCTION TO THE PLANE OF THE WING

The aerodynamicist is usually interested in the forces on the surface of the wing itself and, as a consequence, it is pertinent to consider each of the above formulas in the limiting case as z approaches zero. An explicit expression of these results is given below.

The source distribution.—The limiting value of equation (36) as z approaches zero is obtained immediately by simply setting z equal to zero. The resulting expression is

$$\varphi(x, y, 0) = \frac{-1}{4\pi} \iint_S \frac{\Delta w}{r_0} dx_1 dy_1 \quad (39)$$

where

$$r_0 = [(x-x_1)^2 + \beta^2(y-y_1)^2]^{1/2}$$

Practical interest is usually concentrated on the relation between the pressure on the wing surface and the wing shape. Since in linearized theory pressure coefficient C_p and wing slope λ_u of the upper surface are known to be

$$C_p = \frac{-2u}{V_0}, \quad \lambda_u = \frac{w_u}{V_0} = \frac{1}{2} \frac{\Delta w}{V_0} \quad (40)$$

it follows, after differentiation of equation (39) with respect to x , that pressure coefficient is

$$C_p = \frac{1}{\pi} \frac{\partial}{\partial x} \iint_S \frac{\lambda_u}{r_0} dx_1 dy_1 \quad (41)$$

The elementary-vortex distribution.—When the strength of the elementary horseshoe vortices is known over a wing plan form, there is no difficulty in finding the potential in the $z=0$ plane since it follows from a direct integration of the vortex strength. The pertinent question is, rather, to determine the vertical induced velocity in the plane of the wing from the given vortex strength. If load coefficient is defined in the usual way

$$\frac{\Delta p}{q} = \frac{2\Delta u}{V_0} = \frac{4u_u}{V_0} \quad (42)$$

the answer to this question requires the evaluation of the following limiting process:

$$\frac{w}{V_0} = \lim_{z \rightarrow 0} \frac{-1}{8\pi} \iint_S \frac{\partial}{\partial z} \frac{z(x-x_1)}{[(y-y_1)^2 + z^2] r_c} \frac{\Delta p}{q} dx_1 dy_1$$

If, as in equation (27), the generalized principal part is introduced, the required expression becomes

$$\frac{w}{V_0} = \frac{-1}{8\pi} \iint_S \frac{(x-x_1)}{(y-y_1)^2 r_0} \frac{\Delta p}{q} dx_1 dy_1 \quad (43)$$

The doublet distribution.—In the case of doublet distributions, the relevant problem requires the expression of vertical induced velocity in the plane of the wing as a function of the doublet strength $\Delta\varphi$. If equation (38) is differentiated with respect to z and z is then set equal to zero, one finds without difficulty the final formula

$$\frac{w}{V_0} = \frac{\beta^2}{4\pi V_0} \iint_{S+W} \frac{\Delta\varphi}{r_0^3} dx_1 dy_1 \quad (44)$$

THE THREE FUNDAMENTAL FORMULAS IN SUPERSONIC FLOW

The purpose of this section is to repeat for supersonic wing theory the developments presented in the preceding section for subsonic theory. In order to maintain the formal analogy, it is necessary to introduce the concept of the finite part. This latter concept, in turn, introduces into the analysis integral expressions containing certain *inherent singularities*. Such singularities are, by definition, points across which the order of integration cannot be reversed.³ The study of these singularities and their effect on the fundamental formulas suggests the introduction of an oblique coordinate system defined in the first section of this report. Hence, the following analysis will be presented in the ξ, η, z system, while transformation to the Cartesian and characteristic systems, it will be remembered, can be made by considering the special cases

$$\left. \begin{array}{ll} \text{For} & \text{Let} \\ x, y, z & m_1=0, m_2=\infty \\ r, s, z & m_1=m_2=\beta \end{array} \right\} \quad (45)$$

Following the development of the basic formulas, a summary of results will be given in terms of the x, y and r, s coordinates.

³ More precisely, if an inherent singularity exists in the area over which a double integral is to be evaluated, the difference between the values of the integration made in one order and then over the same area but with reversed order is not zero.

THE PERTURBATION POTENTIAL AT A POINT IN SPACE

The velocity potential due to a unit source, a unit elementary horseshoe vortex, and a unit doublet is given as follows:

$$\left. \begin{array}{ll} \text{Unit source} & \varphi = -1/2\pi r_c \\ \text{Unit elementary horseshoe} & \\ \text{vortex} & \varphi = -z\nu_c/2\pi r_c \\ \text{Unit doublet} & \varphi = z\beta^2/2\pi r_c^3 \end{array} \right\} \quad (46)$$

where r_c and ν_c are defined in equations (31) and $\beta^2 = M_0^2 - 1$. In this notation, the only difference between these expressions and the corresponding ones for subsonic flow is the factor 2. A much more important difference exists, however, in the effect of the change of sign of $1 - M_0^2$ on r_c and ν_c .

The first task is the expression of the perturbation velocity potential at a point in space in terms of distributions of the elementary solutions and this can be accomplished by an appropriate analysis of equation (4). Just as in the subsonic case, the source strength is given by Δw , the vortex strength by Δu , and the doublet strength by $\Delta\varphi$.

The source distribution.—The potential induced by a source distribution can be obtained from equation (4) by setting the term containing $\Delta\varphi$ equal to zero (i. e., by removing all the circulation from the flow field). By means of the notation

$$\omega_c = \frac{x-x_1}{\beta \sqrt{(y-y_1)^2 + z^2}} = \frac{\frac{m_1}{\mu_1}(\eta-\eta_1) + \frac{m_2}{\mu_2}(\xi-\xi_1)}{\beta \sqrt{\left[\frac{1}{\mu_1}(\eta-\eta_1) - \frac{1}{\mu_2}(\xi-\xi_1)\right]^2 + z^2}} \quad (47)$$

The remaining expression can be written in the ξ, η, z coordinate system simply as

$$\varphi(\xi, \eta, z) = \frac{-1}{2\pi\mu_1\mu_2} \left(\mu_2 \frac{\partial}{\partial \xi} + \mu_1 \frac{\partial}{\partial \eta} \right) \iint_\tau \Delta w(\xi_1, \eta_1) \text{arc cosh } \omega_c d\xi_1 d\eta_1 \quad (48)$$

It is possible to "move" the partial derivative operations through the integral signs if the equality

$$\frac{\partial}{\partial x} \int_{b(x)}^{a(x)} f(x, y) dy = f(a, y) \frac{\partial a}{\partial x} - f(b, y) \frac{\partial b}{\partial x} + \int_b^a \frac{\partial f(x, y)}{\partial x} dy \quad (49)$$

is used. Obviously, if the operation indicated by equation (49) is to be applied to equation (48), the order of integration and the limits on the latter equation must be specified.

Consider the case when the ξ and η axes are chosen so that both m_1 and m_2 are less than β . The area τ is then the one shown in figure 2. Further consider the case when the first integration is made with respect to η_1 . Then, equation (48) becomes

$$\varphi(\xi, \eta, z) = \frac{-1}{2\pi\mu_1\mu_2} \left(\mu_2 \frac{\partial}{\partial \xi} + \mu_1 \frac{\partial}{\partial \eta} \right) \int_{-\infty}^{\xi_a} d\xi_1 \int_{\lambda_1}^{\lambda_2} d\eta_1 \Delta w(\xi_1, \eta_1) \text{arc cosh } \omega_c \quad (50)$$

where λ_1 and λ_2 are roots of the quadratic expression $r_c^2(\eta_1) = 0$ and ξ_a, η_a are defined in equation (33). It can be shown that when $\xi_1 = \xi_a$, the equality $\lambda_1 = \lambda_2$ applies, and, further, that the integrand of equation (50) does not vanish. Hence,

the two partial derivatives can be moved through the first integral sign without the appearance of the additional term involving the derivative of the upper limit. It is also not difficult to show the value of ω_c at η_1 equal to either λ_1 or λ_2 is just 1. Hence, the two partial derivatives can also be moved through the second integral sign without the appearance of additional terms. Finally, since

$$\frac{1}{m_1+m_2} \left(\mu_2 \frac{\partial}{\partial \xi} + \mu_1 \frac{\partial}{\partial \eta} \right) \text{arc cosh } \omega_c = \frac{\partial}{\partial x} \text{arc cosh } \omega_c = \frac{1}{r_c}$$

the velocity potential at a point (ξ, η, z) due to a distribution of sources in the $z=0$ plane can be written

$$\varphi(\xi, \eta, z) = -\frac{m_1+m_2}{2\pi\mu_1\mu_2} \iint_{\tau} \frac{\Delta w(\xi_1, \eta_1)}{r_c} d\xi_1 d\eta_1 \quad (51)$$

The elementary-vortex distribution.—The potential induced by a distribution of elementary horseshoe vortices can be derived in a manner analogous to the derivation for the subsonic case. Thus, the solution given by equation (4) is written for the induced velocity u rather than the velocity potential.⁴ Since the flow field contains no sources, $\partial \Delta u / \partial z$ is zero (by the same argument presented for the subsonic derivation) and the solution can be expressed in the form

$$u = \frac{1}{2\pi} \frac{\partial}{\partial x} \iint_{\tau} \frac{z \nu_c}{r_c} \Delta u(x_1, y_1) dx_1 dy_1$$

However, by definition

$$\varphi = \int_{-\infty}^x u dx$$

so the relation becomes

$$\varphi = \frac{1}{2\pi} \iint_{\tau} \frac{z \nu_c}{r_c} \Delta u(x_1, y_1) dx_1 dy_1$$

Finally, in terms of the ξ, η, z coordinate system the equation for the velocity potential due to a distribution of elementary horseshoe vortices in the $z=0$ plane can be written

$$\varphi = \frac{(m_1+m_2)z}{2\pi\mu_1\mu_2} \iint_{\tau} \frac{\nu_c}{r_c} \Delta u(\xi_1, \eta_1) d\xi_1 d\eta_1 \quad (52)$$

The doublet distribution.—The potential induced by a sheet of doublets can be obtained from equation (4) by setting the term involving Δw equal to zero (i. e., by removing all sources from the flow field). Expressing the result in the ξ, η, z coordinates, one has

$$\varphi = \frac{z}{2\pi} \left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \iint_{\tau} \frac{\nu_c}{r_c} \Delta \varphi(\xi_1, \eta_1) d\xi_1 d\eta_1 \quad (53)$$

Again it is necessary to carry the partial derivative operations through the two integral signs. And again, just as was the case for the sources, this requires that the order of integration and the limits on the integrals be specified.

⁴ The fact that equation (4) can be written for u as well as φ does not follow immediately in the case of supersonic flow because of the presence of the discontinuities in u along Mach waves emanating from supersonic edges. Proof of the validity for cases of interest herein is given in reference 6.

Once more consider the case when m_1 and m_2 are both less than β , the area τ is the same as that shown in figure 2, and the first integration is made with respect to η_1 . Then equation (53) becomes

$$\varphi = \frac{z}{2\pi} \left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \int_{-\infty}^{\xi_a} d\xi_1 \int_{\lambda_1}^{\lambda_2} d\eta_1 \frac{\nu_c}{r_c} \Delta \varphi(\xi_1, \eta_1) \quad (54)$$

More caution is necessary in moving the derivatives through the integrals than was required in the study of the source case, since at $\xi_1 = \xi_a$ the η_1 integral is *indeterminate*. It is true that the interval of integration λ_2, λ_1 is zero, but it is also true that the integrand is infinite. The value of such an indeterminate form must be obtained by some process such as the following.

The upper limit to the ξ_1 integral, ξ_a , is a function of the two variables z and ξ (see equation (33)); that is, in functional notation $\xi_a = \xi_a(\xi, z)$. Replace z in ξ_a by $\sqrt{z^2 + \epsilon^2}$, then when ϵ is zero ξ_a has not changed. But if $\xi_a(\xi, z)$ is replaced by $\xi_a(\xi, \sqrt{z^2 + \epsilon^2})$ in equation (54) and the *limit taken as ϵ approaches zero*, the indeterminate form mentioned above can be evaluated. Hence, consider

$$\varphi(\xi, \eta, z) = \lim_{\epsilon \rightarrow 0} \frac{z}{2\pi} \left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \int_{-\infty}^{\xi_a(\xi, \sqrt{z^2 + \epsilon^2})} d\xi_1 \int_{\lambda_1}^{\lambda_2} d\eta_1 \frac{\nu_c}{r_c} \Delta \varphi(\xi_1, \eta_1) \quad (55)$$

By applying the operation described by equation (49) and letting a primed function symbolize its value at $\xi_1 = \xi_a(\xi, \sqrt{z^2 + \epsilon^2})$, the expression

$$\begin{aligned} \varphi(\xi, \eta, z) = & \lim_{\epsilon \rightarrow 0} \frac{z}{2\pi\mu_1} \int_{\lambda_1'}^{\lambda_2'} d\eta_1 \frac{\nu_c'}{r_c'} \Delta \varphi'(\xi_a, \eta_1) + \\ & \frac{z}{2\pi} \int_{-\infty}^{\xi_a} d\xi_1 \left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \int_{\lambda_1}^{\lambda_2} d\eta_1 \frac{\nu_c}{r_c} \Delta \varphi(\xi_1, \eta_1) \end{aligned} \quad (56)$$

is obtained.

The first term in equation (56) can be greatly simplified by use of the mean value theorem. In the limit as ϵ goes to zero both λ_1' and λ_2' approach the common value of η_a . Thus, for ϵ very small the variation of $\Delta \varphi'$ and ν_c' in the range $\lambda_1' < \eta_1 < \lambda_2'$ is slight. The same cannot, of course, be said of $1/r_c'$, since λ_1' and λ_2' are the roots of $r_c' = 0$. Using the functional notation $\nu_c' = \nu_c'(\eta_1)$ and applying the mean value theorem, one can write for the first term in equation (56)

$$\lim_{\epsilon \rightarrow 0} \frac{z}{2\pi\mu_1} \nu_c'(\theta) \Delta \varphi'(\xi_a, \theta) \int_{\lambda_1'}^{\lambda_2'} \frac{d\eta_1}{r_c'}, \quad \lambda_1' < \theta < \lambda_2' \quad (57)$$

Now from the definition of r_c given by equation (31a)

$$\int_{\lambda_1'}^{\lambda_2'} \frac{d\eta_1}{r_c'} = \frac{\mu_1}{\sqrt{\beta^2 - m_1^2}} \int_{\lambda_1'}^{\lambda_2'} \frac{d\eta_1}{\sqrt{(\lambda_2' - \eta_1)(\eta_1 - \lambda_1')}} = \frac{\pi\mu_1}{\sqrt{\beta^2 - m_1^2}}$$

which is independent of ϵ . Hence, the expression given in equation (57) reduces to

$$\frac{1}{2} \Delta \varphi(\xi_a, \eta_a)$$

Moving the partial derivatives through the second integral sign in the last term of equation (56) can be accomplished by introducing the finite-part sign defined previously. Since

$$\frac{\mu_1\mu_2}{m_1+m_2} \left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \frac{v_c}{r_c} = -\frac{\beta^2}{r_c^3}$$

it follows that

$$\left(\frac{1}{\mu_2} \frac{\partial}{\partial \eta} + \frac{1}{\mu_1} \frac{\partial}{\partial \xi} \right) \int_{\lambda_1}^{\lambda_2} d\eta_1 \frac{v_c}{r_c} \Delta\varphi(\xi_1, \eta_1) = - \int_{\lambda_1}^{\lambda_2} \frac{\Delta\varphi(\xi_1, \eta_1) d\eta_1}{r_c^3} \left(\frac{m_1+m_2}{\mu_1\mu_2} \right)$$

By means of these equalities, equation (54) can finally be written in the form

$$\varphi(\xi, \eta, z) = \frac{i}{2} \Delta\varphi(\xi_a, \eta_a) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\xi_1 \int_{\tau} d\eta_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (58)$$

If the area of integration is not changed but if the order of integration is reversed, it can be shown by a process identical to the one just described that

$$\varphi(\xi, \eta, z) = \frac{i}{2} \Delta\varphi(\xi_b, \eta_b) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\eta_1 \int_{\tau} d\xi_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (59)$$

The area τ used in equations (58) and (59) has been defined as that shown in figure 2, the axes ξ and η both chosen so as to lie outside the Mach cone from the origin of the Cartesian system. As the ξ and η axes approach the Mach lines in the x, y plane, that is, as m_2 and m_1 approach β , the residual terms in equations (58) and (59) approach $(\frac{1}{2})\Delta\varphi(\xi_a, -\infty)$ and $(\frac{1}{2})\Delta\varphi(-\infty, \eta_b)$, respectively, which represent the jump in potential infinitely far ahead of and to one side of the point (ξ, η, z) at which the potential is being measured. Hence, in aerodynamic applications, the $(\frac{1}{2})\Delta\varphi(\xi_a, -\infty)$ and $(\frac{1}{2})\Delta\varphi(-\infty, \eta_b)$ can be taken as zero. Thus, when the ξ, η axes lie along the Mach lines, thereby becoming the r, s axes of equations (34), the expressions for φ are without the residue terms and the order of integration is immaterial. When m_1 and m_2 are greater than β the same is true (i. e., the terms $(\frac{1}{2})\Delta\varphi(\xi_a, \eta_a)$ and $(\frac{1}{2})\Delta\varphi(\xi_b, \eta_b)$ are missing from equations (58) and (59), respectively) so that the effect of a distribution of doublets on the velocity potential can be summarized as follows:

For $0 \leq m_1 < \beta, 0 \leq m_2 < \beta$

$$\varphi = \frac{1}{2} \Delta\varphi(\xi_a, \eta_a) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\xi_1 \int_{\tau} d\eta_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60a)$$

$$= \frac{1}{2} \Delta\varphi(\xi_b, \eta_b) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\eta_1 \int_{\tau} d\xi_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60b)$$

For $0 \leq m_1 < \beta, \beta \leq m_2 \leq \infty$

$$\varphi = \frac{1}{2} \Delta\varphi(\xi_a, \eta_a) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\xi_1 \int_{\tau} d\eta_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60c)$$

$$= -\frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\eta_1 \int_{\tau} d\xi_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60d)$$

For $\beta \leq m_1 \leq \infty, 0 \leq m_2 < \beta$

$$\varphi = \frac{1}{2} \Delta\varphi(\xi_b, \eta_b) - \frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\eta_1 \int_{\tau} d\xi_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60e)$$

$$= -\frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \int d\xi_1 \int_{\tau} d\eta_1 \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} \quad (60f)$$

For $\beta \leq m_1 \leq \infty, \beta \leq m_2 \leq \infty$

$$\varphi = -\frac{z\beta^2(m_1+m_2)}{2\pi\mu_1\mu_2} \iint_{\tau} \frac{\Delta\varphi(\xi_1, \eta_1)}{r_c^3} d\xi_1 d\eta_1 \quad (60g)$$

There exists an interesting corollary obtained by subtracting equation (60a) from (60b); namely, that the difference between an integration of supersonic doublets made first in one order and then in the reverse order is equal to the difference in the magnitude of the distribution at two points in the plane.

REDUCTION TO THE PLANE OF THE WING

The next problem is to consider the above formulas in the limiting case as z approaches zero.

The source distribution.—The potential in the plane of the disturbing source sheets follows immediately from equation (51) by simply setting z equal to zero; in this way

$$\varphi(\xi, \eta, 0) = -\frac{(m_1+m_2)}{2\pi\mu_1\mu_2} \iint_{\tau} \frac{\Delta w(\xi_1, \eta_1)}{r_0} d\xi_1 d\eta_1 \quad (61)$$

In order to relate the pressure coefficient C_p to the slope λ_u of the upper surface of the wing (where both C_p and λ_u are defined in equation (40)) the operator

$$-\frac{2}{V_0} \frac{\partial}{\partial x} = -\frac{2\mu_1\mu_2}{V_0(m_1+m_2)} \left(\frac{1}{\mu_1} \frac{\partial}{\partial \xi} + \frac{1}{\mu_2} \frac{\partial}{\partial \eta} \right)$$

must be applied to both sides of equation (61). Hence,

$$C_p = \frac{2}{\pi} \left(\frac{1}{\mu_1} \frac{\partial}{\partial \xi} + \frac{1}{\mu_2} \frac{\partial}{\partial \eta} \right) \iint_{\tau} \frac{\lambda_u(\xi_1, \eta_1)}{r_0} d\xi_1 d\eta_1 \quad (62)$$

The task of moving the partial derivatives through the two integral signs presents a problem identical to the one studied in reducing equation (53) to equations (60). Two inherent singularities in the area occur at the points ξ_a, η_a and ξ_b, η_b and form, just as in equations (60), certain residuals there. In the present discussion, interest is confined to the case when $z=0$. Equation (33) shows immediately

that the values of ξ_a , η_a and ξ_b , η_b for z equal to zero can be written

$$\left. \begin{aligned} (\xi_a)_{z=0} &= (\xi_b)_{z=0} = \xi \\ (\eta_a)_{z=0} &= (\eta_b)_{z=0} = \eta \end{aligned} \right\} \quad (63)$$

It can be shown, therefore (the details being omitted since they are precisely the same as those described in the reduction of equation (53)), that the following relations hold:

For $0 \leq m_1 < \beta$, $0 \leq m_2 < \beta$

$$C_p = \frac{2}{\sqrt{\beta^2 - m_1^2}} \lambda_u(\xi, \eta) - \frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64a)$$

$$= \frac{2}{\sqrt{\beta^2 - m_2^2}} \lambda_u(\xi, \eta) - \frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64b)$$

For $0 \leq m_1 < \beta$, $\beta \leq m_2 \leq \infty$

$$C_p = \frac{2}{\sqrt{\beta^2 - m_1^2}} \lambda_u(\xi, \eta) - \frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64c)$$

$$= -\frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64d)$$

For $\beta \leq m_1 \leq \infty$, $0 \leq m_2 < \beta$

$$C_p = \frac{2}{\sqrt{\beta^2 - m_2^2}} \lambda_u(\xi, \eta) - \frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64e)$$

$$= -\frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) \quad (64f)$$

For $\beta \leq m_1 \leq \infty$, $\beta \leq m_2 \leq \infty$

$$C_p = -\frac{2(m_1 + m_2)}{\pi \mu_1 \mu_2} \iint_\tau \frac{\frac{m_1}{\mu_1}(\eta - \eta_1) + \frac{m_2}{\mu_2}(\xi - \xi_1)}{r_0^3} \lambda_u(\xi_1, \eta_1) d\xi_1 d\eta_1 \quad (64g)$$

The elementary-vortex distribution.—The reduction of equation (52), the formula expressing the potential due to a sheet of elementary horseshoe vortices, to the plane of the wing is of little interest since if Δu is known $\varphi_{z=0}$ can be obtained by the simple relation $\varphi_{z=0} = \frac{1}{2} \int_{-\infty}^x \Delta u \, dx$. However,

if the derivative with respect to z is determined on both sides of equation (52) and the limit is found as z approaches zero, the vertical induced velocity in the plane of the wing will be related to the vortex strength there. In a more physical sense, this will relate the slope of the lifting surface to the load distribution it supports. Such an equation is of basic importance.

The mathematical expression to be studied is

$$w = \lim_{z \rightarrow 0} \frac{\partial}{\partial z} \frac{(m_1 + m_2) V_0}{4 \pi \mu_1 \mu_2} \iint_\tau \frac{z \nu_c}{r_c} \frac{\Delta p(\xi_1, \eta_1)}{q} d\xi_1 d\eta_1 \quad (65)$$

The evaluation of w can be divided into two steps: First, the procedure necessary in order to carry the derivative through the first integral and, second, the calculation of I where

$$I = \lim_{z \rightarrow 0} \frac{(m_1 + m_2) V_0}{4 \pi \mu_1 \mu_2} \int \frac{\partial}{\partial z} \int_\tau \frac{z \nu_c}{r_c} \frac{\Delta p(\xi_1, \eta_1)}{q} d\xi_1 d\eta_1 \quad (66)$$

Again the order of integration is important. As in the preceding discussion of the doublet sheet (equations (53) through (60)) and the source sheet (equations (61) through (64)), assume first that the area of integration is the one given in figure 2. Thus, m_1 is less than β and the η_1 integration is performed first.

If ϵ is introduced in order to evaluate the indeterminate form, equation (65) is expressible in the form

$$w = \lim_{\substack{z \rightarrow 0 \\ \epsilon \rightarrow 0}} \frac{(m_1 + m_2) V_0}{4 \pi \mu_1 \mu_2} \frac{\partial}{\partial z} \int_{-\infty}^{\xi_a(\xi, \sqrt{z^2 + \epsilon^2})} d\xi_1 \int_{\lambda_1}^{\lambda_2} d\eta_1 \frac{z \nu_c}{r_c} \frac{\Delta p}{q} \quad (67)$$

where the terms λ_1 and λ_2 are the roots of the quadratic $r_c^2 = 0$ and where the limiting process for ϵ must be performed before that for z . As before, the primed expression denotes values for the particular case $\xi_1 = \xi_a(\xi, \sqrt{z^2 + \epsilon^2})$, and equation (67) reduces to

$$w = \lim_{\substack{z \rightarrow 0 \\ \epsilon \rightarrow 0}} \left(\frac{\partial \xi_a}{\partial z} \right) \frac{(m_1 + m_2) V_0}{4 \pi \mu_1 \mu_2} \int_{\lambda_1'}^{\lambda_2'} \frac{z \nu_c'}{r_c'} \left(\frac{\Delta p}{q} \right)' d\eta_1 + I \quad (68)$$

By means of the mean value theorem, the first term on the right-hand side of the equation can be simplified. The procedure involved in such an analysis was outlined in the derivation of equation (57). The process used here is identical and equation (68) becomes

$$w = \frac{V_0 \sqrt{\beta^2 - m_1^2}}{4} \frac{\Delta p(\xi, \eta)}{q} + I \quad (69)$$

The term I , defined by equation (66), can be expressed in a simple form by introducing the notation for the generalized principal part (see equation (27)). This term becomes

$$I = \frac{(m_1 + m_2) V_0}{4 \pi \mu_1 \mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\nu_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (70)$$

If the integration of the above expressions had been taken in the opposite order or if the range of m_1 and m_2 had been different, the residual term would change. This phenomena has been presented in connection with both doublet and

source distributions and is by now familiar. Finally, therefore, expressions relating the slope of the wing surface to its loading can be written:

For $0 \leq m_1 < \beta$, $0 \leq m_2 < \beta$

$$\frac{w}{V_0} = -\frac{\sqrt{\beta^2 - m_1^2}}{4} \frac{\Delta p(\xi, \eta)}{q} + \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71a)$$

$$= -\frac{\sqrt{\beta^2 - m_2^2}}{4} \frac{\Delta p(\xi, \eta)}{q} + \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71b)$$

For $0 \leq m_1 < \beta$, $\beta \leq m_2 \leq \infty$

$$\frac{w}{V_0} = -\frac{\sqrt{\beta^2 - m_1^2}}{4} \frac{\Delta p(\xi, \eta)}{q} + \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71c)$$

$$= \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71d)$$

For $\beta \leq m_1 \leq \infty$, $0 \leq m_2 < \beta$

$$\frac{w}{V_0} = -\frac{\sqrt{\beta^2 - m_2^2}}{4} \frac{\Delta p(\xi, \eta)}{q} + \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71e)$$

$$= \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} \quad (71f)$$

For $\beta \leq m_1 \leq \infty$, $\beta \leq m_2 \leq \infty$

$$\frac{w}{V_0} = \frac{m_1 + m_2}{4\pi\mu_1\mu_2} \oint_\tau \oint_\tau \frac{v_0}{r_0} \frac{\Delta p(\xi_1, \eta_1)}{q} d\xi_1 d\eta_1 \quad (71g)$$

The doublet distribution.—The pertinent problem in this case is to find the vertical induced velocity in the plane of the wing as a function of the jump in potential across the plane.

Consider equations (60) and take the partial derivative of both sides with respect to z ; then find the limit of the resulting expression as z approaches zero. If equation (60a) is used, for example, there results for the first term

$$\lim_{z \rightarrow 0} \frac{\partial}{\partial z} \frac{1}{2} \Delta \varphi(\xi_a, \eta_a) = \frac{1}{2} \left(\frac{\partial \Delta \varphi}{\partial \xi_a} \right)_{z=0} \frac{\partial \xi_a}{\partial z} + \frac{1}{2} \left(\frac{\partial \Delta \varphi}{\partial \eta_a} \right)_{z=0} \frac{\partial \eta_a}{\partial z}$$

which becomes

$$\frac{-1}{2(m_1 + m_2)\sqrt{\beta^2 - m_1^2}} \left[\mu_2(\beta^2 - m_1^2) \frac{\partial}{\partial \xi} \Delta \varphi(\xi, \eta) + \mu_1(m_1 m_2 + \beta^2) \frac{\partial}{\partial \eta} \Delta \varphi(\xi, \eta) \right] \quad (72)$$

The second term can be written

$$-\lim_{z \rightarrow 0} \frac{\partial}{\partial z} \frac{z \beta^2 (m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_c^3}$$

and this reduces to

$$-\frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} - \frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \lim_{z \rightarrow 0} z \frac{\partial}{\partial z} \int d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_c^3} \quad (73)$$

Since, by equation (17),

$$\oint_{\lambda_1}^{\lambda_2} \frac{d\eta_1}{[(\lambda_2 - \eta_1)(\eta_1 - \lambda_1)]^{3/2}} = 0$$

the second term in expression (73) vanishes. Finally, therefore, the vertical induced velocity in the plane of the wing becomes:

For $0 \leq m_1 < \beta$, $0 \leq m_2 < \beta$

$$w = -\frac{1}{2(m_1 + m_2)\sqrt{\beta^2 - m_1^2}} \left[\mu_2(\beta^2 - m_1^2) \frac{\partial}{\partial \xi} \Delta \varphi(\xi, \eta) + \mu_1(m_1 m_2 + \beta^2) \frac{\partial}{\partial \eta} \Delta \varphi(\xi, \eta) \right] - \frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74a)$$

$$= -\frac{1}{2(m_1 + m_2)\sqrt{\beta^2 - m_2^2}} \left[\mu_2(m_1 m_2 + \beta^2) \frac{\partial}{\partial \xi} \Delta \varphi(\xi, \eta) + \mu_1(\beta^2 - m_2^2) \frac{\partial}{\partial \eta} \Delta \varphi(\xi, \eta) \right] - \frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74b)$$

For $0 \leq m_1 < \beta$, $\beta \leq m_2 \leq \infty$

$$w = -\frac{1}{2(m_1 + m_2)\sqrt{\beta^2 - m_1^2}} \left[\mu_2(\beta^2 - m_1^2) \frac{\partial}{\partial \xi} \Delta \varphi(\xi, \eta) + \mu_1(m_1 m_2 + \beta^2) \frac{\partial}{\partial \eta} \Delta \varphi(\xi, \eta) \right] - \frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74c)$$

$$= -\frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74d)$$

For $\beta \leq m_1 \leq \infty$, $0 \leq m_2 < \beta$

$$w = -\frac{1}{2(m_1 + m_2)\sqrt{\beta^2 - m_2^2}} \left[\mu_2(m_1 m_2 + \beta^2) \frac{\partial}{\partial \xi} \Delta \varphi(\xi, \eta) + \mu_1(\beta^2 - m_2^2) \frac{\partial}{\partial \eta} \Delta \varphi(\xi, \eta) \right] - \frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\eta_1 \oint_\tau d\xi_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74e)$$

$$= -\frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint d\xi_1 \oint_\tau d\eta_1 \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} \quad (74f)$$

For $\beta \leq m_1 \leq \infty$, $\beta \leq m_2 \leq \infty$

$$w = -\frac{\beta^2(m_1 + m_2)}{2\pi\mu_1\mu_2} \oint_\tau \oint_\tau \frac{\Delta \varphi(\xi_1, \eta_1)}{r_0^3} d\xi_1 d\eta_1 \quad (74g)$$

SUMMARY OF RESULTS FOR φ , C_p , AND w IN THE PLANE OF THE WING;
CARTESIAN-COORDINATE SYSTEM

The special forms of equations (64), (71), and (74) when the ξ, η axes become the Cartesian axes are given in the following sections. In these cases, $\xi \rightarrow x$, $\eta \rightarrow y$, $m_1 \rightarrow 0$, and $m_2 \rightarrow \infty$.

Potential in terms of vertical velocity, nonlifting case.—

$$\varphi(x, y) = -\frac{1}{\pi} \int_{\tau} \int \frac{w_u(x_1, y_1)}{\sqrt{(x-x_1)^2 - \beta^2(y-y_1)^2}} dx_1 dy_1 \quad (75)$$

Pressure coefficient in terms of surface slope, nonlifting case.—

$$C_p = \frac{2}{\beta} \lambda_u(x, y) - \frac{2}{\pi} \int_{\tau} dx_1 \int_{\tau} dy_1 \frac{(x-x_1) \lambda_u(x_1, y_1)}{[(x-x_1)^2 - \beta^2(y-y_1)^2]^{3/2}} \quad (76a)$$

$$C_p = -\frac{2}{\pi} \int_{\tau} dy_1 \int_{\tau} dx_1 \frac{(x-x_1) \lambda_u(x_1, y_1)}{[(x-x_1)^2 - \beta^2(y-y_1)^2]^{3/2}} \quad (76b)$$

Vertical velocity in terms of loading coefficient, lifting case.—

$$\frac{w_u}{V_0} = -\frac{\beta}{4} \frac{\Delta p(x, y)}{q} + \frac{1}{4\pi} \int_{\tau} dx_1 \int_{\tau} dy_1 \frac{(x-x_1) \frac{\Delta p(x_1, y_1)}{q}}{(y-y_1)^2 \sqrt{(x-x_1)^2 - \beta^2(y-y_1)^2}} \quad (77a)$$

$$\frac{w_u}{V_0} = \frac{1}{4\pi} \int_{\tau} dy_1 \int_{\tau} dx_1 \frac{(x-x_1) \frac{\Delta p(x_1, y_1)}{q}}{(y-y_1)^2 \sqrt{(x-x_1)^2 - \beta^2(y-y_1)^2}} \quad (77b)$$

Vertical velocity in terms of surface potential, lifting case.—

$$w_u = -\frac{\beta}{2} \Delta u(x, y) - \frac{\beta^2}{\pi} \int_{\tau} dx_1 \int_{\tau} dy_1 \frac{\varphi_u(x_1, y_1)}{[(x-x_1)^2 - \beta^2(y-y_1)^2]^{3/2}} \quad (78a)$$

$$w_u = -\frac{\beta^2}{\pi} \int_{\tau} dy_1 \int_{\tau} dx_1 \frac{\varphi_u(x_1, y_1)}{[(x-x_1)^2 - \beta^2(y-y_1)^2]^{3/2}} \quad (78b)$$

SUMMARY OF RESULTS FOR φ , C_p , AND w IN THE PLANE OF THE WING;
CHARACTERISTIC COORDINATE SYSTEM

The special forms of equations (64), (71), and (74) when the ξ, η axes become the characteristic axes are given in the following sections. In these cases, $\xi \rightarrow r$, $\eta \rightarrow s$, $m_1 \rightarrow \beta$, and $m_2 \rightarrow \beta$.

Potential in terms of vertical velocity, nonlifting case.—

$$\varphi = -\frac{1}{\pi M_0} \int_{\tau} \int \frac{w_u(r_1, s_1)}{\sqrt{(r-r_1)(s-s_1)}} dr_1 ds_1 \quad (79)$$

Pressure coefficient in terms of surface slope, nonlifting case.—

$$C_p = -\frac{1}{2\pi\beta} \int_{\tau} \int \frac{(r-r_1) + (s-s_1)}{[(r-r_1)(s-s_1)]^{3/2}} \lambda_u(r_1, s_1) dr_1 ds_1 \quad (80)$$

Vertical velocity in terms of loading coefficient, lifting case.—

$$\frac{w_u}{V_0} = \frac{\beta}{4\pi} \int_{\tau} \int \frac{(r-r_1) + (s-s_1)}{[(s-s_1) - (r-r_1)]^2 \sqrt{(r-r_1)(s-s_1)}} \frac{\Delta p(r_1, s_1)}{q} dr_1 ds_1 \quad (81)$$

Vertical velocity in terms of surface potential, lifting case.—

$$w_u = -\frac{M_0}{4\pi} \int_{\tau} \int \frac{\varphi_u(r_1, s_1)}{[(r-r_1)(s-s_1)]^{3/2}} dr_1 ds_1 \quad (82)$$

PART II—THE DIRECT PROBLEM

DISCUSSION

The term "direct problem" shall be defined herein as a problem requiring for its solution the evaluation of integrals with known integrands. The three fundamental formulas presented in part I, equations (64), (71), and (74), apply, respectively, to source, vortex, and doublet distributions, and a consideration of them shows that there are essentially only two different boundary-value problems of wing theory that lead to the direct classification. In the first of these problems (see equation (64)), the pressure coefficient is given by an integral involving the shape of a wing having thickness, but no angle of attack, twist, or camber. The other direct problem is represented by equations (71) and (74), where the angle of attack, twist, or camber of a wing having no thickness is given in terms of an integration involving, respectively, the wing loading or its streamwise integral, the discontinuity in velocity potential. The circumstances of the particular problem will determine which of the two alternative formulas is to be used.

THE AERODYNAMIC PROBLEM

The statement of the two problems can be given from a physical viewpoint as follows.

The thickness case.—The thickness of a wing that is symmetrical above and below a horizontal plane is given and the pressure distribution over the wing is to be determined. Such problems are of special interest in the study of wings in a supersonic flow since their evaluation is necessary for the calculation of the wave drag.

The lifting case.—The load distribution on a lifting plane, a surface without thickness, is given and the slope of the surface that will support such a loading is to be determined.

THE MATHEMATICAL PROBLEM

The mathematical statement of the two problems can be made by referring to the equations expressing the three fundamental formulas in the plane of the wing. For the thickness case, equations (41) or (64) apply, λ_u is given over the wing plan form and C_p is to be determined. For the lifting case, equations (43), (44), (71) or (74) apply, $\Delta p/q$ or $\Delta \varphi$ is given over the wing plan form and w_u is to be determined.

The solution of problems in the direct classification depends only on the analyst's facility in evaluating integrals. Although the integrations may be quite difficult to perform, this nevertheless must be regarded as a question of technique and, in a mathematical sense, a direct problem is solved.

PART III—THE INVERSE PROBLEM

INTRODUCTION

The term "inverse problem" shall be defined herein as a problem requiring for its solution the inversion of an integral equation. In application to the study of problems in aerodynamic wing theory, two different boundary-value problems appear in the inverse classification. These are provided, as was discussed in the presentation of the direct problem, by the two basic relationships that exist in the three fundamental formulas. In those equations the two basic relationships are: First, the pressure is given in terms of an integration involving the shape of a wing having thickness but with no angle of attack, twist, or camber; second, the angle of attack, twist, and camber of a wing having no thickness is given in terms of an integration involving either the wing loading or the discontinuity in the velocity potential.

THE AERODYNAMIC PROBLEM

The physical interpretation of the two types of inverse boundary-value problems is made as follows.

The thickness case.—The pressure distribution over a wing that is symmetrical above and below a horizontal plane is given and the shape of the wing is to be determined. To this bare statement of the problem, however, must be added certain auxiliary considerations. For example, it is physically evident that solutions yielding wings with negative volumes must be excluded. Consideration must also be given to the question of wing closure. It is apparent that these two conditions will serve to restrict the arbitrariness of the pressure distributions which can be prescribed. Finally, the question of the uniqueness of the wing shape arises. For example, it is known that the thin-airfoil-theory solution in the two-dimensional case is unique, provided the prescribed pressure distribution is one leading to a real and closed wing section. In the supersonic three-dimensional case, however, these conditions are no longer sufficient to guarantee a unique shape from a given pressure distribution (although the reverse is always true, i. e., a given shape produces a unique pressure). This fact will be illustrated later (Part IV) in connection with quasi-conical flow problems.

The lifting case.—The slope of a lifting plate, a surface without thickness, is given and the resulting load distribution is to be determined. To insure uniqueness in problems of this type it is sometimes necessary to impose an additional condition. For example, it is necessary to assume that the Kutta condition applies to all trailing edges for which the normal component of the free-stream velocity is subsonic.

THE MATHEMATICAL PROBLEM

The mathematical statement of the two problems can be made at once. Thus, for the thickness case, equations (41) or (64) apply, C_p is given over the area occupied by the wing plan form and λ_u is to be determined. For the lifting case, equations (43), (44), (71), or (74) apply, w_u is given over the wing plan form and $\Delta p/q$ is to be determined.

Of course, by definition, the solutions of both of these problems require the inversion of an integral equation. Further, these particular equations are known as singular

integral equations. Complete inversions to all the cases considered have not as yet been obtained. Some progress has been made, however, and the following section outlines one method by means of which certain singular integral equations can be inverted.

ON THE INVERSION OF SINGULAR INTEGRAL EQUATIONS

DEFINITIONS

An integral equation.—Consider the equation

$$\int_{L_1} g(x) K(x, y) dx = w(y) \quad (83)$$

If $w(y)$ and $K(x, y)$ are given functions and $g(x)$ is unknown, equation (83) is known as integral equation, and more specifically as an integral equation of the first kind. The path of integration L_1 lies along the x axis (in this report only real variables are considered although the methods and results can be generalized to include complex variables) and, in general, can depend on y . The term $K(x, y)$ is known as the kernel of the integral equation.

A singular integral equation.—An integral equation is referred to as singular either when the path of integration, L_1 , has infinite extent, or when the kernel, $K(x, y)$, is infinite at points of the interval L_1 . In other words, equation (83) is a singular integral equation if $K(x, y)$ is unbounded somewhere on L_1 .

An integral transform.—Again consider equation (83). If both sides of this equation are multiplied by the function $H(\lambda, y)$ and integrated with respect to y along the interval L_2 (which is, of course, independent of y but can be a function of λ), the equation is said to have been transformed and the operator

$$\int_{L_2} H(\lambda, y) dy \quad (84)$$

is referred to as an integral transform. The resulting expression

$$\int_{L_2} dy \int_{L_1} dx g(x) H(\lambda, y) K(x, y) = \int_{L_2} w(y) H(\lambda, y) dy \quad (85)$$

is obviously a function only of λ , both x and y being dummy variables of integration.

INHERENT SINGULARITIES

An inherent singularity can be defined first in terms of a function of two variables. Consider the function $f(x, y)$ and let the point a, b lie somewhere in the x, y plane. Then an inherent singularity will be said to exist at the point a, b if

$$\lim_{\epsilon \rightarrow 0} \epsilon^2 f(\epsilon \xi + a, \epsilon \eta + b) \neq 0$$

where

$$x - a = \epsilon \xi, \quad y - b = \epsilon \eta$$

In other words, a square of width 2ϵ is first placed on the x, y plane with a, b at its center, the function $f(x, y)$ is then evaluated at any point on the boundary of the square and multiplied by one-fourth the area of the square. Finally, in the limit as the width of the square vanishes, if this product is not

zero, the function $f(x, y)$ contains an inherent singularity at the point a, b .

Such a concept can obviously be generalized to include functions of three and more variables. For example, the function $f(x_1, x_2, \dots, x_n)$ contains an inherent singularity at the point $a_1, a_2, \dots, a_n$ if

$$\lim_{\epsilon \rightarrow 0} \epsilon^n f(\epsilon \xi_1 + a_1, \epsilon \xi_2 + a_2, \dots, \epsilon \xi_n + a_n) \neq 0$$

where

$$x_i - a_i = \epsilon \xi_i$$

RESIDUALS

Consider a double integration with respect to x and y of the function $f(x, y)$ over the area S in the x, y plane. Perform the integration of the same function over the same area but with the order of integrations reversed. The difference between the results of these two operations will be defined as the residual. Thus

$$R = \int dy \int_S dx f(x, y) - \int dx \int_S dy f(x, y) \quad (86)$$

Ordinarily the residual R is zero, since the order of integration for a double integral is usually immaterial. In the manipulation of singular integrals and singular integral transforms, however, a nonvanishing residual often exists. The evaluation of the residual can be accomplished in the following manner. Let the point a_1, b_1 be an inherent singularity in the area S . Then the residual from such a point is

$$R_1 = \lim_{\epsilon \rightarrow 0} \left[\int_{b_1-\epsilon}^{b_1+\epsilon} dy \int_{a_1-\epsilon}^{a_1+\epsilon} dx f(x, y) - \int_{a_1-\epsilon}^{a_1+\epsilon} dx \int_{b_1-\epsilon}^{b_1+\epsilon} dy f(x, y) \right]$$

Setting $\epsilon \xi + a_1 = x$ and $\epsilon \eta + b_1 = y$, one can write

$$R_1 = \int_{-1}^1 d\eta \int_{-1}^1 d\xi \lim_{\epsilon \rightarrow 0} \epsilon^2 f(\epsilon \xi + a_1, \epsilon \eta + b_1) - \int_{-1}^1 d\xi \int_{-1}^1 d\eta \lim_{\epsilon \rightarrow 0} \epsilon^2 f(\epsilon \xi + a_1, \epsilon \eta + b_1) \quad (87)$$

Hence the necessary condition for the existence of a residual is the occurrence of an inherent singularity in the area of integration over which the double integration is performed. The total residual is the sum of the residuals from each inherent singularity in the area involved.

THE NULL TRANSFORM

Definition.—The integral operator $\int_{L_3} H(\lambda, y) dy$ is said to be a null transform of order n to the function $K(x, y)$ in the interval L_3 if

$$\left(\frac{\partial}{\partial x} \right)^n \int_{L_3} H(\lambda, y) K(x, y) dy = 0 \quad (88)$$

where x, λ and, of course, y are on L_3 .

Examples.—The operator

$$\int_{L_3} H(\lambda, y) dy = \int_x^\lambda \frac{dy}{(\lambda - y)^{3/2}}$$

is a null transform of order zero to the function

$$K(x, y) = 1/\sqrt{y - x}$$

in the interval $x \leq y \leq \lambda$. Thus, (see equation (18)),

$$\int_x^\lambda \frac{dy}{\sqrt{(y-x)(\lambda-y)^3}} = 0 \quad (89)$$

The operator

$$\int_{L_3} H(\lambda, y) dy = \int_\lambda^1 \frac{dy}{\sqrt{(1-y)(y-\lambda)}}$$

is a null transform of order zero to the function $K(x, y) = 1/(y-x)$ in the interval $\lambda \leq y \leq 1$. Thus

$$\int_\lambda^1 \frac{dy}{(y-x)\sqrt{(1-y)(\lambda-y)}} = 0, \lambda < x < 1 \quad (90)$$

Finally, it can be shown from equation (90) that

$$\int_{L_3} H(\lambda, y) dy = \int_a^b \frac{\sqrt{(b-y)(y-a)}}{\lambda - y} dy, a < b$$

where a and b are constants, is a null transform of order one to the function $K(x, y) = 1/(y-x)$ in the interval $a < y < b$. Thus

$$\frac{\partial}{\partial x} \int_a^b \frac{\sqrt{(b-y)(y-a)}}{(y-x)(\lambda-y)} dy = 0, \begin{cases} a < x < b \\ a < \lambda < b \end{cases} \quad (91)$$

THE INVERSION OF SINGULAR INTEGRAL EQUATIONS BY MEANS OF NULL TRANSFORMS

Consider an integral equation of the first kind

$$w(y) = \int_{L_1} g(x) K(x, y) dx \quad (92)$$

such that the kernel $K(x, y)$ tends to infinity as x approaches y and let the point $x=y$ lie in L_1 . Equation (92) is, by definition, a singular integral equation of the first kind. Apply to both sides of this equation the integral transform

$\int_{L_2} H(\lambda, y) dy$ so that

$$\int_{L_2} w(y) H(\lambda, y) dy = \int_{L_2} dy \int_{L_1} dx g(x) H(\lambda, y) K(x, y) \quad (93)$$

Suppose that the area $L_1 + L_2$ of the double integral is bounded by a simple closed curve having the property that any line parallel to the x or y axis crosses its boundary at most twice. For such an area, it is always possible to write the reversed form of the double integral in equation (93) as

$$\int_{L_4} dx \int_{L_3} dy g(x) H(\lambda, y) K(x, y) \quad (94)$$

where L_3 can be a function of x and λ , and L_4 can be a function only of λ .

Subtracting expression (94) from the double integral in equation (93), one finds

$$\int_{L_2} dy \int_{L_1} dx g(x) H(\lambda, y) K(x, y) = \int_{L_4} dx \int_{L_3} dy g(x) H(\lambda, y) K(x, y) + R(\lambda) \quad (95)$$

where $R(\lambda)$ is, by definition, the residual. Hence, equation (93) can be rewritten in the form

$$\int_{L_2} w(y) H(\lambda, y) dy = \int_{L_4} dx \int_{L_3} dy g(x) H(\lambda, y) K(x, y) + R(\lambda) \quad (96)$$

One can now show that if $H(\lambda, y)K(x, y)$ contains an inherent singularity at the point $x=y=\lambda$, equation (96) is the inversion to equation (92) when $H(\lambda, y)$ is a null transform of order one or zero to the kernel $K(x, y)$ in the interval L_3 .

First, it is necessary to relate $R(\lambda)$ to $g(\lambda)$. By the definition given as equation (87), $R(\lambda)$ can be written

$$R(\lambda) = R_0(\lambda) + \int_{-1}^1 d\eta \int_{-1}^1 d\xi \lim_{\epsilon \rightarrow 0} g(\epsilon\xi + \lambda) K(\epsilon\xi + \lambda, \epsilon\eta + \lambda) H(\lambda, \epsilon\eta + \lambda) - \int_{-1}^1 d\xi \int_{-1}^1 d\eta \lim_{\epsilon \rightarrow 0} g(\epsilon\xi + \lambda) K(\epsilon\xi + \lambda, \epsilon\eta + \lambda) H(\lambda, \epsilon\eta + \lambda) \quad (97)$$

where $R_0(\lambda)$ is the sum of the remaining residuals (if there are any) from the other inherent singularities that might exist in the area $L_1 + L_2$. This reduces to

$$R(\lambda) = R_0(\lambda) + g(\lambda) R^*(\lambda) \quad (98)$$

where

$$R^*(\lambda) = \int_{-1}^1 d\eta \int_{-1}^1 d\xi \lim_{\epsilon \rightarrow 0} K(\epsilon\xi + \lambda, \epsilon\eta + \lambda) H(\lambda, \epsilon\eta + \lambda) - \int_{-1}^1 d\xi \int_{-1}^1 d\eta \lim_{\epsilon \rightarrow 0} K(\epsilon\xi + \lambda, \epsilon\eta + \lambda) H(\lambda, \epsilon\eta + \lambda) \quad (99)$$

If inherent singularities other than the one at $x=y=\lambda$ exist in $L_1 + L_2$, they must be at a point on the line $x=y$. The residual at such a point say $x=y=a$, would be the product of $g(a)$ and $R_0^*(a)$, the difference between the two appropriate double integrals. Hence, $R_0(\lambda)$ cannot contain $g(\lambda)$.

Now, if $\int_{L_3} H(\lambda, y) dy$ is a null transform of zero order, equation (96) becomes

$$\int_{L_2} w(y) H(\lambda, y) dy = R_0(\lambda) + g(\lambda) R^*(\lambda)$$

or

$$g(\lambda) = \frac{1}{R^*(\lambda)} \left[-R_0(\lambda) + \int_{L_2} w(y) H(\lambda, y) dy \right] \quad (100)$$

which is an inversion of equation (92). Further, if

$$\int_{L_3} H(\lambda, y) dy$$

is a null transform of the first order, so that

$$\int_{L_3} H(\lambda, y) K(x, y) dy = C(\lambda)$$

equation (96) becomes

$$\int_{L_2} w(y) H(\lambda, y) dy = C(\lambda) \int_{L_4} g(x) dx + R_0(\lambda) + g(\lambda) R^*(\lambda) \quad (101)$$

If L_4 is independent of λ this already is an inversion of equation (92). However, if L_4 contains λ then, after dividing through by $C(\lambda)$ and taking the derivative with respect to λ , a first-order differential equation in $g(\lambda)$ results. This is considered to be an inversion.

THE INVERSION OF SOME PARTICULAR SINGULAR INTEGRAL EQUATIONS

ABEL'S INTEGRAL EQUATION

Consider the special form of Abel's integral equation

$$w(y) = \int_a^y \frac{g(x) dx}{\sqrt{y-x}}, \quad a < y \quad (102)$$

It has been shown (see equation (89)) that

$$\int_x^\lambda \frac{dy}{(\lambda-y)^{3/2}}$$

is a null transform of order zero to the kernel $1/\sqrt{y-x}$ in the interval $x \leq y \leq \lambda$. Hence, applying the transform

$$\int_a^\lambda \frac{dy}{(\lambda-y)^{3/2}}$$

to both sides of equation (102), reversing the order of integration, and noting that

$$\int_a^\lambda dy \int_a^y dx \frac{g(x)}{\sqrt{y-x} (\lambda-y)^{3/2}} = \int_a^\lambda g(x) dx \int_x^\lambda dy \frac{1}{\sqrt{y-x} (\lambda-y)^{3/2}} + R(\lambda) = R(\lambda) \quad (103)$$

leads one to the result

$$\int_a^\lambda \frac{w(y) dy}{(\lambda-y)^{3/2}} = R(\lambda) \quad (104)$$

The only inherent singularity that appears in the area of integration occurs at the point $x=y=\lambda$. The residual is obtained by integrating over the shaded area in figure 5 and finding the limit as ϵ goes to zero.

FIGURE 5.—Region of integration for equation (105a).

Thus

$$R(\lambda) = \lim_{\epsilon \rightarrow 0} \left[\int_{\lambda-\epsilon}^{\lambda} dy \int_{\lambda-\epsilon}^y dx \frac{g(x)}{\sqrt{y-x}(\lambda-y)^{3/2}} - \int_{\lambda-\epsilon}^{\lambda} g(x) dx \int_x^{\lambda} dy \frac{1}{\sqrt{y-x}(\lambda-y)^{3/2}} \right] \quad (105a)$$

and, since the second double integral is zero, the transformations $\epsilon\xi = \lambda - x$ and $\epsilon\eta = \lambda - y$ reduce this to

$$R(\lambda) = \lim_{\epsilon \rightarrow 0} \int_1^0 d\eta \int_1^{\eta} d\xi \frac{g(-\epsilon\xi + \lambda)}{\sqrt{\xi - \eta} \eta^{3/2}}$$

Finally, in the limit as ϵ goes to zero,

$$R(\lambda) = g(\lambda) \int_1^0 d\eta \int_1^{\eta} \frac{d\xi}{\eta^{3/2} \sqrt{\xi - \eta}} = -2\pi g(\lambda) \quad (105b)$$

Substitute equation (105b) into equation (104) and the inversion of the integral equation (102) can be written

$$g(\lambda) = \frac{-1}{2\pi} \int_a^{\lambda} \frac{w(y) dy}{(\lambda - y)^{3/2}} \quad (106)$$

By applying the definition of the finite part, one can rewrite equation (106) in the alternative form

$$g(\lambda) = \frac{1}{\pi} \frac{d}{d\lambda} \int_a^{\lambda} \frac{w(y) dy}{\sqrt{\lambda - y}} \quad (107)$$

which is the form of the inversion usually presented.

THE AIRFOIL EQUATION

The study of the singular integral equation known as the airfoil equation is closely associated with the study of boundary-value problems related to Laplace's equation in two dimensions. These boundary conditions are sometimes given along a straight line as is the case, for example, in the linearized study of two-dimensional subsonic wings. If the boundary conditions are given along a suitably prescribed curve, the curve can, by application of complex variable concepts, be mapped onto a straight line. For example, the Joukowski transformation maps a circle in one plane onto a straight line in another and in both planes the governing formula is the two-dimensional form of Laplace's equation. The solution to such boundary-value problems can be reduced to the inversion of the following singular integral equation:

$$w(y) = \int_a^b \frac{g(x) dx}{y - x}, \quad a < y < b \quad (108)$$

where a and b are constants.

It has been shown (see equation (91)) that

$$\int_a^b \frac{\sqrt{(b-y)(y-a)}}{\lambda - y} dy$$

is a null transform of order one to the kernel $1/(y-x)$ in the interval $a \leq y \leq b$. Applying this transform to equation (108), and using the definition of the residual, one obtains

$$\int_a^b \frac{w(y) \sqrt{(b-y)(y-a)}}{\lambda - y} dy = \int_a^b g(x) dx \int_a^b \frac{\sqrt{(b-y)(y-a)}}{(\lambda - y)(y - x)} dy + R(\lambda)$$

which reduces to the form

$$\int_a^b \frac{w(y) \sqrt{(b-y)(y-a)}}{\lambda - y} dy = \pi \int_a^b g(x) dx + R(\lambda) \quad (109)$$

Again the only inherent singularity in the area of integration is at the point $x=y=\lambda$. Evaluating the residual according to equation (87), one finds

$$R(\lambda) = g(\lambda) \sqrt{(b-\lambda)(\lambda-a)} \left[\int_{-1}^1 d\eta \int_{-1}^1 \frac{d\xi}{\eta(\xi-\eta)} - \int_{-1}^1 d\xi \int_{-1}^1 \frac{d\eta}{\eta(\xi-\eta)} \right]$$

and since

$$\int_{-1}^1 \frac{d\eta}{\eta(\xi-\eta)} = \frac{-1}{\xi} \ln \frac{1-\xi}{1+\xi}$$

this becomes

$$R(\lambda) = 2g(\lambda) \sqrt{(b-\lambda)(\lambda-a)} \int_{-1}^1 \frac{d\eta}{\eta} \ln \frac{1-\eta}{1+\eta} = -\pi^2 g(\lambda) \sqrt{(b-\lambda)(\lambda-a)} \quad (110)$$

By the combination of equation (110) with (109), the inversion to the airfoil integral equation (108) thus becomes

$$g(\lambda) = \frac{1}{\pi^2 \sqrt{(b-\lambda)(\lambda-a)}} \left[\pi \int_a^b g(x) dx - \int_a^b \frac{w(y) \sqrt{(b-y)(y-a)} dy}{\lambda - y} \right] \quad (111)$$

It is apparent that the inversion to equation (108) provided by equation (111) is not unique (because of the existence of the term $\int_a^b g(x) dx$ which can be thought of as an arbitrary constant). Hence, in the application of equation (108) to physical boundary-value problems it is not sufficient to specify the value of w along the y axis; some additional condition must also be supplied. Examples of such additional conditions in the study of aerodynamic problems are the specification of closure in the study of two-dimensional sections and the assumption of the Kutta condition along the trailing edge of two-dimensional lifting surfaces.

THE SUPERSONIC DOUBLET EQUATION

The general concepts of the method just applied to the solution of single-integral equations with a singular kernel can also be used to invert double-integral equations with singular kernels. Success in solving these more complicated forms depends again on the discovery of an appropriate integral transform—in this case a double integral transform—and the usefulness of these operators depends, in turn, on both the structure of their integrand and, what is just as important, the space (now four-dimensional) of integration. As it turns out, however, inversions can be obtained in many cases that are of importance in the study of supersonic aerodynamic problems.

Case 1—Supersonic leading edge.—Consider the equation that gives the vertical induced velocity in the plane of the wing in terms of the perturbation velocity potential on the upper surface of a lifting surface in a supersonic free stream, equation (82),

$$w_u(r_2, s_2) = \frac{-M_o}{4\pi} \iint_{\tau(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{[(r_2 - r_1)(s_2 - s_1)]^{3/2}} \quad (112)$$

The area $\tau(r_2, s_2)$ represents the area within the forecone from the point r_2, s_2 at which the vertical induced velocity is being measured. The details of the solution to equation (112) will now be presented for two different types of boundaries to the area $\tau(r_2, s_2)$, that is, from an aerodynamic standpoint, for two different types of wing plan forms.

First consider the case when $\tau = \tau_0$ is an area such as the one shown in figure 6. The two lines $r_1 = r_2$ and $s_1 = s_2$, which represent the traces of the Mach forecones from the point r_2, s_2 , form two bounds of the area while the third is given by the wing leading edge, the equation for which may be written as either $s_1 = f_0(r_1)$ or $r_1 = f_0^*(s_1)$.

FIGURE 6.—Region of integration for wing with supersonic leading edge.

In the present case, it is assumed, furthermore, that $s_1 = f_0(r_1)$ is a continuous monotonic function with a negative slope, or, physically, that the wing has a supersonic type leading edge.⁵

The kernel of equation (112) is formed by the product of two functions, one independent of r_1 and r_2 and the other independent of s_1 and s_2 . It follows, therefore, that if an integral operator is used that contains the product of two linear functions of s_2 and r_2 to the $-1/2$ power, there exists the possibility of obtaining a null transform of order zero according to the equality given as equation (18). One can show, in fact, that the operator

$$\iint_{\tau_0(r, s)} \frac{dr_2 ds_2}{\sqrt{(r - r_2)(s - s_2)}} = \frac{2\beta}{M_o} \iint_{\tau_0(r, s)} \frac{dr_2 ds_2}{r_o(r, s; r_2, s_2)} \quad (113)$$

is a null transform of order zero to the right-hand side of equation (112) where $\tau_o(r, s)$ is the same area that appears in the integral equation.

If the transform given by equation (113) is applied to equation (112) the resulting expression is

$$\iint_{\tau_0(r, s)} \frac{w_u dr_2 ds_2}{r_o} = \frac{-2\beta^3}{\pi M_o^2} \iint_{\tau_0(r, s)} dr_2 ds_2 \iint_{\tau_0(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{r_o(r, s; r_2, s_2) r_o^3(r_2, s_2; r_1, s_1)} \quad (114)$$

Consider next the right-hand side of this equation but with the r_2, s_2 integrals taken first. Then by definition of the residual

$$\begin{aligned} & \frac{-2\beta^3}{\pi M_o^2} \iint_{\tau_0(r, s)} dr_2 ds_2 \iint_{\tau_0(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{r_o(r, s; r_2, s_2) r_o^3(r_2, s_2; r_1, s_1)} = \\ & \frac{-2\beta^3}{\pi M_o^2} \iint_{[\tau_0(r, s) + \tau_0(r_2, s_2)]} \varphi_u(r_1, s_1) dr_1 ds_1 \iint_{\tau_0(r, s)} \frac{dr_2 ds_2}{r_o(r, s; r_2, s_2) r_o^3(r_2, s_2; r_1, s_1)} + \\ & R(r, s) \end{aligned} \quad (115)$$

When the integration is made first with respect to r_2 and s_2 , the area of integration for these two variables can be visualized with the aid of figure 7. In such a case the points r_1, s_1 and r, s are fixed and the area is simply the one which lies in the forecone from the point r, s and in the aftercone from the point r_1, s_1 . This is represented by the shaded area in the figure. It is apparent from a study of figure 7 that, when the edge $s_2 = f_0(r_2)$ is a monotonic function as previously defined, the r_2 and s_2 integrals are always taken between the limits r_1 and r and s_1 and s , respectively. Hence, according to equation (18) the inte-

FIGURE 7.—Area of integration for fixed r_1, s_1, r, s ; equation (115).

⁵ Supersonic and subsonic edges have the property that the normal component of the free-stream velocity is supersonic and subsonic, respectively.

gral term on the right-hand side of equation (115) vanishes and equation (114) becomes

$$\int_{\tau_0(r,s)} \int \frac{w_u dr_2 ds_2}{r_0} = R(r,s) \quad (116)$$

The complete inversion of the integral equation can now be realized if an expression for $R(r,s)$ can be obtained in terms of $\varphi_u(r,s)$. The evaluation of this residual term follows along lines quite similar to those used in calculating the residual for the special form of Abel's integral equation given previously. Now, however, there is no longer a single inherent singularity; rather, the lines $r_1=r_2=r$ and $s_1=s_2=s$ are densely covered with them. First consider an integration made over the region close to the line $s_1=s_2=s$ (i. e., the sum of the areas a and b shown in fig. 8).

FIGURE 8.—Region of integration for evaluation of residual, equation (116).

Make the substitutions $s_1=s-\epsilon\sigma_1$ and $s_2=s-\epsilon\sigma_2$ and take the limit as ϵ goes to zero. There results for the portion of the residual due to the inherent singularities $R_{a+b}(r,s)$ along the line $s_1=s_2=s$ the equation⁶

$R_{a+b}(r,s)=$

$$\frac{-M_0^2}{8\pi\beta} \int_{f_0^*(s)}^r dr_2 \int_1^0 d\sigma_2 \int_{f_0^*(s)}^{r_2} dr_1 \int_1^{\sigma_2} d\sigma_1 \frac{\varphi_u(r_1,s)}{(\sigma_1-\sigma_2)^{3/2}(r_2-r_1)^{3/2}\sqrt{\sigma_2(r-r_2)}} \quad (117)$$

This becomes, after integrating with respect to σ_1 and σ_2 (which can be done immediately since the limits of the r_1 integral do not now contain σ_2 and, further, since the r_1, σ_2 plane contains no inherent singularity)

⁶ The first term on the right-hand side of equation (115) contributes nothing to the residual since it always contains an integral equivalent to that in equation (18) and, therefore, is identically zero. This same phenomenon also appeared in the study of the residual appearing in the inversion of Abel's integral equation. (See the development of equation (105).)

$$R_{a+b}(r,s) = \frac{M_0^2}{4\beta} \int_{f_0^*(s)}^r dr_2 \int_{f_0^*(s)}^{r_2} dr_1 \frac{\varphi_u(r_1,s)}{(r_2-r_1)^{3/2}\sqrt{r-r_2}} \quad (118)$$

It is now proposed to reverse the order of integration of the double integral in equation (118). But the r_1, r_2 plane contains an inherent singularity at the point $r_2=r_1=r$. By definition of the residual from this singularity as $R'(r,s)$, it follows that

$$R_{a+b}(r,s) = \frac{M_0^2}{4\beta} \int_{f_0^*(s)}^r dr_1 \varphi_u(r_1,s) \int_{r_1}^r \frac{dr_2}{(r_2-r_1)^{3/2}\sqrt{r-r_2}} + R'(r,s) = R'(r,s)$$

since the integral term is zero by the equality that has been used repeatedly. The evaluation of $R'(r,s)$ follows the identical line of argument used in obtaining equation (105b) from (105a). Hence, setting $r_2=r-\epsilon\rho_2$ and $r_1=r-\epsilon\rho_1$, and letting ϵ go to zero, one finds

$$R_{a+b}(r,s) = R'(r,s) = \frac{M_0^2}{4\beta} \varphi_u(r,s) \int_1^0 d\rho_2 \int_1^{\rho_2} \frac{d\rho_1}{(\rho_1-\rho_2)^{3/2}\sqrt{\rho_2}} = -\frac{\pi M_0^2}{2\beta} \varphi_u(r,s) \quad (119)$$

The part of the residual in equation (116) contributed by the inherent singularities in the areas a and b in figure 8 is, therefore, $-\frac{\pi M_0^2}{2\beta} \varphi_u(r,s)$. A similar calculation shows that the singularities in the areas $c+b$ give the same result; and, finally, a calculation for the area b itself also yields $-\frac{\pi M_0^2}{2\beta} \varphi_u(r,s)$. The value of R in equation (116) is obtained by combining the results for the various areas. Hence,

$$R = R_{a+b} + R_{b+c} - R_b = -\frac{\pi M_0^2}{2\beta} \varphi_u(r,s) \quad (120)$$

Combining the result expressed by the last equation with equation (116), one can finally write for the inversion of the integral equation (112), when $\tau=\tau_0$, the expression

$$\varphi_u(r,s) = \frac{-1}{\pi M_0} \iint_{\tau_0(r,s)} \frac{w_u dr_2 ds_2}{\sqrt{(r-r_2)(s-s_2)}} \quad (121)$$

Case 2—Combined subsonic and supersonic leading edges.—Consider the equation

$$w_u = \frac{-M_0}{4\pi} \iint_{\tau_1(r_2,s_2)} \frac{\varphi_u(r_1,s_1) dr_1 ds_1}{[(r_2-r_1)(s_2-s_1)]^{3/2}} \quad (122)$$

where $\tau_1(r_2,s_2)$ is the more complicated area shown in figure 9. Again the lines $r_1=r_2$ and $s_1=s_2$, which are the traces of the forecone from the point r_2, s_2 , form two bounds of the area. The remaining two boundaries are formed by the curves $s_1=f_0(r_1)$ (or in the inverse sense $r_1=f_0^*(s_1)$) and $s_1=f_1(r_1)$ (or $r_1=f_1^*(s_1)$) where f_0 has the same definition it had in the study of Case 1, that is, a monotonic curve with a negative slope. The curve $s_1=f_1(r_1)$ is also a monotonic function, but with a positive slope. For convenience the origin is placed at the point of intersection of the f_0 and f_1 curves.

(a) x_1, y_1 plane.
(b) (r_1, s_1) plane.

FIGURE 9.—Region of integration for wing with combined subsonic and supersonic edges.

A physical interpretation of the area τ_1 with regard to problems in supersonic wing theory is simple. The lines $r_1=r_2$ and $s_1=s_2$, as has been mentioned, are the traces of the Mach forecone from the point r_2, s_2 . The f_0 and f_1 curves are the edges of the wing plan form, the line $s_1=f_0(r_1)$ representing a supersonic leading edge and the line $s_1=f_1(r_1)$ representing a subsonic leading edge.

Proceeding exactly as in Case 1, consider the operator

$$\iint_{\tau_1(r,s)} \frac{dr_2 ds_2}{\sqrt{(r-r_2)(s-s_2)}}$$

and find whether or not it is a null transform of zero order to the kernel of equation (122), that is, whether or not the equality

$$\iint_{\tau_1(s,r)+\tau_1(r_2,s_2)} \varphi_u(r_1,s_1) dr_1 ds_1 \oint \oint \frac{dr_2 ds_2}{[(r_2-r_1)(s_2-s_1)]^{3/2} \sqrt{(r-r_2)(s-s_2)}} = 0 \quad (123)$$

is satisfied. A study of figure (10) shows that it is not, since for a point r_1, s_1 located above the line $r_2=f_1^*(s)$, a portion of the s_2 integral becomes

$$\int_{s_1}^{f_1(r_2)} \frac{ds_2}{(s_2-s_1)^{3/2} \sqrt{s-s_2}}$$

FIGURE 10.—Area of integration for fixed r_1, s_1, r, s ; equation (123).

which is not zero unless $f_1(r_2)$ is identically equal to s . For the same reason, portions of the r_2 integral will not vanish for the point r_1, s_1 so located.

However, the construction of a null transform of zero order can be accomplished by studying the above failure. Thus, if the s_2 integration were carried between the limits s_1 and s , for every location of the points r_1, s_1 and r, s , the operator $\oint h(r, s, r_2) dr_2 \oint (s-s_2)^{-1/2} ds_2$ would be a null transform of zero order regardless of the choice of h . The area of integration producing such a transform is simply the one shown in figure 11(a), an area bounded by the lines $s_2=s, r_2=r, s_2=f_0(r_2)$ and $r_2=f_2^*(s)$ where $r_2=f_2^*(s)$ is any line such that $f_2^*(s) \geq f_1^*(s)$. This area shall be designated as $\tau_2(r, s)$. When such a transform is applied and the s_2 integration performed first, it is apparent from figure 11(b) that the limits of the s_2 integral

(a) Area of integration for transform.
(b) Area of integration for fixed r_1, s_1, r, s .

FIGURE 11.—Integration regions for equations (124).

are always s_1 and s , even when the point r_1, s_1 is located above the line $r_2=f_1^*(s)$. Hence, if the residual $R(r, s)$ is defined by the relation

$$-\frac{M_0}{4\pi} \int h(r, s, r_2) dr_2 \int_{\tau_2(r, s)} \frac{ds_2}{\sqrt{s-s_2}} \iint_{\tau_1(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{[(r_2-r_1)(s_2-s_1)]^{3/2}} +$$

$$\frac{M_0}{4\pi} \int h(r, s, r_2) dr_2 \iint_{\tau_2(r, s)+\tau_1(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{(r_2-r_1)^{3/2}} \int_{s_1}^s \frac{ds_2}{\sqrt{s-s_2}(s_2-s_1)^{3/2}} = R(r, s) \quad (124a)$$

the second term on the left-hand side is zero, and equation (122) transforms into

$$\int_{f_2^*(s)}^r h(r, s, r_2) dr_2 \int_{f_0(r_2)}^s \frac{w_u(r_2, s_2)}{\sqrt{s-s_2}} ds_2 = R(r, s) \quad (124b)$$

The evaluation of the residual in equation (124b) follows the same pattern used in Case 1. Thus, after isolating the line of inherent singularities, $R(r, s)$ is given by the expression

$$R(r, s) = -\frac{M_0}{4\pi} \int_{f_2^*(s)}^r h dr_2 \int_{s-\epsilon}^s \frac{ds_2}{\sqrt{s-s_2}} \int_{f_1^*(s_2)}^{r_2} ds_1 \int_{s-\epsilon}^{s_2} dr_1 \frac{\varphi_u(r_1, s_1)}{[(r_2-r_1)(s_2-s_1)]^{3/2}}$$

which becomes (after setting $s_2=s-\epsilon\sigma_2$ and $s_1=s-\epsilon\sigma_1$ and letting ϵ go to zero)

$$R = \frac{M_0}{2} \int_{f_2^*(s)}^r h dr_2 \int_{f_1^*(s)}^{r_2} \frac{\varphi_u(r_1, s)}{(r_2-r_1)^{3/2}} dr_1 \quad (125)$$

It is now apparent that after setting $f_2^*(s)=f_1^*(s)$ and $h=1/\sqrt{r-r_2}$, equation (125) can be evaluated exactly as equation (118) was evaluated, so that for these values of f_2^* and h , $R(r, s) = -M_0\pi\varphi_u(r, s)$. Substituting into equation (124b), one finds for the inversion of equation (122) the result

$$\varphi_u(r, s) = \frac{-1}{\pi M_0} \iint_{\tau_3(r, s)} \frac{w_u(r_2, s_2) dr_2 ds_2}{\sqrt{(r-r_2)(s-s_2)}} \quad (126)$$

where τ_3 is the shaded area in figure 12.

Case 3—Mixed boundary conditions.—Another very important kind of integral equation which can be solved directly by the proper choice of h in equation (125) is the "mixed" type problem, the boundary values of which are illustrated in figure 13. In this particular problem w_u is known over the portion of the r, s plane bounded by the curves $s=f_0(r)$ and $s=f_2(r)$ (the curve $s=f_2(r)$ is a monotonic function with a positive slope just like $s=f_1(r)$), while over another portion, bounded by the curves $s=f_2(r)$ and $s=f_1(r)$ the quantity $u_u(r, s) = \frac{M_0}{2\beta} \left(\frac{\partial}{\partial r} + \frac{\partial}{\partial s} \right) \varphi_u(r, s)$ is given. (This corresponds in aerodynamic applications to the specification of the vertical induced velocity over the former region and the loading over the latter.) It is also assumed that $u_u(r, s)$ is continuous across the line $s=f_2(r)$ and that $\varphi(r, s)$ vanishes along the line $s=f_1(r)$, that is, $\varphi(f_1^*(r), s)=0$.

Taking for the value of h the expression

$$h = \frac{1}{\sqrt{r-r_2}} \left(\frac{\partial}{\partial r_2} + \frac{\partial}{\partial s} \right)$$

(a) x_2, y_2 plane.
(b) r_2, s_2 plane.

FIGURE 12.—Integration area τ_3 (equation (126)).

(a) x, y plane.
(b) r, s plane.

FIGURE 13.—Mixed boundary conditions.

and for the area of integration the region $\tau_2(r, s)$ shown in figure 11(a), one finds from equation (125) that the residual can be written

$$R = \frac{M_0}{2} \int_{f_2^*(s)}^r \frac{dr_2}{\sqrt{r-r_2}} \left(\frac{\partial}{\partial r_2} + \frac{\partial}{\partial s} \right) \int_{f_1^*(s)}^{r_2} \frac{\varphi_u(r_1, s) dr_1}{(r_2 - r_1)^{3/2}}$$

The partial derivative can be taken through the second integral sign (first integrating by parts in the case of $\partial/\partial r_2$) since $\varphi(f_1^*(s), s) = 0$, so that

$$R = \frac{M_0}{2} \int_{f_2^*(s)}^r dr_2 \int_{f_1^*(s)}^{r_2} dr_1 \frac{\left(\frac{\partial}{\partial r_1} + \frac{\partial}{\partial s} \right) \varphi_u(r_1, s)}{\sqrt{r-r_2}(r_2-r_1)^{3/2}}$$

Part of the boundary condition is that $u_u(r, s)$ is given over the region indicated in figure 13. Hence, the residual can be written

$$R = \beta \int_{f_2^*(s)}^r dr_2 \int_{f_1^*(s)}^{f_2^*(s)} dr_1 \frac{u_u(r_1, s)}{\sqrt{r-r_2}(r_2-r_1)^{3/2}} + \beta \int_{f_2^*(s)}^r dr_2 \int_{f_2^*(s)}^{r_2} dr_1 \frac{u_u(r_1, s)}{\sqrt{r-r_2}(r_2-r_1)^{3/2}}$$

The latter of these two terms is again just like the one given in equation (118) so its evaluation is immediate. The first term may be simplified by reversing the order of integration. (There is no residual since the point $r=r_1=r_2$ is not included in the area of integration.) Finally, R becomes

$$R = 2\beta \sqrt{r-f_2^*(s)} \int_{f_1^*(s)}^{f_2^*(s)} \frac{u_u(r_1, s) dr_1}{(r-r_1)\sqrt{f_2^*(s)-r_1}} - 2\pi\beta u_u(r, s)$$

and the inversion of this mixed type problem can be written

$$u_u(r, s) = \frac{\sqrt{r-f_2^*(s)}}{\pi} \int_{f_1^*(s)}^{f_2^*(s)} \frac{u_u(r_1, s) dr_1}{(r-r_1)\sqrt{f_2^*(s)-r_1}} - \frac{1}{2\beta\pi} \int_{f_2^*(s)}^r \frac{dr_2}{\sqrt{r-r_2}} \left(\frac{\partial}{\partial r_2} + \frac{\partial}{\partial s} \right) \int_{f_0(r_2)}^s \frac{w_u(r_2, s_2) ds_2}{\sqrt{s-s_2}} \quad (127)$$

An equation which does not impose the condition that $u_u(r, s)$ be continuous across the line $s=f_2(r)$ can readily be developed by using the operator $h=1/\sqrt{r-r_2}$. This leads directly to the result

$$\varphi(r, s) = \frac{\sqrt{r-f_2^*(s)}}{\pi} \int_{f_1^*(s)}^{f_2^*(s)} \frac{\varphi_u(r_1, s) dr_1}{(r-r_1)\sqrt{f_2^*(s)-r_1}} - \frac{1}{\pi M_0} \int_{f_2^*(s)}^r dr_2 \int_{f_0(r_2)}^s ds_2 \frac{w_u(r_2, s_2)}{\sqrt{(s-s_2)(r-r_2)}} \quad (128)$$

THE SUPERSONIC SOURCE EQUATION

The null transforms to the supersonic doublet equation were constructed by applying an integral operator having an integrand which, when combined with the kernel, would produce the integral

$$\int \frac{dx}{(x-b)^{3/2} \sqrt{a-x}}$$

and having an area which, when combined with that of the integral equation and traversed in reverse order, would pro-

duce the limits a and b on the integral. If one now considers the supersonic source equation (see equation (79))

$$\varphi_u(r_2, s_2) = \frac{-1}{\pi M_0} \iint_{\tau(r_2, s_2)} \frac{w_u(r_1, s_1) dr_1 ds_1}{\sqrt{(r_2-r_1)(s_2-s_1)}} \quad (129)$$

it is apparent that the null transform will differ from the transform used for the supersonic doublet equation only in the exponent of the integrand. Thus, for the area $\tau_0(r_2, s_2)$ (see fig. 6) the operator

$$\iint_{\tau_0(r, s)} \frac{dr_2 ds_2}{[(r-r_2)(s-s_2)]^{3/2}}$$

is a null transform of order zero to equation (129), and its application yields the solution

$$w_u(r, s) = \frac{-M_0}{4\pi} \iint_{\tau_0(r, s)} \frac{\varphi_u(r_2, s_2) dr_2 ds_2}{[(r-r_2)(s-s_2)]^{3/2}} \quad (130)$$

For the area $\tau_1(r_2, s_2)$ (see fig. 9), the operator

$$\iint_{\tau_1(r, s)} \frac{dr_2 ds_2}{[(r-r_2)(s-s_2)]^{3/2}}$$

is a null transform of order zero. Its application, under conditions like those specified in the development of equation (126), yields the inversion

$$w_u(r, s) = \frac{-M_0}{4\pi} \iint_{\tau_1(r, s)} \frac{\varphi_u(r_2, s_2) dr_2 ds_2}{[(r-r_2)(s-s_2)]^{3/2}} \quad (131)$$

Equation (130) gives vertical velocity in terms of a prescribed surface potential for a wing with a supersonic leading edge, while equation (131) does the same for a wing with a leading edge which is partly subsonic and partly supersonic. The transform with the area τ_3 (see fig. 12) can also be used to obtain inversions to equation (129) under conditions such as those imposed in the development of equations (127) and (128).

DISCUSSION OF INVERSION OF SUPERSONIC SOURCE AND DOUBLET EQUATIONS FROM A PHYSICAL BASIS

Each of the above examples used to illustrate the application of the null transform method to the inversion of double integral equations represents the solution of a class of supersonic problems. However, most of these solutions are well known and were originally obtained by reasoning that was suggested by knowledge of the physical structure of the problem. For example, the reciprocal relation between the source and doublet integral equations

$$\left. \begin{aligned} \varphi_u(r, s) &= \frac{-1}{\pi M_0} \int_{\tau_0} \int \frac{w_u(r_1, s_1) dr_1 ds_1}{\sqrt{(r-r_1)(s-s_1)}} \\ w_u(r, s) &= \frac{-M_0}{4\pi} \int_{\tau_0} \int \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{[(r-r_1)(s-s_1)]^{3/2}} \end{aligned} \right\} \quad (132)$$

when considered with respect to the area τ_0 , has a simple physical meaning. By definition τ_0 is an area bounded by the Mach forecone and a supersonic leading-edge. From a

physical standpoint it is clear that the flow field at a point, affected only by a supersonic edge, on the upper surface of a wing cannot be influenced by the shape of any part of the lower surface of the wing. In other words, the upper and lower surfaces are noninteracting. Hence, the upper surface of a wing does not "know" whether it is the upper surface of a lifting plate that is supporting loading and has no thickness, or the upper surface of a wing section that is symmetrical above and below the $z=0$ plane. Thus the source equation must be the inversion to the doublet equation and vice versa, and from a physical point of view the reciprocal relation given by equation (132) is obvious.

The solution to wing problems involving one supersonic and one subsonic edge, giving an area of integration for the integral equations corresponding to the area τ_1 in the previous discussion, was originally obtained by Evvard (see reference 7). It should be noted here that the inversions to the source and doublet equations (equations (126) and (131)) considered with respect to the area τ_1 , no longer form reciprocal relations.

Finally, the examples presented herein with regard to the mixed type of problem have also been derived (see references 8 and 9) using more or less physical arguments. The solutions to these mixed type problems form the basis of a lift cancellation technique that provides a very useful extension of Evvard's original discovery.

ITERATIVE METHODS OF SOLUTION

Other types of plan forms.—The question that naturally arises from a practical viewpoint is how the source and doublet equations can be inverted when the area τ_1 is not of the two special kinds discussed, or, in other words, when the wing plan forms are complicated by having more than one monotonic (in the r, s plane) subsonic edge. The answer must be that, unless null transforms with respect to these new integration areas can be discovered, the methods discussed here will not give the direct inversion to the problem. Several possibilities remain, however, so that even when the null transform cannot be found the concepts of the residual, inherent singularity, etc., can be used to simplify, if not solve, the supersonic source and doublet integral equations.

With respect to the lift cancellation techniques already mentioned, references 8 and 9 outline these methods in considerable detail and show how they can be applied to find the loading on wings in regions affected by two or more subsonic edges.

Regions influenced by multiple reflections of Mach waves.—A more direct example of how some of the concepts presented heretofore can be applied, even when the null transform is not available, is given by considering the following problem: Find the loading at the point (x, y) on the flat wing tip shown in figure 14. If the r, s coordinate system is used and the operator

$$\int_{f_2(s)}^r \frac{dr_2}{\sqrt{r-r_2}} \left(\frac{\partial}{\partial r_2} + \frac{\partial}{\partial s} \right) \int_{f_3(r)}^s \frac{ds_2}{\sqrt{s-s_2}}$$

(where the area of integration is region 4 in fig. 14 (b)) is applied to the doublet equation (equation (82)), two results

FIGURE 14.—Tip of swept forward wing and regions of integration.

can be anticipated: One, since the loading off the wing is zero, the residual will be $-2\pi\beta u_a(r, s)$; and the other, the transformed integral with the s_2 (in the notation of equation (124a)) integration performed first, is zero for all points r_1, s_1 lying in regions 2 and 4 in figure 14. These results follow directly from the discussion presented above in case 3 of the similar integral transform applied to the doublet equation (equation (122)) with the τ_1 area. Without proceeding further, therefore, it is apparent that the original integral equation has been reduced to: (1), an integral of the known function w_a over region 4 in figure 14; and (2), an integral of the unknown function φ_a over the regions 1 and 3 in figure 14. (It can be shown that the integration over region 3 will also vanish.) But regions 1 and 3 are ahead of the Mach forecone from (r, s) . Hence, by repeating the above process for regions farther and farther up (toward the origin) the wing, the problem must eventually be reduced to one of finding the solution for an area such as τ_1 ; in other words, to a problem involving only two edges, one subsonic and one supersonic. Since the latter problem is solved, the one considered in this section is also (theoretically at least) solved.

Triangular plan form with subsonic leading edges.—As a final exemplification of the preceding concepts, consider the problem of finding the loading on a flat triangular wing fly-

ing at a supersonic speed but with both leading edges subsonic (see fig. 15). To the supersonic doublet equation (equation (82)) apply the integral transform

$$\frac{-1}{\pi M_0} \int_{s/\mu}^r dr_2 \int_{r/\mu}^s ds_2 \frac{1}{\sqrt{(r-r_2)(s-s_2)}}$$

where the area of integration is region 4 in figure 15(b). There results

$$\begin{aligned} \frac{-1}{\pi M_0} \int_{s/\mu}^r dr_2 \int_{r/\mu}^s ds_2 \frac{w_u(r_2, s_2)}{\sqrt{(r-r_2)(s-s_2)}} = \\ \frac{1}{4\pi^2} \int_{s/\mu}^r dr_2 \int_{r/\mu}^s ds_2 \oint_{\tau_1(r_2, s_2)} \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{\sqrt{(r-r_2)(s-s_2)[(r_2-r_1)(s_2-s_1)]^{3/2}}} \end{aligned} \quad (133)$$

where $\tau_1(r_2, s_2)$ is the original area of integration as shown in figure 15(a). Since w_u is a constant equal to $-V_0\alpha$, the left-hand side of equation (133) becomes

$$\frac{4V_0\alpha}{\pi M_0} \sqrt{\left(r-\frac{s}{\mu}\right)\left(s-\frac{r}{\mu}\right)} \quad (134)$$

(a) x_1, y_1 plane.
(b) r_2, s_2 plane.

FIGURE 15.—Integration areas for triangular wing.

where $\mu = (1+m\beta)/(1-m\beta)$, m being the slope of the leading edge in the x, y plane. Inverting the order of integration and evaluating the residual, one finds that equation (133) can be written

$$\begin{aligned} \varphi_u(r, s) = \frac{4V_0\alpha \sqrt{\left(r-\frac{s}{\mu}\right)\left(s-\frac{r}{\mu}\right)}}{\pi M_0} \\ \frac{\sqrt{\left(r-\frac{s}{\mu}\right)\left(s-\frac{r}{\mu}\right)}}{\pi^2} \int_{\tau_5} \int \frac{\varphi_u(r_1, s_1) dr_1 ds_1}{(r-r_1)(s-s_1) \sqrt{\left(\frac{r}{\mu}-s_1\right)\left(\frac{s}{\mu}-r_1\right)}} \end{aligned} \quad (135)$$

where τ_5 is the area shown as region 1 in figure 15(b).

Equation (135) is not, of course, the inversion of the supersonic doublet equation for the triangular flat plate. In fact, it simply represents the transformation of the doublet equation, which is a singular integral equation of the first kind, to a singular integral equation of the second kind. However, this latter form has the advantage that it is readily susceptible to the process of iteration. Thus, in the particular case of equation (135), it is possible to take as a first approximation to φ_u the value

$$\varphi_1(r, s) = \frac{4V_0\alpha}{\pi M_0} \sqrt{\left(r-\frac{s}{\mu}\right)\left(s-\frac{r}{\mu}\right)} \quad (136)$$

and, as the second, the value

$$\begin{aligned} \varphi_2(r, s) = \frac{4V_0\alpha}{\pi M_0} \sqrt{\left(r-\frac{s}{\mu}\right)\left(s-\frac{r}{\mu}\right)} \\ \left[1 - \frac{1}{\pi^2} \int_{\tau_5} \int \frac{\sqrt{\left(r_1-\frac{s_1}{\mu}\right)\left(s_1-\frac{r_1}{\mu}\right)} dr_1 ds_1}{(r-r_1)(s-s_1) \sqrt{\left(\frac{r}{\mu}-s_1\right)\left(\frac{s}{\mu}-r_1\right)}} \right] \end{aligned} \quad (137)$$

and so on. By means of the substitutions

$$\left. \begin{aligned} \mu r_1 &= \frac{s+r\mu\rho_1+s\sigma_1}{1+\rho_1+\sigma_1} \\ \mu s_1 &= \frac{r+r\rho_1+s\mu\sigma_1}{1+\rho_1+\sigma_1} \end{aligned} \right\} \quad (138)$$

the double integral in the equation for φ_2 can be evaluated. Thus, after some manipulation, one finds⁷

$$\begin{aligned} \int_{\tau_5} \int \frac{\sqrt{\left(r_1-\frac{s_1}{\mu}\right)\left(s_1-\frac{r_1}{\mu}\right)} dr_1 ds_1}{(r-r_1)(s-s_1) \sqrt{\left(\frac{r}{\mu}-s_1\right)\left(\frac{s}{\mu}-r_1\right)}} \\ = 2\pi[2E_1 - (1-k_1^2)K_1] - \pi^2 \end{aligned} \quad (139)$$

where K_1 and E_1 are complete elliptic integrals of the first and second kinds, respectively, with moduli $k_1 = 1/\mu$. Using the identity

⁷ Notice that the area of integration, i. e., the area τ_5 , is bounded by the lines which represent the four roots to the radicals in the integrand. Notice also that the value of this double integral is independent of r and s and depends only on the parameter μ , the slope of the leading edges in the r, s plane.

$$2E_1 - (1 - k^2)K_1 = \frac{2E}{1 + m\beta} \quad (140)$$

where E has the modulus $k = \sqrt{1 - m^2\beta^2}$, and returning to the Cartesian coordinate system, one finds for the values of φ_1 and φ_2 ,

$$\varphi_1 = \frac{4V_0\alpha}{\pi(1+m\beta)} \sqrt{m^2x^2 - y^2} \quad (141)$$

$$\varphi_2 = \frac{4V_0\alpha}{\pi(1+m\beta)} \sqrt{m^2x^2 - y^2} \left[2 - \frac{4E}{\pi(1+m\beta)} \right] \quad (142)$$

The process of iteration could be continued, and φ_u would be expressed as an infinite series of terms containing the parameter $m\beta$. However, since the terms in the series expansion are all independent of x and y , or, in the characteristic system, of r and s , it is more efficient to write φ in the form

$$\varphi_u(r, s) = A \sqrt{\left(s - \frac{r}{\mu}\right) \left(r - \frac{s}{\mu}\right)} = \frac{M_0 A \sqrt{m^2x^2 - y^2}}{1 + m\beta} \quad (143)$$

and determine the magnitude of A by substituting this expression into equation (135). There results the equality

$$A = \frac{4V_0\alpha}{\pi M_0} \frac{A}{\pi^2} \left(\frac{4\pi E}{1 + m\beta} - \pi^2 \right)$$

from which it can be shown that

$$A = \frac{V_0\alpha}{M_0 E} (1 + m\beta) \quad (144)$$

Finally, therefore, the velocity potential on the upper surface of a triangular wing with subsonic leading edges can be written

$$\varphi_u(x, y) = \frac{V_0\alpha}{E} \sqrt{m^2x^2 - y^2} \quad (145)$$

and the familiar expression for the loading coefficient (see, e. g., reference 10) follows immediately

$$\frac{\Delta p}{q} = \frac{4\alpha m^2 x}{E \sqrt{m^2x^2 - y^2}} \quad (146)$$

The purpose of examining this particular problem was not, of course, to obtain the solution presented as equation (145) or (146), since that solution is by now quite well known. Rather, the purpose was to show how the supersonic doublet equation could be transformed to a singular-integral equation of the second kind and how this equation could, in turn, be solved by applying an iteration process. Such a method has far more general applications than are given here and is by no means limited to problems in which the flow is conical or quasi-conical.

PART IV—APPLICATIONS

DIRECT PROBLEMS

The following three examples will serve to illustrate how the formulas derived in Part I can be used to solve the direct problems outlined in Part II. The applications will be limited to supersonic flow problems.

RECTANGULAR WING WITH BICONVEX SECTION

Consider a rectangular, nonlifting wing with a chordwise section given everywhere by the equation

$$\lambda_u(x, y) = \frac{2t}{c^2} (c - 2x) \quad (147)$$

where λ_u is the slope of the upper surface, c is the chord, and t is the maximum thickness. The equation for the pressure on the surface of such a wing will change form in each of the four regions indicated in figure 16. In region 1 the pressure is the same as for a two-dimensional wing with the same section, and the remaining regions contain the three-dimensional or tip effects.

FIGURE 16.—Rectangular nonlifting wing with biconvex section.

The equation for pressure coefficient on the wing can be determined from either equation (76a) or (76b). Equation (76a), for example, becomes for region 1

$$C_p = \frac{4t}{\beta c^2} (c - 2x) - \frac{4t}{\pi c^2} \int_0^x (c - 2x_1)(x - x_1) dx_1 \int_{y - \frac{x-x_1}{\beta}}^{y + \frac{x-x_1}{\beta}} \frac{dy_1}{r_0^3}$$

From the result given as equation (17), it is apparent that the integral term is zero and the pressure coefficient in region 1 of figure 16 is simply

$$C_p = \frac{4t}{\beta c^2} (c - 2x) \quad (148)$$

One can easily show that equation (76b) yields the same result.

The evaluation of pressure coefficient in regions 2, 3, and 4 can be carried out in a similar fashion. A slightly different approach can be used, however, that is useful in obtaining results in this and similar problems. Consider a wing with regions as shown in figure 17. Regions a, b, and c include all the area ahead of the line $x_1 = x$. It is obvious that r_0^3 is a pure real number for all x_1, y_1 inside region b (i. e., inside

 FIGURE 17.—Regions used in discussion of τ_i .

the forecone from x, y and a pure imaginary number for all x_1, y_1 inside regions a and c. Further, it is clear from physical considerations that λ_u is always real on the wing plan form. Hence, if the symbol τ_i is introduced to represent the combined area in regions a, b, and c, the area τ in equations (76)

can be replaced by the area τ_i and the real part of the result will be the correct answer for the pressure coefficient.⁸

By means of this concept, pressure coefficient for all points on the wing can be written in the form

$$C_p(x, y) = \frac{4t}{\beta c^2} (c - 2x) - \frac{4t}{\pi c^2} \text{R.P.} \int_0^x dx_1 \int_{-s}^s dy_1 \frac{(c - 2x_1)(x - x_1)}{r_0^3} \quad (149)$$

or, alternatively,

$$C_p(x, y) = \frac{-4t}{\pi c^2} \text{R.P.} \int_{-s}^s dy_1 \int_0^x dx_1 \frac{(c - 2x_1)(x - x_1)}{r_0^3} \quad (150)$$

where the letters R. P. indicate that the real part of the integral is to be taken. Evaluating, for example, the former equation one finds

$$C_p = \frac{4t}{\beta c^2} (c - 2x) + \frac{4t}{\pi c^2} \text{R.P.} \left[-\frac{c - 2x}{\beta} \arccos \frac{\beta(s - y)}{x} + 2(y - s) \operatorname{arcosh} \frac{x}{\beta(s - y)} - \frac{c - 2x}{\beta} \arccos \frac{\beta(s + y)}{x} - 2(y + s) \operatorname{arcosh} \frac{x}{\beta(y + s)} \right] \quad (151)$$

The real and imaginary parts of the arc cosine and arc cosh terms in this equation are given in the following table for all real values of the argument.

⁸ The areas d and e could also be included in the definition of τ_i since r_0^3 is imaginary within these regions also. However, region f must not be included since there the term r_0^3 is again real. The definition of τ_i adopted is usually the most convenient.

Range of x	$-1 > x$	$-1 < x < 1$	$1 < x$
$\operatorname{arcosh} x = \int_1^x \frac{dt}{\sqrt{t^2 - 1}}$	$i\pi + \operatorname{arcosh}(-x)$	$i \arccos x$	$\operatorname{arcosh} x$
$\arccos x = \int_x^1 \frac{dt}{\sqrt{1 - t^2}}$	$\pi - i \operatorname{arcosh}(-x)$	$\arccos x$	$i \operatorname{arcosh} x$
$\arcsin x = \int_0^x \frac{dt}{\sqrt{1 - t^2}}$	$-\frac{\pi}{2} + i \operatorname{arcosh}(-x)$	$\arcsin x$	$\frac{\pi}{2} - i \operatorname{arcosh} x$

Equation (151) contains, at once, the entire solution to the wing shown in figure 16. Thus, in region 1 none of the terms in the braces has a real part. Hence, equation (148) follows immediately. In region 3 the solution can be written

$$C_p = \frac{4t}{\pi \beta c^2} \left\{ (c - 2x) \left[\pi - \arccos \frac{\beta(y + s)}{x} \right] - 2\beta(y + s) \operatorname{arcosh} \frac{x}{\beta(y + s)} \right\}$$

The solution in region 2 follows from the one given in region 3 by symmetry; and, finally, the expression for the pressure coefficient in region 4 is given by equation (151) wherein every term is real.

DRAW REVERSIBILITY THEOREM

The well-known theorem that the drag of a symmetrical sharp-edged, nonlifting body is the same in forward and

reversed flight at the same speed (see references 11 and 12) can be derived in another way using the methods described in the above sections.

By definition, drag coefficient is

$$C_D = \frac{1}{S} \iint_S 2\lambda_u(x, y) C_p(x, y) dx dy \quad (152)$$

where S is the area of the wing. Using the real part concept outlined in the discussion of the preceding example, one can write

$$C_D = \frac{-4}{\pi S} \iint_S \lambda_u(x, y) dx dy \text{R.P.} \int_{\tau_i} dy_1 \int_{-s}^s dx_1 \frac{(x - x_1)\lambda_u(x_1, y_1)}{r_0^3} \quad (153)$$

The equation for the drag coefficient in reversed flight can be obtained by:

1. Replacing the area τ_i by τ_{ii} where $\tau_i + \tau_{ii} = S$

2. Rotating the axial system in the xy plane through 180°

3. Reversing the signs of $\lambda_u(x, y)$ and $\lambda_u(x_1, y_1)$

There results

$$C_{D_r} = \frac{-4}{\pi S} \int_S \lambda_u(x, y) dx dy \text{ R.P. } \int_{\tau_i} dy_1 \oint dx_1 \frac{(x_1 - x) \lambda_u(x_1, y_1)}{r_0^3} \quad (154)$$

Subtracting equation (154) from (153) gives

$$C_D - C_{D_r} = \frac{-4}{\pi S} \text{ R.P. } \int dy \int_S dx \int dy_1 \oint dx_1 \frac{x \lambda_u(x_1, y_1) \lambda_u(x, y)}{r_0^3} + \frac{4}{\pi S} \text{ R.P. } \int dy \int_S dx \int dy_1 \oint dx_1 \frac{x_1 \lambda_u(x_1, y_1) \lambda_u(x, y)}{r_0^3} \quad (155)$$

Since the symbols x_1, y_1, x, y are dummy variables of integration, the last term in equation (155) can be written

$$\frac{4}{\pi S} \text{ R.P. } \int dy_1 \int_S dx_1 \int dy \oint dx \frac{x \lambda_u(x, y) \lambda_u(x_1, y_1)}{r_0^3}$$

But reversing the operators $\oint dy_1 \oint dx_1$ and $\oint dy \oint dx$ (always preserving the same order within the operation) and subtracting gives

$$\int dy_1 \int_S dx_1 \int dy \oint dx \frac{x \lambda_u(x, y) \lambda_u(x_1, y_1)}{r_0^3} = \int dy \int_S dx \int dy_1 \oint dx_1 \frac{x \lambda_u(x, y) \lambda_u(x_1, y_1)}{r_0^3}$$

since the residual is zero. Hence, the second term in equation (155) is the same expression as the first except for the sign and

$$C_D - C_{D_r} = 0$$

or

$$C_D = C_{D_r} \quad (156)$$

as was to be shown.

LIFT ON WINGS WITH SUPERSONIC EDGES

The lift on any wing can be written

$$\frac{L}{q} = \iint_S \frac{\Delta p}{q} dy dx \quad (157)$$

Moreover,

$$\int_{\text{L.E.}}^{\text{T.E.}} \frac{\Delta p}{q} dx = \frac{4 \varphi_{\text{T.E.}}}{V_0}$$

where T. E. and L. E. denote the trailing and leading edges, respectively, and $\varphi_{\text{T.E.}}$ is the value of the velocity potential on the upper surface of the wing at the trailing edge.

Consider now a wing with all edges supersonic and a straight trailing edge not necessarily at right angles to the free-stream direction (see fig. 18). Let the wing be a plate having arbitrary twist and camber. Then, for a point on the wing, the velocity potential can be written in the x, y coordinate system on the basis of equation (121) as

$$\varphi_u = \frac{-1}{\pi} \text{ R.P. } \int_{\tau_i} \int \frac{w_u(x_1, y_1) dx_1 dy_1}{\sqrt{(x - x_1)^2 - \beta^2(y - y_1)^2}} \quad (158)$$

FIGURE 18.—Wing with supersonic edges.

where τ_i , as in the previous examples, is the area on the wing ahead of the line $x_1 = x$. If the equation of the trailing edge is

$$x_1 = a + y_1 \tan \Lambda$$

where a is some constant, the value of the potential at the trailing edge can be written

$$\varphi_{\text{T.E.}} = \frac{-1}{\pi} \text{ R.P. } \iint_S \frac{w_u(x_1, y_1) dx_1 dy_1}{\sqrt{(a + y \tan \Lambda - x_1)^2 - \beta^2(y - y_1)^2}} \quad (159)$$

where the area of integration is the whole wing plan form since the trailing edge of the wing is supersonic and the aftercone from the point at which $\varphi_{\text{T.E.}}$ is being evaluated cannot intersect the wing. The total lift L on the wing can, therefore, be written in the form

$$\frac{L}{q} = \frac{-4}{\pi V_0} \text{ R.P. } \int_{s_1}^{s_2} dy \iint_S \frac{w_u(x_1, y_1) dx_1 dy_1}{\sqrt{(a + y \tan \Lambda - x_1)^2 - \beta^2(y - y_1)^2}} \quad (160)$$

The area S does not depend on y , so the y integration can be made first and, since the edges are all supersonic, the interval $s_1 \leq y \leq s_2$ must always contain the roots λ_1 and λ_2 of the expression under the radical. Hence

$$\text{R.P. } \int_{s_1}^{s_2} \frac{dy}{\sqrt{(\beta^2 - \tan^2 \Lambda)(\lambda_1 - y)(y - \lambda_2)}} = \int_{\lambda_1}^{\lambda_2} \frac{dy}{\sqrt{(\beta^2 - \tan^2 \Lambda)(\lambda_1 - y)(y - \lambda_2)}}$$

and since

$$\int_{\lambda_1}^{\lambda_2} \frac{dy}{\sqrt{(\lambda_1 - y)(y - \lambda_2)}} = \pi$$

then

$$\frac{L}{q} = \frac{-4}{\sqrt{\beta^2 - \tan^2 \Lambda}} \iint_S \frac{w_u(x_1, y_1)}{V_0} dx_1 dy_1 \quad (161)$$

Defining the average angle of attack $\bar{\alpha}$ by the expression

$$\bar{\alpha} = \frac{1}{S} \iint_S \frac{-w_u(x_1, y_1) dx_1 dy_1}{V_0} \quad (162)$$

one can write equation (161) in the alternative form

$$C_L = \frac{4\bar{\alpha}}{\sqrt{\beta^2 - \tan^2 A}} \quad (163)$$

It is interesting to notice that the lift coefficient for the wing just studied is the same as that for a two-dimensional flat plate flying at an angle of attack $\bar{\alpha}$ into a free stream, the speed of which is given by the component of velocity normal to the trailing edge of the three-dimensional wing. This result has been derived previously in reference 13.

INVERSE PROBLEMS

LOW-ASPECT-RATIO RECTANGULAR WING

It will be noted in the summary of results for the fundamental formulas applicable to supersonic flow (equations (75) through (82)) that the results are presented for both orders of integration in the x, y coordinate system. While the analysis of direct problems can be carried out in all cases if, say, the x_1 integration is always performed first, it may sometimes be more convenient to perform the y_1 integration first. In the analysis of inverse problems, however, it is much more important that freedom exists in the choice of the first variable of integration. A good example of this is provided by the following approximate derivation of the loading on a slender (in the streamwise sense) rectangular flat plate.

By considering the special case when the wing chord is long compared to the span, one can obtain an approximate solution for the slender flat plate by assuming the loading coefficient has the form

$$\frac{\Delta p}{q} = 4\alpha f\left(\frac{x}{s}\right) \sqrt{1 - \left(\frac{y}{s}\right)^2} \quad (164)$$

where s is the semispan (see fig. 19) and $f(x/s)$ is an unknown function. The function f is to be determined by the condition that w_u is constant along the center line of the wing. If the solution to such a problem is to be determined by use of the doublet or vortex equation, it is obviously important that the first integration be made with respect to y_1 since the variation of $\Delta p/q$ with y_1 is known.

Since $\Delta p/q$ is given, let the vortex equation be used and let equation (164) be placed into (77a). For $y=0$ (and for added simplicity for $\beta=1$) the area τ is shown by the shaded area in figure 19 and the resulting equation can be written for $x > s$

$$\begin{aligned} \frac{w_u}{V_0} = & -\alpha f\left(\frac{x}{s}\right) + \frac{\alpha}{\pi} \int_0^{x-s} (x-x_1) f\left(\frac{x_1}{s}\right) dx_1 \\ & + \frac{\alpha}{\pi} \int_{-s}^s \frac{\sqrt{1-(y_1/s)^2}}{y_1^2 \sqrt{(x-x_1)^2 - y_1^2}} dy_1 + \frac{\alpha}{\pi} \int_{x-s}^x (x-x_1) f\left(\frac{x_1}{s}\right) dx_1 \\ & + \frac{\alpha}{\pi} \int_{-(x-x_1)}^{x-x_1} \frac{\sqrt{1-(y_1/s)^2}}{y_1^2 \sqrt{(x-x_1)^2 - y_1^2}} dy_1 \end{aligned}$$

for $0 < x < s$

$$\begin{aligned} \frac{w_u}{V_0} = & -\alpha f\left(\frac{x}{s}\right) + \frac{\alpha}{\pi} \int_0^x (x-x_1) f\left(\frac{x_1}{s}\right) dx_1 \\ & + \frac{\alpha}{\pi} \int_{-(x-x_1)}^{x-x_1} \frac{\sqrt{1-(y_1/s)^2}}{y_1^2 \sqrt{(x-x_1)^2 - y_1^2}} dy_1 \end{aligned}$$

FIGURE 19.—Integration area for slender rectangular wing.

Introduce the notation

$$\theta_1 = \frac{x_1}{s}, \quad \theta = \frac{x}{s}, \quad k_1 = \frac{1}{\theta - \theta_1}, \quad k_2 = \theta - \theta_1$$

and these equations become,⁹ since $\alpha = -w_u/V_0$, for $0 < \theta < 1$

$$1 = f(\theta) + \frac{2}{\pi} \int_0^\theta k_2 B_2 f(\theta_1) d\theta_1 \quad (165a)$$

for $1 < \theta$

$$1 = f(\theta) + \frac{2}{\pi} \int_{\theta-1}^\theta k_2 B_2 f(\theta_1) d\theta_1 + \frac{2}{\pi} \int_0^{\theta-1} E_1 f(\theta_1) d\theta_1 \quad (165b)$$

Equations (165) are integral equations of the second kind (more specifically, Volterra's integral equations of the second kind) and the kernels are regular and bounded everywhere in the interval of integration. Hence, their solution can be determined readily by numerical processes. This has been done and the result in terms of the loading coefficient on the center line $\left(\frac{\Delta p}{q\alpha}\right)_0$ (from equation (164) $\left(\frac{\Delta p}{q\alpha}\right)_0 = 4f\left(\frac{x}{s}\right)$) is shown in figure 20.

For the purpose of comparison, the exact linearized value also is shown in the interval where it is known, together with another approximate solution obtained by Stewartson (reference 14) using a different approach. Near the leading edge, where the comparison with the exact results can be made, the agreement between the exact and approximate solutions obtained herein will be poorest because in this region the spanwise variation deviates most radically from the value assumed in the construction of the integral equation.

⁹ The symbols B and E indicate elliptic integrals. See the table of symbols.

FIGURE 20.—Load coefficient for unit angle of attack along center line of rectangular wing.

CONICAL AND QUASI-CONICAL FLOW

Equation (108) and its solution, equation (111), occur repeatedly in the study of aerodynamics. In fact, equation (108) is often referred to as the airfoil equation since it plays a dominant role in the development of linearized, two-dimensional, subsonic wing theory. It appears also in the study of slender wings (reference 15) or wings flying at near sonic speeds (reference 16) since the boundary conditions lead again to the required inversion of the same type of integral relationship. In the present section, problems arising in supersonic conical or quasi-conical flow fields will be reduced also to this basic equation.

Several methods exist whereby the solution to conical flow problems can be determined. The one to be studied here is based on the construction of conical elements extending radially from the apex of the field and inclined at an angle arc $\tan m$ to the x axis (see fig. 21(a)). In order to obtain such an element it is sufficient to subtract two plan forms of prescribed loading or thickness, each plan form having one side directed along the x axis while the other sides are inclined at angles that differ only infinitesimally.

Consider first the construction of a quasi-conical,¹⁰ radial, lifting element that carries a load given by the expression

$$\frac{\Delta p}{q} = C y^{\kappa} \quad (166)$$

where C is a constant. The upwash field of a triangular plan form such as the one shown in figure 21(b) can be found by integrating elementary horseshoe vortices over the appropriate area τ . Thus, using equation (77b), performing an integration, and making the substitutions

$$\theta = m\beta, \quad \eta = \beta y/x, \quad \eta_1 = \beta y_1/x \quad (167)$$

one finds the result

$$\left(\frac{\beta}{x}\right)^{\kappa} \frac{w_u}{V_0} = \frac{\beta C}{4\pi} \int_0^{\theta} \frac{\eta_1^{\kappa} d\eta_1}{(\eta - \eta_1)^2} \sqrt{\left(1 - \frac{\eta_1}{\theta}\right)^2 - (\eta - \eta_1)^2}, \quad 0 < \theta, \eta < \theta \quad (168a)$$

$$= \frac{\beta C}{4\pi} \int_0^{\theta} \frac{\eta_1^{\kappa} d\eta_1}{(\eta - \eta_1)^2} \sqrt{\left(1 - \frac{\eta_1}{\theta}\right)^2 - (\eta - \eta_1)^2}, \quad 0 < \theta, \theta < \eta \quad (168b)$$

¹⁰ A conical field is defined as one in which the induced velocities are constant along rays through a point. In the subsequent analysis this corresponds to the case when $\kappa = 0$. Quasi-conical fields are those in which κ is greater than zero.

(a)

(b)

(a) Lifting element.
(b) Triangular wing.

FIGURE 21.—Construction of conical element.

Equations (168) can be written in the functional notation

$$w_u = f(\theta, \eta)$$

It follows that if the analysis were repeated for a wing with a slightly larger apex angle, there would have resulted

$$w_u = f(\theta + \Delta\theta, \eta)$$

Subtracting these two expressions for w_u gives the increment in vertical induced velocity due to a quasi-conical element

$$dw_u = \lim_{\Delta\theta \rightarrow 0} \frac{f(\theta + \Delta\theta, \eta) - f(\theta, \eta)}{\Delta\theta} \Delta\theta = \frac{\partial f}{\partial \theta} d\theta \quad (169)$$

Carrying out the operation indicated by equation (169), making the substitution

$$\eta_1 = \theta \frac{\eta - t}{\theta - t}, \quad t = \theta \frac{\eta - \eta_1}{\theta - \eta_1}$$

and distributing these elements between θ_1 and θ_0 with weight $C(\theta)$, one can finally show that the equation

$$\left(\frac{\beta}{x}\right)^\kappa \frac{w_u}{V_0} = \frac{-\beta(\kappa+1)}{4\pi} \int_{\theta_1}^{\theta_0} \theta^\kappa C(\theta) H(\theta, \eta) d\theta \quad (170)$$

applies where

$$H(\theta, \eta) = \int_1^\eta \frac{(\eta-t)^\kappa \sqrt{1-t^2}}{(\theta-t)^{\kappa+2} t} dt, \quad \theta_1 \leq \theta < \eta$$

$$= \int_{-1}^\eta \frac{(\eta-t)^\kappa \sqrt{1-t^2}}{(\theta-t)^{\kappa+2} t} dt, \quad \eta < \theta \leq \theta_0$$

The function $H(\theta, \eta)$ has a simple pole at $\theta = \eta$ and the integral expression for w_u is therefore evaluated as a Cauchy principal part.

The boundary condition to be satisfied by equation (170) is that $\beta^* w_u / x^\kappa V_0$ is a given polynomial of degree κ in the variable η . Hence, equation (170) is a singular integral equation with a pole of the same order as that in the airfoil equation. In its present form the equation appears somewhat formidable, but it can be simplified considerably by a simple operation. Since $\beta^* w_u / x^\kappa V_0$ is a polynomial of degree κ , it follows that the $(\kappa+1)^{\text{st}}$ derivative of the right-hand member of equation (170) must vanish. Thus, using the concept of the generalized principal part, one has

$$0 = \frac{\sqrt{1-\eta^2}}{\eta} \int_{\theta_1}^{\theta_0} \frac{\theta^\kappa C(\theta) d\theta}{(\theta-\eta)^{\kappa+2}} \quad (171)$$

which, by definition, can be put in the form

$$\left(\frac{\partial}{\partial \eta}\right)^{\kappa+1} \int_{\theta_1}^{\theta_0} \frac{\theta^\kappa C(\theta) d\theta}{\theta-\eta}$$

The function $\theta^\kappa C(\theta)$ is therefore to be found through the inversion of the integral equation

$$\int_{\theta_1}^{\theta_0} \frac{\theta^\kappa C(\theta) d\theta}{\theta-\eta} = \sum_{i=0}^{\kappa} a_i \eta^i \quad (172)$$

But equation (172) is precisely the airfoil equation and its solution is given by equation (111). Hence,

$$\theta^\kappa C(\theta) = \frac{1}{\pi^2 \sqrt{(\theta_0-\theta)(\theta-\theta_1)}} \left[A - \int_{\theta_1}^{\theta_0} \frac{\sum_{i=0}^{\kappa} a_i \eta^i \sqrt{(\theta_0-\eta)(\eta-\theta_1)}}{\theta-\eta} d\eta \right] \quad (173)$$

so that, finally,

$$\frac{\Delta p}{q} = \left(\frac{x}{\beta}\right)^\kappa \sum_{i=0}^{\kappa+1} \frac{b_i \theta^i}{\sqrt{(\theta_0-\theta)(\theta-\theta_1)}} \quad (174)$$

where the coefficients b_i are functions of the constants θ_0 and θ_1 but not of θ . These coefficients must be determined from known conditions about the surface geometry.

Consider the unyawed (i. e., $\theta_1 = -\theta_0$) triangular wing shown in figure 22. If the loading is to be determined on a flat plate with such a plan form $\beta^* w_u / x^\kappa V_0$ becomes $-\alpha$, and equation (174) reduces to

$$\begin{aligned} \text{---} & w_u/V_0 = -\alpha \\ \text{---} & w_u/V_0 = -\alpha x \\ \text{---} & w_u/V_0 = -\alpha y^2/\beta^2 \end{aligned}$$

(a) Wing plan form.

(b) Load distribution at $x=1$.

FIGURE 22.—Load distribution on triangular wings with specified twist.

$$\frac{\Delta p}{q} = \frac{b_0 + b_1 \theta}{\sqrt{\theta_0^2 - \theta^2}} \quad (175)$$

By symmetry, the coefficient b_1 in equation (175) must be zero and b_0 can be evaluated by placing equation (175) into (170) and integrating. There results the solution for the pressure coefficient shown in figure 22 where $\alpha = a$ and already presented as equation (146).

One can go on to show that if, as for a wing pitching about the apex at a rate Q , (see reference 18),

$$w_u = -Qx, \quad \frac{\beta^* w_u}{x^\kappa V_0} = \frac{-\beta Q}{V_0}, \quad \kappa=1 \quad (176)$$

then

$$\frac{\Delta p}{q} = \frac{4xQ}{V_0 \beta \sqrt{\theta_0^2 - \theta^2}} \left[\frac{2\theta_0^2 - \theta^2}{\frac{\theta_0^2 K}{1-\theta_0^2} + \frac{1-2\theta_0^2}{1-\theta_0^2} E} \right] \quad (177)$$

where the complete elliptic integrals K and E have a modulus equal to $k = \sqrt{1-\theta_0^2}$. Further, if

$$\frac{w_u}{V_0} = h y^2, \quad \frac{\beta^* w_u}{x^\kappa V_0} = h \eta^2, \quad \kappa=2 \quad (178)$$

then

$$\frac{\Delta p}{q} = \frac{8h}{\beta} \left(\frac{x}{\beta}\right)^2 \theta_0^4 \left\{ \frac{[2\theta_0^2 K - (1+\theta_0^2)E] + [-(3-\theta_0^2)K + (4-2\theta_0^2)E]\theta^2}{[-5\theta_0^4 K^2 + 8\theta_0^2(1+\theta_0^2)KE + (4\theta_0^4 - 19\theta_0^2 + 4)E^2] \sqrt{\theta_0^2 - \theta^2}} \right\} \quad (179)$$

where $k = \sqrt{1 - \theta_0^2}$ ($= \sqrt{1 - m^2 \beta^2}$) is the modulus of the complete elliptic integrals. These solutions are all shown in figure 22, where in one case $a = Q/V_0$ and in the other $a = -h/\beta^2$.

If the function $\beta^* w_u/x^* V_0$ is discontinuous but a polynomial in each interval of continuity, the solution given as equation (173) still applies. For example, consider the case when $\kappa = 0$ and w_u/V_0 is a constant that changes sign in crossing the x axis. (See fig. 23.) For simplicity let $\theta_1 = -\theta_0$, then by equation (173)

$$\frac{w_u}{V_0} = -\delta \frac{\eta}{|\eta|}, \quad \kappa = 0 \quad (180)$$

FIGURE 23.—Loading on differentially deflected triangular plate.

Again, as in the development of equation (175),

$$\frac{\Delta p}{q} = \frac{b_0 + b_1 \theta}{\sqrt{\theta_0^2 - \theta^2}} \quad (181)$$

Now, however, the solution must exhibit odd symmetry and the constant b_0 is zero. The constant b_1 can be evaluated by substituting equation (181) into equation (170). There results, finally,

$$\frac{\Delta p}{q} = \frac{8 \delta \theta_0 \theta}{\pi \beta \sqrt{\theta_0^2 - \theta^2}} \quad (182)$$

This solution is shown graphically in figure 23.

The methods described above can also be applied to problems involving wings with thickness and without lift. In these cases one constructs a radial element emanating from the origin and possessing a quasi-conical thickness distribution

$$\frac{dz_u}{dx} = \lambda_u = C y^* \quad (183)$$

The derivation of the induced pressure field associated with the element follows closely the analysis in the lifting case. First a triangular plan form is considered with one side having the slope m and the other parallel to the free-stream direction. The thickness is assumed to have the form given by equation (183) so that the pressure coefficient can be obtained from the equation

$$C_p = \frac{-2}{\pi} \int \lambda_u dy \int \frac{(x-x_1) dx_1}{[(x-x_1)^2 - \beta^2 (y-y_1)^2]^{3/2}} \quad (184)$$

Make the same notational changes as in the analysis of the lifting case; construct the element by taking the partial derivative with respect to θ ; and, finally, distribute weighted elements over the wing plan form by making C a function of θ and integrating with respect to θ between the limits θ_1 and θ_0 . There results

$$\left(\frac{\beta}{x}\right)^* C_p = \frac{-2(\kappa+1)}{\pi \beta} \int_{\theta_1}^{\theta_0} \theta^* C(\theta) H_1(\theta, \eta) d\theta \quad (185)$$

where

$$H_1(\theta, \eta) = \int_1^\eta \frac{t(\eta-t)^* dt}{(\theta-t)^{\kappa+2} \sqrt{1-t^2}}, \quad \theta_1 \leq \theta \leq \eta$$

$$= \int_{-1}^\eta \frac{t(\eta-t)^* dt}{(\theta-t)^{\kappa+2} \sqrt{1-t^2}}, \quad \eta < \theta \leq \theta_0$$

The boundary conditions require $(\beta/x)^* C_p$ to be a polynomial of degree κ in η . If the $(\kappa+1)^{\text{st}}$ derivative of equation (185) is set equal to zero, the relation

$$0 = \frac{\partial^{\kappa+1}}{\partial \eta^{\kappa+1}} \int_{\theta_1}^{\theta_0} \frac{\theta^* C(\theta) d\theta}{(\theta-\eta)^{\kappa+2}} = \left(\frac{\partial}{\partial \eta}\right)^{\kappa+1} \frac{1}{(\kappa+1)!} \int_{\theta_1}^{\theta_0} \frac{\theta^* C(\theta) d\theta}{\theta - \eta} \quad (186)$$

results. The function $C(\theta)$ satisfies the same integral equation that arose in the lifting case, and the solution can therefore be written immediately in the form

$$\lambda_u = y^* C(\theta) = \left(\frac{x}{\beta}\right)^* \sum_{i=0}^{\kappa+1} \frac{b_i \theta^i}{\sqrt{(\theta_0 - \theta)(\theta - \theta_1)}} \quad (187)$$

Again the coefficients b_i must be determined from known conditions about the surface geometry.

Consider first the case when the pressure is constant over an unyawed triangular plan form as in figure 24. Thus

$$C_p = C_{p_0}, \quad \kappa = 0 \quad (188)$$

and (b_1 being zero by symmetry)

$$\lambda_u = \frac{dz_u}{dx} = \frac{b_0}{\sqrt{\theta_0^2 - \theta^2}} \quad (189)$$

Evaluating the constant b_0 by substituting equation (189) into (185), it can be shown that the surface ordinate is

$$z_u = \frac{(1 - \theta_0^2) C_{p_0}}{2m^2(K - E)} \sqrt{m^2 x^2 - y^2} \quad (190)$$

where the modulus of K and E is $k = \sqrt{1 - \theta_0^2}$. This result, which is the equation of an elliptical section, is shown in figure 24.

(a)

(b)

(c)

- (a) Triangular wing with subsonic edges.
 (b) Section AA for C_p constant.
 (c) Section AA for C_p varying linearly with x .

FIGURE 24.—Symmetrical triangular wing with specified pressure distributions.

Finally, consider an unyawed triangular wing for which the pressure varies linearly in the x direction. For such a case

$$C_p = (C_{p_0})x, \quad \kappa = 1 \quad (191)$$

and (b_1 again being zero by symmetry)

$$\lambda_u = \frac{dz_u}{dx} = \frac{x}{\beta} \frac{b_0 + b_2 \theta^2}{\sqrt{\theta_0^2 - \theta^2}} \quad (192)$$

from which it immediately follows by integration

$$z_u = \frac{b_0 x}{2\beta^2 m^2} \sqrt{m^2 x^2 - y^2} + \frac{y^2}{2\beta^2 m^2} (b_0 + 2\beta^2 m^2 b_2) \operatorname{arcosh} \frac{mx}{y} \quad (193)$$

Placing equation (192) into (185) and integrating, one can eventually show

$$C_{p_0} = \frac{2x}{\beta^2 (1 - \theta_0^2)^2} \{ b_0 [2K - E(3 - \theta_0^2)] + b_2 [(\theta_0^4 + \theta_0^2)K - 2\theta_0^2 E] \} \quad (194)$$

It is immediately apparent that the wing shape required to support a linear pressure gradient in the x direction is not unique, that there are, in fact, an infinite number of shapes that will induce the same pressure distribution. (The converse, however, is not true. That is, a given shape has only one possible distribution of pressure.)

Squire (reference 17) considered the thickness distribution that is obtained by neglecting the arc hyperbolic function in equation (193). His result corresponds to the case when b_0 is $-2\beta^2 m^2 b_2$ and can be written specifically

$$z_u = \frac{b_0 x}{2\beta^2 m^2} \sqrt{m^2 x^2 - y^2} \quad (195a)$$

$$C_{p_0} = \frac{b_0 x}{\beta^2 (1 - \theta_0^2)^2} [(3 - \theta_0^2)K - E(4 - 2\theta_0^2)] \quad (195b)$$

where b_0/β^2 can be related to the thickness chord ratio of the wing and the apex angle. Figure 24 shows how equation (194) can be used to obtain several triangular wing shapes all having the same linear pressure distribution. (It is interesting to note that no combination of b_0 and b_2 exists that will give a real wing shape with zero pressure coefficient since the resulting negative ordinates would require the surface to cross itself.)

REPORT 1055

COMPARISON OF THEORETICAL AND EXPERIMENTAL HEAT-TRANSFER CHARACTERISTICS OF BODIES OF REVOLUTION AT SUPERSONIC SPEEDS ¹

By RICHARD SCHERRER

SUMMARY

An investigation of the three important factors that determine convective heat-transfer characteristics at supersonic speeds, location of boundary-layer transition, recovery factor, and heat-transfer parameter has been performed at Mach numbers from 1.49 to 2.18. The bodies of revolution that were tested had, in most cases, laminar boundary layers, and the test results have been compared with available theory. Boundary-layer transition was found to be affected by heat transfer. Adding heat to a laminar boundary layer caused transition to move forward on the test body, while removing heat caused transition to move rearward. These experimental results and the implications of boundary-layer-stability theory are in qualitative agreement. Theoretical and experimental values of the recovery factor, based on the local Mach number just outside the boundary layer, were found to be in good agreement for both laminar and turbulent boundary layers on both of the body shapes that were investigated. In general, values of the heat-transfer parameter (Nusselt number divided by the square root of the Reynolds number) as determined for both heated and cooled cones with uniform and nonuniform surface temperatures, were in good agreement with theory. It was also found that the theory for cones could be used to predict the values of heat-transfer parameter for a pointed body of revolution with large negative pressure gradients with good accuracy.

INTRODUCTION

Aerodynamic heating of a body flying at high speeds results from the viscous dissipation of kinetic energy in the boundary layer. Although the viscosity of air is quite low, the increase in surface temperature due to aerodynamic heating becomes large at supersonic speeds. At speeds as low as 1,000 feet per second under conditions where the ambient temperature is above 40° F, the temperature rise is sufficient to make cabin cooling a necessity for man-carrying aircraft. At higher speeds the temperature rise can become large

enough to cause serious structural problems. Although some natural cooling by radiation can be expected, continuous flight of airplanes and missiles at supersonic speeds requires some form of surface or internal temperature control.

In order to design cooling systems or adequate insulation for high-speed aircraft, the heat-transfer coefficients and the reference surface temperature (recovery temperature) must be known. The basic variables, the recovery temperature, and the Nusselt number are primarily functions of Mach number and Reynolds number. In addition to being influenced by the Mach number and Reynolds number, the Nusselt number is affected by a variety of other factors, the most important of which are surface-temperature gradients, longitudinal surface-pressure gradients, and body shape.

The recovery temperature and heat-transfer characteristics of bodies with laminar boundary layers are markedly different from those with turbulent boundary layers and for this reason the extent of the laminar-flow region in the boundary layer must be known. Because the over-all rates of heat transfer are, in general, less for laminar than for turbulent boundary layers, a body with a laminar boundary layer would be heated less rapidly than one with a turbulent boundary layer. This fact is of particular importance in the design of very high-speed missiles, and information on conditions which control the extent of the laminar-flow region in the boundary layer is needed. The theoretical work by Lees, reported in reference 1, indicates that heat transfer has a marked effect on the stability of laminar boundary layers on smooth flat plates; as a result, it is expected that there is a corresponding marked effect of heat transfer on the location of transition. Lees' theory indicates that the effect of transferring heat from a surface to a laminar boundary layer is to decrease the damping of small disturbances in the boundary layer, whereas extracting heat tends to increase the damping of small disturbances. The theory also indicates that at each supersonic Mach number a rate of heat extraction from a laminar boundary layer greater than a certain value results in complete damping of any small disturbances. This is of importance in the design of supersonic aircraft because of the possibility of extending the laminar region of the boundary layer.

The laminar boundary layer in compressible flow has proven to be much more amenable to theoretical treatment than the turbulent boundary layer. For this reason, a large

Gowen, 1949; NACA TN 1975, "Experimental Investigation of Temperature Recovery Factors on Bodies of Revolution at Supersonic Speeds" by William R. Wimbrow, 1949; NACA TN 2087, "Comparison of Theoretical and Experimental Heat Transfer on a Cooled 20° Cone with a Laminar Boundary Layer at a Mach Number of 2.02" by Richard Scherrer and Forrest E. Gowen, 1950; NACA TN 2131, "Boundary-Layer Transition on a Cooled 20° Cone at Mach Numbers of 1.5 and 2.0" by Richard Scherrer, 1950; and NACA TN 2148, "Laminar-Boundary-Layer Heat-Transfer Characteristics of a Body of Revolution with a Pressure Gradient at Supersonic Speeds" by William R. Wimbrow and Richard Scherrer, 1950.

body of theory exists for the laminar case while only a few investigators have developed heat-transfer theories for the turbulent case. For an example of the latter, see reference 2.

The heat-transfer literature devoted to temperature-recovery factors, reviewed in reference 3, indicates that theoretically the recovery factor for laminar boundary layers is equal to the square root of the Prandtl number, and, for turbulent boundary layers, is approximately equal to the cube root of the Prandtl number. Because in theory the recovery factors at moderate Mach numbers (1.0 to 3.0) are largely determined by the type of boundary layer, little variation would be expected between the recovery factors measured on flat plates, cones, and bodies with longitudinal pressure gradients.

The theory for determining heat transfer in the laminar boundary layer on a smooth, flat plate with a uniform surface temperature has been developed by both Crocco, and Hantsche and Wendt (reference 4).² The work of Crocco has been extended by Chapman and Rubesin (reference 5) to include the effects of nonuniform surface temperatures. The effects of body shape and longitudinal surface pressure gradients on the heat-transfer characteristics of laminar boundary layers have been investigated theoretically in references 6 and 7. Because of the additional variables considered, the results of these two investigations are complex and therefore are difficult to apply. In reference 8, Mangler has presented relations whereby the characteristics of laminar boundary layers on any body of revolution can be determined if the characteristics of the laminar boundary layer on a related two-dimensional body are known. These relations can be used to determine the heat-transfer characteristics of a cone from those of a flat plate, but beyond this application the relations are somewhat restricted because of the difficulty in determining laminar boundary-layer characteristics on two-dimensional bodies with pressure gradients. For a body of revolution with negative pressure gradients (ogive, parabolic arc, etc.) one can infer that the boundary layer, and hence the heat transfer, is affected by two factors not affecting the boundary layer on cones. One is the decreasing rate of change of circumference with length, and the other is the pressure gradient. Since the effects of these two factors on the heat transfer tend to be compensating, it is possible that the theory for laminar boundary layers on cones may be used to predict the heat transfer in the negative-pressure-gradient regions of other bodies of revolution.

The present investigation was undertaken to determine the applicability of the available theoretical results of boundary-layer transition, recovery factor, and heat-transfer parameter. The purposes of the experimental phase of the investigation are:

1. To determine if heat transfer, both to and from a surface, affects boundary-layer transition.
2. To measure recovery factor on cones and on a body with a negative longitudinal pressure gradient for both laminar and turbulent boundary layers.
3. To measure the heat transfer in laminar boundary layers on cones with uniform and nonuniform surface temperatures.
4. To measure the heat transfer in a laminar boundary layer on a body with a negative longitudinal pressure gradient

Tests were conducted at several Mach numbers from 1.49 to 2.18 on three bodies of revolution under the following conditions:

1. Uniform surface pressure and a uniform temperature, heated surface (20° cone).
2. Uniform surface pressure and a uniform temperature, cooled surface (20° cone).
3. Uniform surface pressure and a nonuniform temperature, heated surface (20° cone, modified).
4. Nonuniform surface pressure and a uniform temperature, heated surface (parabolic-arc body).

Although the theory for laminar boundary layers indicates no basic change in heat-transfer processes between heated and cooled surfaces, it was considered desirable to obtain data under both conditions of heat flow in order to have the comparison of theory and experiment cover a broad range of surface temperature.

NOTATION

The following symbols have been used in the presentation of the theoretical and experimental data:

A	surface area of an increment of body length, square feet
C_d	skin-friction drag coefficient based on surface area, dimensionless
c_p	specific heat at constant pressure, Btu per pound, °F
C_r	temperature recovery factor, $\left(\frac{T_r - T_v}{T_0 - T_v}\right)$, dimensionless
g	gravitational acceleration, 32.2 feet per second squared
H	wind-tunnel total pressure, pounds per square inch absolute
h	local heat-transfer coefficient $\left[\frac{Q}{A(T_r - T_s)}\right]$, Btu per second, square foot, °F
k	thermal conductivity, Btu per second, square foot, °F per foot
l	total body length, feet
M	Mach number, dimensionless
Nu	local Nusselt number $\left(\frac{h_s}{k_v}\right)$, dimensionless
p	static pressure, pounds per square inch absolute
Pr	Prandtl number $\left(\frac{c_p \mu_v}{k_v}\right)$, dimensionless
Q	total rate of heat transfer for an increment of body length, Btu per second
q	local rate of heat transfer, Btu per second, square foot
Re	local Reynolds number $\left(\frac{\rho_v V s}{\mu_v}\right)$, dimensionless
Re_l	free-stream Reynolds number based on body length $\left(\frac{\rho_a U l}{\mu_a}\right)$
r	body radius, feet
s	distance from nose along body surface, feet
T	temperature, °F
ΔT	temperature increment, °F
T_r	recovery temperature (surface temperature at condition of zero heat transfer), °F

² The work of Crocco, Hantsche and Wendt, and others has been conveniently summarized by Johnson and Rubesin in reference 4.

$$T_r^* = \frac{T_r + 460}{T_e + 460}$$

$$T_s^* = \frac{T_s + 460}{T_r + 460}$$

$T_{s\infty}$	theoretical surface temperature for infinite boundary-layer stability, °F
U	free-stream velocity, feet per second
V	velocity just outside the boundary layer, feet per second
W	flow rate of coolant, pounds per second
x	distance from the nose along the body axis, feet
x^*	length ratio $\left(\frac{x}{l}\right)$, dimensionless
μ	viscosity, pounds per foot, second
ρ	air density, pounds per cubic foot

SUBSCRIPTS

In addition, the following subscripts have been used:

a	fluid conditions in free stream
c	coolant
0	stagnation conditions in the free stream
s	conditions at the body surface
v	fluid conditions just outside the boundary layer
w	wind-tunnel wall

APPARATUS AND TESTS

Heat-transfer tests were conducted with three bodies: a heated 20° cone, a cooled 20° cone, and a heated parabolic-arc body. The two conical bodies were also used to investigate the effect of heat transfer on boundary-layer transition. The surface of each of the three models was ground and polished until the maximum roughness was less than 20 micro-inches in an attempt to eliminate surface finish as a variable in the investigation. All of the heat-transfer tests were similar in that measurements of the test conditions, local surface temperature T_s , and the incremental rates of heat transfer Q were made with each body. The recovery temperature, T_r , was measured in each set of experiments with the test-body heating or cooling system shut off and after both the wind tunnel and surface temperatures had reached equilibrium. The dimensionless heat-transfer parameter ($Nu/Re^{1/2}$, for laminar boundary layers) was determined from the experimental data by use of the following equation:

$$\frac{Nu}{Re^{1/2}} = \frac{Qs}{Ak_s(T_s - T_r)} \left(\frac{\mu_s}{\rho_s V s} \right)^{1/2} \quad (1)$$

WIND TUNNEL

The tests with all of the models were performed in the Ames 1- by 3-foot supersonic wind tunnel No. 1. This closed-circuit, continuous-operation wind tunnel is equipped with a flexible-plate nozzle that can be adjusted to give test-section Mach numbers from 1.2 to 2.4. Reynolds number variation is accomplished by changing the absolute pressure in the tunnel from one-fifth of an atmosphere to approximately three atmospheres—the upper limit on pressure being a function of Mach number and ambient temperature. The water content of the air in the wind tunnel is maintained at less than 0.0001 pound of water per pound of dry air in order to eliminate

humidity effects in the nozzle. All of the bodies tested were mounted in the center of the test section on sting-type supports. The total temperature of the air stream was measured by nine thermocouples in the wind-tunnel settling chamber.

HEATED CONE TESTS

Test body.—The details of the heated cone are shown in figure 1, and a photograph of the cone in the wind tunnel is shown in figure 2. The shell was machined from stainless steel because of its high electrical resistance, and all other parts were made of copper. Several longitudinal wall-thickness distributions, obtained by remachining the inside surface of the cone, were used to obtain different longitudinal surface-temperature distributions. The cone was heated by passing a high-amperage alternating electrical current (800 amperes maximum) at low voltage (0.45 volts maximum) longitudinally through the cone shell. Because the electrical resistance of the solid nose of the cone was very small, the forward 25 percent of the cone was, in effect, unheated.

Instrumentation.—The wiring diagram of the cone, showing the electrical heating circuit and the temperature- and power-measurement apparatus, is shown in figure 3. Nine iron-constantan thermocouples were installed at equal length increments along the cone to determine the surface-temperature distributions. The thermocouples were installed in holes drilled completely through the shell and were soldered in place. The ten voltage leads were installed in a similar manner and were arranged on the selector switch so as to measure the voltage drop of each successive increment along the cone. These measurements, with the current measurements, determined the local heat input to the cone.

Test procedure.—Data were obtained at length Reynolds numbers of approximately 2.5 and 5.0 million at Mach numbers of 1.50 and 1.99. Cone temperatures of 30° F and 60° F above the wind-tunnel total temperature were selected as nominal values at which to obtain data. The surface temperatures were set to the desired values by adjusting the input voltage, and, with the cone at the desired temperature, the following data were recorded: air stream total temperature and pressure, test-section static pressure, air stream humidity, current, incremental voltages, and surface temperatures.

Accuracy.—The accuracy of the experimental data was determined by estimating the uncertainty of the individual measurements which entered into the determination of the final results. The estimated uncertainties of the basic measurements are as follows:

Total temperature, T_0	$\pm 1.5^\circ \text{ F}$
Surface temperature, T_s	$\pm 0.5^\circ \text{ F}$
Total pressure, H	$\pm 0.01 \text{ psia}$
Static pressure, p	$\pm 0.01 \text{ psia}$
Current	$\pm 2 \text{ percent}$
Incremental voltages	$\pm 2 \text{ percent}$
Cone dimensions	$\pm 0.005 \text{ inch}$

The maximum probable error of any given parameter was obtained from the component uncertainties by the method described in reference 9. The maximum probable error of the heat-transfer parameter $Nu/Re^{1/2}$ is ± 6.8 percent and

FIGURE 1.—Details of the electrically heated 20° cone.

FIGURE 2.—Heated 20° cone installed in the test section of the 1- by 3-foot supersonic wind tunnel No. 1.

that of the recovery factor is ± 1.5 percent. Because the over-all accuracy is largely controlled by the accuracy of the total-temperature measurements, the experimental scatter of data points obtained at a fixed value of the total temperature is much less than that indicated by the values of over-all accuracy. Although the small pressure gradient (± 1 percent of the average dynamic pressure) in the test section of the wind tunnel was neglected in the reduction of the test data, its effect has been included in the calculation of the maximum probable error.

An effort was made to determine the magnitude of the error due to heat radiation from the cone to the tunnel walls by experimental means. The radiant-heat loss was evaluated by the extrapolation to zero pressure of data obtained at several low values of total pressure with the wind tunnel in operation³ and was found to be negligible.

COOLED-CONE TESTS

Air-cooled cone.—The construction details and the path of the cooling air through the cone are shown in figure 4. The outer shell was made of stainless steel and had a wall thickness of only 0.028 inch in order to minimize the heat conduction along the shell in the instrumented area. The inner cone also was made of stainless steel and had a wall thickness of 0.070 inch which was thin enough to make all conduction effects in the inner cone negligible. The annular gap between the cones was designed to give a uniform surface temperature in the instrumented region ($x^*=0.4$ to 0.8). Turbulent flow in this annular gap was necessary to obtain the most uniform distribution of coolant temperature across the gap; therefore, the internal cooling system was designed to operate at a Reynolds number sufficiently high to insure turbulent flow. In addition, the outer surface of the inner cone was roughened with $\frac{1}{32}$ -inch-wide circumferential grooves spaced at $\frac{1}{4}$ -inch intervals. During the investigation

³ An attempt was made to obtain the radiation calibration with the tunnel inoperative, but the cone surface temperatures were found to be very erratic because of free-convection currents. For this reason, the method was abandoned.

FIGURE 3.—Wiring diagram for the electrically-heated 20° cone.

FIGURE 4.—Air-cooled cone.

on, tests were made with coolant flow rates of 70 percent and 40 percent of the design value to determine the effect of changes in the internal-flow Reynolds number on the internal-temperature measurements. The results indicated that this effect was negligible.

Cooling system.—The primary requirement of the cooling system was that it provide an adjustable and stable outlet temperature at a constant coolant flow rate. This requirement was satisfied by the cooling system shown in figure 5. The clean, dry air which was used as the coolant in the cone was obtained from the make-up air system of the wind tunnel and could be cooled to a minimum temperature of -90°F . In the development of the cooling system it was found that the use of the recovery heat exchanger provided a marked increase in thermal stability. The temperature drift of the cooling system was extremely slow and amounted to less than $\pm 0.1^{\circ}\text{F}$ per minute.

Instrumentation.—Local rates of heat transfer were obtained by measuring the incremental temperature changes of a known weight-flow of coolant flowing along the annular gap between the inner and outer cones. The incremental coolant temperatures were measured by iron-constantan thermo-

couples spaced 1 inch apart along the annular gap. Three thermocouple junctions were located 120° apart midway between the walls of the gap at each of the five longitudinal stations. The surface temperature was measured with stainless-steel-constantan thermocouples consisting of the cone shell and thin (0.002 inch thick) constantan ribbons. The tips of the ribbons were soldered into holes in the shell. The thin strips were cemented to the inner surface of the shell. This installation minimized the interference of the constantan wires with the flow of air in the coolant passage. The flow rate of cooling air was measured with a rotameter located at the outlet of the cooling system.

Test procedure.—The tests were performed at three values of the wind-tunnel total pressure which gave length Reynolds numbers of 2.2, 3.6, and 5.0 million. Data were taken at the recovery temperature and at three nominal surface temperatures at each Reynolds number. The minimum surface temperature obtainable with the cooling system at each pressure, and temperatures approximately 20°F and 40°F above the minimum temperatures, were selected. The investigation was performed only at one Mach number (2.02) because the theory for heat transfer

FIGURE 5.—Diagram of the air cooling system for the cooled 20° cone.

with uniform surface temperature and previous tests with the heated cone both indicated that the effect of Mach number on heat-transfer parameter is small within the range available in the wind tunnel (1.2 to 2.4). Schlieren observations, liquid-film tests, and the absence of discontinuities in the temperature-distribution measurements that would denote transition indicated that the boundary layer remained laminar for all test conditions.

In order to measure the effects of cooling on boundary-layer transition, it was necessary to have the transition point near the center of the instrumented area of the cone. However, it was known from the results of tests of the unheated cone that transition would occur downstream from the instrumented area at the condition of zero heat transfer at the maximum available Reynolds number. The required forward movement of transition was accomplished by the use of three small grooves around the cone at approximately the 8-, 10-, and 12-percent-length stations. All the grooves were 0.010 inch wide and 0.015 inch deep, and extreme care was taken to make them of uniform depth and with uniformly sharp edges in an attempt to obtain the same longitudinal position of transition on all rays of the cone. Data were obtained at several surface temperatures below the recovery temperature in successive decrements of about 10° F. The minimum surface temperatures investigated were the temperatures at which transition moved out of the instrumented area of the cone. The boundary-layer transition tests were conducted at a nominal length Reynolds number of 5.0 million at Mach numbers of 1.5 and 2.0.

Accuracy.—The accuracy of the final results is based on the accuracy of the individual measurements involved and on the probable uncertainty of some of the measurements

due to peculiarities of the test apparatus. The estimated accuracy of the individual measurements in this test is as follows:

Total temperature, T_0	$\pm 1.5^\circ$ F
Surface temperature, T_s	
At maximum T_s	$\pm 1.5^\circ$ F
At minimum T_s	$\pm 4.5^\circ$ F
Coolant-temperature increment, ΔT_c	
At maximum T_s	$\pm 0.07^\circ$ F
At minimum T_s	$\pm 0.05^\circ$ F
Internal air-flow rate, W (at design flow rate).....	$\pm 1.4\%$
Cone dimensions.....	± 0.002 in.
Cone-segment surface areas, A	$\pm 1.4\%$
Total pressure, H	± 0.01 psia
Static pressure, p	± 0.01 psia

Although the surface-temperature thermocouples were calibrated and were accurate to within $\pm 0.5^\circ$ F, the experimental variations from curves faired through the sets of surface-temperature data were found to exceed this value. These variations are believed to have resulted from a non-uniform coolant distribution in the annular gap. The accuracy of the surface-temperature measurements at each set of test conditions was taken as the local difference between the faired curves and the data point farthest from the curves. The local values of surface temperature used in the reduction of the data were obtained from the faired curves.

Because the range of temperature differences between the cone and wind-tunnel-wall temperatures is similar to that in the heated-cone tests, the effect of radiant heat transfer on the experimental accuracy again has been neglected. The effects of longitudinal and circumferential heat conduction in the thin stainless-steel inner cone aft of the 50-percent-length station have been neglected. An approximate calculation of

the actual conduction along the inner cone and through the inner-cone shell revealed that these effects were only about three-tenths of 1 percent of the total heat transfer. As in the case of the heated cone, the effect of the small static pressure gradient in the wind-tunnel test section has been neglected.

As in the heated-cone tests, the over-all accuracy of the final values of the heat-transfer parameter was calculated from the accuracy or uncertainty of each of the individual measurements for all test conditions by the method of reference 9. Because of the variation in the uncertainty of the surface temperature and internal-temperature increments, the final accuracy of the heat-transfer parameter varies from ± 12 percent at the most forward section of the cone to ± 8 percent at the rear of the cone.

PRESSURE-GRADIENT BODY TESTS

Body and instrumentation.—The body was axially symmetric and its radius at any longitudinal station is given by the relation

$$\frac{r}{L} = \frac{1}{3} \left[\left(\frac{x}{L} \right) - \left(\frac{x}{L} \right)^2 \right] \quad (2)$$

Since the forward portion of the body was adequate for the purpose of the present investigation, the length L in equation (2) was assigned a value of 18 inches, but only the first 8½ inches of the total length were employed. The vertex angle of the test body was 37° and its fineness ratio was 2.83. Like the cones, the exterior shell of the body was machined from stainless steel. The heating circuit, instrumentation and general design of the parabolic-arc body were similar to those of the heated cone; details of the body are shown in figure 6. The shell thickness was designed to provide a uni-

form surface temperature at a Mach number of 1.5 by assuming that the theory for cones was applicable. In addition to the heated body, another body identical in contour was employed to determine the pressure distribution and, consequently, the Mach number distribution just outside the boundary layer along the body.

Procedure and accuracy.—The test procedure and accuracy with the parabolic-arc body were the same as those with the electrically-heated 20° cone. Data were obtained at nominal length Reynolds numbers of 2.5, 3.75, and 5.0 million at Mach numbers of 1.49 and 2.18. Surface temperatures of 120°F , 160°F , and 200°F were arbitrarily chosen as values at which to obtain data. Pressure-distribution measurements also were made at the same Mach numbers and total pressures as for the heat-transfer measurements. Because the local static pressures on the parabolic-arc body were measured, the maximum probable error of the recovery factor is ± 1 percent rather than ± 1.5 percent as in the case of the conical bodies.

RESULTS AND DISCUSSION

EFFECT OF HEAT TRANSFER ON BOUNDARY-LAYER TRANSITION

The effect on transition of adding heat to a laminar boundary layer at a Mach number of 1.99 is shown by the longitudinal surface-temperature distributions in figure 7. The effect of removing heat from a laminar boundary layer at Mach numbers of 1.50 and 2.02 is shown in figure 8. The start of transition is indicated by an abrupt decrease in surface temperature for the case of heat addition and by a rise in surface temperature with no heat transfer or when heat is removed from the boundary layer. These changes in surface temperature result from the difference in heat-

FIGURE 6.—Details of the electrically-heated parabolic body.

transfer coefficients between the laminar and turbulent boundary-layer regions. Only the data from one side of the cooled cone are presented in figure 8 because transition occurred in a similar manner on the opposite side, but at a position approximately 5 percent of the cone length aft of that shown at all test conditions. It should be noted that the lower curve in figure 7 and the upper curves in figure 8 were obtained at the condition of zero heat transfer ($T_s = T_r$).

FIGURE 7.—The effect on transition of adding heat to the laminar boundary layer on a 20° cone; $M=1.99$, $Re_l=5.0 \times 10^6$.

In the case of the cooled cone (fig. 8), the fact that the rise in surface temperature is indicative of transition has been verified in four ways:

1. Liquid-film tests at the same length Reynolds number, at recovery temperature, have indicated transition in the region where the rise in surface temperature occurs.

2. The surface-temperature distributions ahead of the rise in surface temperature are almost identical in shape with those obtained in tests with the same body for which the measured heat transfer indicated laminar flow.

3. The region in which the rise in surface temperature occurs moved forward with an increase in the number of grooves.

4. The recovery factor increased by 0.04 in the region where the rise in surface temperature occurs,⁴ which is in agreement with the change between laminar and turbulent flow obtained both in theory and in other experiments.

The variation of the extent of the laminar boundary layer along the heated and cooled cones indicates that heat addition promotes early transition while removal delays transition. The theory of reference 1 and these results are in

⁴ The recovery factor on this model, without grooves, was 0.85, which is in agreement with the results for a laminar boundary layer obtained with the other models. The absolute values of the recovery factors ahead of and behind the rise in surface temperature were found to decrease continuously with an increase in number of grooves, but their difference was always 0.04 ± 0.005 . With the three grooves that were used, the laminar boundary-layer recovery factor was 0.81 and the turbulent boundary-layer value was 0.85. The reason for this change in recovery factor with number of grooves is unknown.

FIGURE 8.—Effect on transition of removing heat from a laminar boundary layer on a 20° cone with a small initial roughness.

qualitative agreement. For the present test conditions with the cooled cone, the theory indicates that the boundary layer should be infinitely stable at surface temperatures ($T_{s\infty}$) of -6.6°F and 49.0°F at Mach numbers of 1.5 and 2.0 respectively. The data shown in figure 8(b) show that transition occurred at surface temperatures below the theoretical infinite-stability limit at a Mach number of 2.02, and the data shown in figure 8(a) indicate that a similar result is possible at a Mach number of 1.50.

The limited range of the present experiments makes it impossible to draw any definite conclusions regarding the quantitative effect of heat transfer or Mach number on transition. The data indicate, however, that the movement of transition with surface temperature for the cooled cone is at least similar at both Mach numbers. The constant slopes of the lines (in figs. 7 and 8) through the points at the beginning of transition for both cones indicate that, for the present experiments, the increase in the length of laminar run is directly proportional to the difference between the surface and recovery temperatures, and therefore is a linear function of the rate of heat transfer. Although the present experiments have proven qualitatively that heat transfer affects transition, additional experiments at higher Reynolds numbers (without roughness) and in a low-turbulence air stream are required to obtain quantitative data on the effect of heat transfer on boundary-layer transition.⁵

⁵ A recent quantitative study of the effect of heat addition on transition has been made by Higgins and Pappas and published as NACA TN 2351.

RECOVERY FACTOR,*

Typical values of the recovery factor obtained at several Reynolds numbers at nominal Mach numbers of 1.5 and 2.0 with the heated-cone model at the condition of zero heat transfer are shown in figure 9. Data obtained with the cone at a Mach number of 2.0 with various means of causing transition are also shown. Data obtained with the parabolic-arc body are shown in figure 10. The theoretical values indicated in both figures are based on a Prandtl number of 0.719 which is the value for dry air at 70° F. The theoretical recovery factors are therefore 0.848, $Pr^{1/2}$, for laminar boundary layers and 0.896, $Pr^{1/3}$, for turbulent boundary layers.

The experimental values of the recovery factor for turbulent boundary layers on the heated cone were obtained by resorting to artificial means of causing transition. Three methods were used—a ring of 0.005-inch diameter wire, a coat of lampblack-lacquer mixture, and a band of salt crystals. The wire and salt crystals were located at about 1 inch from the cone tip, and the lampblack covered the cone forward of the 1-inch position.

The data shown in figure 9 for laminar boundary layers are in fairly good agreement with theory. The difference between the values for the two Mach numbers in the region $x^*=0.3$ to 0.6 is believed to be partly due to the fact that the average Mach number was used in the reduction of the data. The most rearward data points obtained with a laminar boundary layer at the maximum Reynolds numbers (fig. 9) indicate the beginning of natural transition. The data obtained with turbulent boundary layers are somewhat lower than the theoretical value, but the agreement is considered to be good enough to justify use of the theoretical value for design purposes. The differences between the results obtained with the various roughnesses decrease to small values toward the rear of the cone.

* A detailed discussion of the physical concept of the temperature recovery factor for laminar boundary layers is given by Wimbro in NACA TN 1975.

FIGURE 9.—Typical values of the temperature recovery factor for the 20° cone.

FIGURE 10.—Typical values of the temperature-recovery factor for the parabolic-arc body.

Since the external geometry and surface finish of the heated and cooled cones were identical, there were no essential differences in their recovery factors. For this reason, the recovery factors for the cooled cone are not presented.

The values of recovery factor for the parabolic-arc body with both laminar and turbulent boundary layers were based on the local Mach number just outside the boundary layer and these recovery factors are substantially constant along the body (fig. 10). The values of recovery factor for turbulent boundary layers, obtained by the use of lampblack, are somewhat greater than the values obtained with the cone (fig. 9). The data obtained with a laminar boundary layer on the parabolic-arc body at a Mach number of 2.0 show a gradual increase in recovery factor along the length of the body. This trend in the data is believed to have been caused by a gradual deterioration in the surface finish of the model due to testing and handling. Data obtained at a Mach number of 2.18 with this body when it was new and had a mirror-like finish indicated a constant recovery factor of 0.850. It is possible that surface roughness may cause some increase in the laminar boundary-layer recovery factor.

In general, the agreement between theory and experiment indicates that the recovery temperature on cones and in the negative-pressure-gradient region on bodies of revolution can be computed with satisfactory accuracy by use of the theoretical recovery factors and the local Mach number just outside the boundary layer.

HEAT TRANSFER

Results.—The theoretical values of the heat-transfer parameter for cones with laminar boundary layers and uniform surface temperatures are given by the following equation from reference 4:

$$\frac{Nu}{Re^{1/2}} = \frac{C_d \cdot Re^{1/2}}{2} Pr^{1/3} \sqrt{3} \quad (3)$$

in which the physical properties of the fluid are based on the temperature just outside the boundary layer. Crocco's theoretical calculations give values of the factor $C_d \cdot Re^{1/2}$ of 0.66 and 0.63 for small temperature differences ($T_s - T_r \approx 100^\circ \text{F}$) at Mach numbers of 1.5 and 2.0, respectively. If the Prandtl number is assumed to be 0.72, then the theoretical values of heat-transfer parameter at the two Mach numbers are 0.51 and 0.49.

The surface-temperature and heat-transfer-parameter data for the heated cone with an approximately uniform surface temperature at a Mach number of 1.50 are shown in figure 11 together with the theoretical value of the heat-transfer parameter for a uniform surface temperature (0.51). Similar data obtained at a Mach number of 1.99 for both the approximately uniform and the nonuniform surface temperatures are shown in figure 12, and the theoretical value of heat-transfer parameter for a uniform surface temperature (0.49) is shown for comparison. The data for the least uniform surface temperature shown in figure 12 is replotted in figure 13 and compared with a curve obtained by use of the theory of reference 5. The surface temperature distribution, converted according to the method of reference 8, is also shown in figure 13 and will be discussed later. The values of heat-transfer parameter for the nonuniform surface temperatures have been corrected for the effect of heat conduction in the shell due to the local surface temperature

FIGURE 11.—Heat-transfer characteristics of the heated 20° cone with the most uniform surface temperature; $M=1.50$, $Re_1=2.6 \times 10^6$.

gradients. This correction for the approximately uniform surface temperatures was found to be negligible.

The heat-transfer data obtained with the cooled cone are

FIGURE 12.—Heat-transfer characteristics of the heated 20° cone with various surface-temperature distributions; $M=1.99$, $Re_1=2.6 \times 10^6$.

FIGURE 13.—Comparison of the theory for nonuniform surface temperatures with data from tests of the heated 20° cone; $M=1.99$, $Re_1=2.6 \times 10^6$.

presented in figure 14. All of the longitudinal surface-temperature distributions obtained during the tests were similar in shape, and therefore only three typical distributions, those for a Reynolds number of 2.2 million, are shown. Local values of heat-transfer parameter for the three surface temperatures at each of the three length Reynolds numbers are also presented. The surface-temperature gradient that existed over part of the segment nearest the tip resulted in a conduction loss of $3\frac{1}{2}$ to 4 percent. The heat-transfer data has been corrected for this effect. Downstream of the first element there was no longitudinal conduction correction because the surface temperature in this region was nearly constant. The scatter in the experimental data (fig. 14) is about equal to the estimated maximum probable error which resulted from the inaccuracy of the measurements of the incremental changes in coolant temperature along the heat-transfer passage and from the scatter of the surface-temperature data. The theoretical value of the heat-transfer parameter, 0.49, is also shown in figure 14. The data nearest the nose deviate quite markedly from theory, a fact which is attributed to the effects of surface-temperature gradients on the laminar boundary layer. The values of heat-transfer parameter obtained with the heated cone with the approximately uniform surface temperature at a nominal surface temperature of 100°F (fig. 12) have been plotted in figure 14 for comparison.

FIGURE 14.—Heat-transfer characteristics of the cooled 20° cone; $M=2.02$.

The measured pressure distributions required for the reduction of the heat-transfer data on the parabolic-arc body were reduced to the more convenient form of Mach number distributions and are shown in figure 15. The values of local Mach number were used to determine the local temperature at the outer edge of the boundary layer.

FIGURE 15.—Variation of local Mach number with length as determined by pressure measurements on the parabolic-arc body.

The heat-transfer data for the parabolic-arc body at a free-stream Mach number of 1.49 are shown in figure 16 and data obtained at a Mach number of 2.18 are shown in figure 17. Although heat-transfer data were obtained at three Reynolds numbers, 2.5, 3.75, and 5.0 million, at each Mach number, only representative data are presented in figures 16 and 17. The theoretical values of the heat-transfer parameter for cones are shown in figures 16 and 17 for comparison with the experimental data. In addition, local values of the heat-transfer parameter for a Mach number of 1.5 were computed for the test body by the method of reference 7. These values are shown in figure 16.

Inspection of the surface-temperature curves in figures 16(a), 16(b), and 17 reveals that the temperature at the first measuring station was considerably higher than the temperature at subsequent stations. After the tests were completed it was found that this local hot region was partially caused by poor electrical contact between the copper stinging and the stainless-steel shell. This connection was improved and the body was tested again at a Mach number of 1.49. As shown in figure 16 (c), a much more uniform surface temperature was obtained.

Heat transfer with uniform surface temperature.—All three of the bodies tested had severe surface temperature gradients near the noses because the noses were solid and essentially unheated or uncooled. In the case of the heated bodies, the data obtained with approximately uniform

(a) Original surface-temperature distribution $Re_l = 2.6 \times 10^6$.FIGURE 16.—Heat-transfer characteristics of the parabolic-arc body; $M=1.49$.FIGURE 16.—Continued. (b) Original surface-temperature distribution $Re_l = 3.7 \times 10^6$.FIGURE 16.—Continued. (c) Modified surface-temperature distribution $Re_l = 2.6 \times 10^6$.

surface temperatures (figs. 11, 12, and 16 (c)) indicate that when the large initial surface-temperature gradient is confined to the nose region on a body the effect on the local values of the heat-transfer parameter is small downstream of the initial gradient. In the case of the parabolic-arc body which had the most confined initial gradient region ($x^* = 0$ to 0.16), the data (fig. 16 (c)) indicate that the effect at the most forward data point $x^* = 0.23$ was almost negligible.

The fact that the effect of a surface-temperature gradient is dependent on its lengthwise location on the body can also be shown by the theory of reference 5. In this theory the surface-temperature distribution is expressed in a polynomial form such as the following:

$$T_s^* = a_0 + a_1 x^* + a_2 x^{*2} \dots a_n x^{*n} \quad (4)$$

The heat-transfer parameter for cones is then given by the following equation:

$$\frac{Nu}{Re^{1/2}} = -\frac{1}{2} \sqrt{3} \left[\sqrt{\frac{(T_s + 460)}{(T_v + 460)}} \frac{(T_v + 460) + 216}{(T_s + 460) + 216} \right] \sum_{n=0}^{\infty} \frac{a_n x^{*n} Y_n'(0)}{T_s^* - T_v^*} \quad (5)$$

where a and n are coefficients and exponents, respectively, as shown in equation (4) and the values of $Y_n'(0)$, taken from reference 5, are given in the following table:

n	$Y_n'(0)$
0	-0.5915
1	-0.9775
2	-1.1949
3	-1.3680
4	-1.4886
5	-1.5975
10	-2.0121

Although only the values of $Y_n'(0)$ for positive integer values of n are tabulated, it has been found that forms of equation (4) employing fractional exponents are particularly

useful in reducing the required number of terms in polynomials to give certain surface-temperature distributions. Since polynomials with fractional exponents satisfy the basic differential equations of reference 5, the use of fractional-exponent terms in equation 5 is acceptable. The appropriate values of $Y_n'(0)$ can be obtained for any fractional value of n by interpolation between the values tabulated above.

To illustrate that the effect of a surface-temperature gradient depends upon its position along the body, assume a number of separate surface-temperature distributions all given by the equation

$$T_s^* = a + b(x^*)^n \quad (6)$$

where, for a given distribution, $n = 1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, \frac{1}{16}$, or zero. In going from the larger to the smaller values of n , the region of the large initial temperature gradients for each curve will be confined to a smaller and smaller region near the origin. It is obvious that at $n=0$ the surface temperature will be uniform. Now, turning to the values of $Y_n'(0)$, it can be seen that the values decrease as n decreases. Therefore, the heat-transfer parameter curves (equation (5)) for each successively smaller value of n approach the constant value for a uniform surface temperature ($n=0$). This is the effect that was observed in the experiments. (See fig. 12.)

In the case of the cooled cone, the region of nonuniform surface temperature extended to the 40-percent length station, and the surface-temperature gradient reversed in sign between the 20- and 40-percent length stations. (See fig. 14.) It might be expected from the theory of reference 5 that the lag in the boundary-layer temperature profile could result in a local decrement in the heat-transfer parameter when the surface-temperature gradient reversed. From the previous discussion, where it was shown that the effects of a surface-temperature gradient decrease downstream of the gradient, it would be expected that the agreement between the experimental and theoretical values of heat-transfer parameter would improve toward the rear of the body. These effects are shown by the data of figure 14. It is interesting to note that the local hot region ($x^*=0.2$) on the parabolic-arc body caused surface-temperature distributions similar to those of the cooled cone. (See figs. 14, 16(a), 16(b), and 17.) The effect of the reversal in surface-temperature gradients again caused the local values of heat-transfer parameter to be less than the "uniform-temperature" value.

The curve representing the heat-transfer data from tests of the heated cone with the most uniform surface temperature (see fig. 12) has been replotted in figure 14. As can be seen, in the regions where the effects of the initial surface-temperature gradient are small, the results from tests of the heated and cooled cones are in good agreement. It can be concluded that for the case of laminar boundary layers on bodies with uniform pressures and uniform surface temperatures, the available theory is satisfactory for engineering purposes.

Heat transfer with nonuniform surface temperatures.—The data obtained from tests of the heated cone with the least uniform surface-temperature distribution are replotted in

FIGURE 17.—Heat-transfer characteristics of the parabolic-arc body with the original surface-temperature distribution; $M=2.18$, $Re_1=2.6 \times 10^6$.

figure 13 for comparison with the theory of reference 5. (See equation (5) of the present report.) The first step in this comparison was the conversion of the experimental surface-temperature distribution from that of a cone to the equivalent distribution on a flat plate. Mangler, reference 8, has shown that the conversion is:

$$(x^*_{\text{cone}})^3 = x^*_{\text{plate}} \quad (7)$$

The converted distribution is shown by the "flagged" symbols in figure 13. The second step in the comparison was to determine the values of the coefficients $a_0, a_1, a_2, \dots, a_n$ and values of the exponents of equation (4) so that the equation would fit the converted surface-temperature distribution. It has been assumed from the shape of the curve through the experimental surface-temperature data shown in figure 13 that the dashed extension of the curve in the region $x^* = 0$ to 0.3 is a satisfactory approximation to the actual surface-temperature distribution. Although this assumed portion of the curve and the analytical curve may both be in error in the region $x^* = 0$ to 0.1 on the converted scale, it has already been shown that initial temperature gradients are not critical in determining heat transfer a short distance downstream from the gradients. For this reason, and others that will be discussed later, an expression was derived that fits the data quite accurately only from $x^* = 0.1$ to 0.7.

This equation in dimensionless form is

$$T_s^* - T_\infty^* = 0.425 (x^*)^{1/4} - 0.22 x^* \quad (8)$$

The local heat-transfer parameters obtained by using equations (5) and (8), and converted back to the x^* values for

cones, are shown in the lower half of figure 13. Agreement between theory and experiment would not be expected ahead of the 47-percent length station on the experimental curve because of the increasingly poor fit of the experimental and analytical temperature curves ahead of the 10-percent length station on the converted curve ($0.10^{1/3}=0.47$, equation (7)). However, the theory of reference 5 and the experiments are in quite good agreement downstream of the 47-percent length station.

The abrupt rise in heat-transfer parameter at the rear of the heated cone as shown in figures 11, 12, and 13 ($x^*=0.93$) is not due to surface-temperature gradient effects, but is due to the beginning of transition.

In the preceding discussion it was necessary to accept a poor fit between the data and the analytical surface-temperature distribution (equation (8)) in the region $x^*=0$ to 0.1. Considerable difficulty has been experienced in obtaining sufficiently accurate analytical expressions for the surface-temperature distributions. The obvious approach to obtaining polynomial expressions is the method of least squares or some other method of curve fitting using real, positive integers as exponents. In general, the analytical curves obtained with such methods oscillated about the experimental curve and near $x^*=1.0$ abruptly diverged due to the influence of the last term in the polynomial. It was found that the alternating positive and negative surface-temperature gradients due to the oscillation of the analytical curves resulted in even greater relative oscillations in the corresponding calculated heat-transfer-parameter curves. Also, because of the effect of the values of $Y_n'(0)$ on the coefficients of the polynomial, the abrupt divergence of the heat-transfer parameter resulting from the divergence of the temperature occurred at values of x^* below 1.0. It appears that any satisfactory polynomial with integer exponents must have a large number of terms and must give a fair curve to well beyond $x^*=1.0$. The coefficients of such polynomials are tedious to determine. An alternative procedure which was used in the present investigation, consisted of using a fairly simple analytical expression to obtain a good fit between the curves over the major part of the cone length while accepting differences in the nose region. Although the results for the particular case shown in figure 13 indicate agreement between theory and experiment, downstream of the 47-percent length station, it is evident from the previous discussion that the restrictions imposed by the form of equation (4) limit the application of the theory of reference 5 to only simple variations of surface temperature with body length.

Heat transfer on a body with nonuniform pressure.—The boundary layer on a flat plate grows only in thickness with distance along the surface, while the boundary layer on a pointed body of revolution must spread circumferentially as it grows in thickness. The effect of this circumferential spreading on the boundary-layer thickness, and hence on the heat transfer, varies with the rate of change of circumference with respect to length and can be evaluated for any fair contour by relations given in reference 8. For example, it can be shown that on a cone, for which the pressure and the rate of change of circumference are constant with length, the boundary-layer thickness is less than that on a flat plate by

the factor $1/\sqrt{3}$ and the rate of heat transfer is greater by the factor $\sqrt{3}$. For a parabolic-arc body, the factors defining the boundary-layer thickness and the rate of heat transfer relative to a two-dimensional surface with an equivalent pressure distribution vary from the conical values ($1/\sqrt{3}$ and $\sqrt{3}$, respectively) at the vertex to unity at the point where the rate of change of circumference becomes zero. Therefore, the rate of growth of the boundary layer and the rate of heat transfer on such a body are the same as on a cone at the apex, but the decreasing rate of change of circumference along the body tends to increase the rate of growth of the boundary layer relative to that on a cone and tends to decrease the rate of heat transfer. Although the effect of a pressure gradient on the characteristics of a boundary layer cannot be predicted exactly, it is known that a negative pressure gradient causes the boundary layer to thicken less rapidly with length than is the case if the pressure were constant, regardless of the body shape. Thus, on a body for which both the pressure and the rate of change of circumference decrease with length, the effect of the pressure gradient tends to counteract the effect of the variation of circumference on the boundary-layer characteristics.

The heat-transfer data obtained with the parabolic-arc body and the theoretical values of heat-transfer parameter for uniform-temperature cones (0.51 at a Mach number of 1.49 and 0.48 at a Mach number of 2.18) are shown in figures 16 and 17. It is apparent in figure 16 that the data, the theory for cones, and the method of reference 7, are in fairly good agreement. After the local hot region at the nose of the body had been eliminated, the data shown in figure 16 (c) were obtained. Good agreement between the experimental data, the theory for cones, and the method of reference 7, is again apparent. Because of the good agreement between the theory for cones and the experimental data shown in figure 16 (c), and the agreement shown in figures 16 (a), 16 (b), and 17, it can be expected that when the surface temperature is uniform, good agreement would be obtained at least throughout the test range of Mach number and Reynolds number. It should be noted that the small variation of the individual values of heat-transfer parameter from a fair curve is consistent throughout and is possibly due to small deviations in thickness of the cone shell. Comparison of the data of figure 16 (c) with the data of figures 16 (a), 16 (b), and 17 reveal that there was a slight reduction in the local values of the heat-transfer parameter over most of the body when the negative temperature gradient at the nose was reduced. However, the reduction at each station on the body where it occurred is within the experimental accuracy.

Since the experimental values of the heat-transfer parameter remained essentially constant along the parabolic-arc body, the effect of the negative pressure gradient is apparently opposite and, approximately equal to the effect of the decreasing rate of change of the circumference on the growth of the boundary layer. The present investigation, however, is inconclusive as to the exact individual effects of the pressure gradient and body shape on heat transfer. It has been shown that the local heat transfer for a parabolic-arc body can be calculated with satisfactory accuracy by applying the

theory for cones. Because of the agreement between the results of the experiments, the method of reference 7, and the theory for cones, it appears reasonable to assume that this agreement would be obtained with other pointed body shapes that give rise to uniform negative-pressure gradients. On a body that is more slender than the one tested, the effects of the changing circumference and the pressure gradient would be less and would still tend to counteract each other. Conversely, on a more blunt body both effects should be larger. However, additional experiments with other body shapes covering a wider range of Mach numbers are necessary before the theory for cones can be considered to be applicable to all fair bodies of revolution with negative pressure gradients.

CONCLUSIONS

The results obtained from tests of three bodies of revolution at supersonic velocities have provided information on three important phases of the heat-transfer problem—boundary-layer transition, temperature-recovery factor, and heat-transfer parameter (for laminar boundary layers). The following conclusions are based on these results and comparisons with available theories:

1. The effect of adding heat to a laminar boundary layer is to cause premature transition and the effect of extracting heat is to delay transition although to lesser degree than could be expected from the implications of the theory of Lees (NACA Rep. 876).

2. The recovery temperature on cones and in the negative pressure-gradient region on bodies of revolution can be computed with satisfactory accuracy by use of the theoretical recovery factors for laminar and turbulent boundary layers and the local Mach number just outside the boundary layer.

3. The values of heat-transfer parameter for laminar boundary layers obtained from the theories for uniform surface temperatures (Crocco, and Hantsche and Wendt) are in good agreement with experiment for both heated and cooled bodies.

4. Values of heat-transfer parameter for laminar boundary layers obtained from the theory of Chapman and Rubesin

for nonuniform surface temperatures are in good agreement with experiment; however, the agreement is markedly dependent upon obtaining an exact analytical expression for the experimental surface-temperature distribution.

5. The values of heat-transfer parameter on the forward half of a pointed parabolic-arc body with a laminar boundary layer when based on the local Mach number just outside the boundary layer are almost identical to those of cones.

REPORT 1056

THEORETICAL ANTISYMMETRIC SPAN LOADING FOR WINGS OF ARBITRARY PLAN FORM AT SUBSONIC SPEEDS¹

By JOHN DEYOUNG

SUMMARY

A simplified lifting-surface theory that includes effects of compressibility and spanwise variation of section lift-curve slope is used to provide charts with which antisymmetric loading due to arbitrary antisymmetric angle of attack can be found for wings having symmetric plan forms with a constant spanwise sweep angle of the quarter-chord line. Consideration is given to the flexible wing in roll. Aerodynamic characteristics due to rolling, deflected ailerons, and sideslip of wings with dihedral are considered. Solutions are presented for straight-tapered wings for a range of swept plan forms.

INTRODUCTION

Reference 1 has been for many years the standard reference for estimating the stability and control characteristics of wings. The lifting-line theory on which this work was based gave generally satisfactory results for straight wings having the aspect ratios considered; however, the use of wing sweep combined with low aspect ratio has made an extension of this work desirable. Lifting-line theory cannot adequately account for the increased induction effects due to sweep and low aspect ratio; consequently, it has been found necessary to turn to the more complex lifting-surface theories.

Of the many possible procedures, a simplified lifting-surface theory proposed by Weissinger and further developed and extended in reference 2 has been found especially suited to the rapid computation of characteristics of wings of arbitrary plan form. Comparisons with experiment have generally verified the theoretical predictions. In reference 2, this method has been used to compute for plain, unflapped wings, the aerodynamic characteristics dependent on symmetric loading. The same simplified lifting-surface theory can be extended to predict the span loading resulting from antisymmetric² distribution of the wing angle of attack. From such loadings the damping moment due to rolling, the rolling moment due to deflected ailerons, and the rolling moment due to dihedral angle with the wing in sideslip can be determined. A recent publication (reference 3) makes use of the simplified lifting-surface theory to find span-loading characteristics of straight-tapered swept wings in roll and loading due to dihedral angle with the wing in sideslip. Experimental checks of the theory for the damping-in-roll coefficient and rolling moment due to sideslip were very favorable. The range of plan forms considered in reference

3 is somewhat limited and aileron effectiveness was not included. The loading due to aileron deflection normally involves excessive labor when computed by means of the simplified lifting-surface theory; however, development of the theory, presented in reference 4, that deals with flap and aileron effectiveness for low-aspect-ratio wings provides a means by which the simplified lifting-surface method can be used to obtain spanwise loading due to aileron deflection.

It is the purpose of the present analysis to provide simple methods of finding antisymmetric loading and the associated aerodynamic coefficients and derivatives for wings with symmetric plan forms limited only by a straight quarter-chord line over the semispan. Means will be presented for finding quickly the aerodynamic coefficients of span loading due to rolling, of span loading due to deflected ailerons, and of span loading due to sideslip of wings with dihedral. Flexible wings, when the flexure depends principally on span loading as in loading due to rolling, can be included in the analysis.

G	spanwise loading coefficient or dimensionless circulation $\left(\frac{c_l c}{2b}\right)$ or $\left(\frac{\Gamma_c}{bV}\right)$	$\eta_{c.p.}$	spanwise center of pressure on one wing panel $\left(\frac{y_{c.p.}}{b/2}\right)$
$\bar{G}$	spanwise loading coefficient due to rolling $\left(\frac{G}{pb/2V}\right)$, per radian	θ	trigonometric spanwise coordinate ϕ , indicating the edge of the aileron span, radians
$\overline{\bar{G}}$	spanwise loading coefficient due to aileron deflection $\left(\frac{G}{\delta}\right)$, per radian	κ_v	ratio of section lift-curve slope at a span station v to $\frac{2\pi}{\beta}$, both at the same Mach number
H_v	wing geometry, compressibility, and section lift-curve-slope parameter $\left[d_v \left(\frac{1}{\kappa_v}\right) \left(\frac{b}{c_v/\beta}\right)\right]$	Λ	sweep angle of the wing quarter-chord line, positive for sweepback, degrees
h_n	integration factors for spanwise loading due to ailerons	Λ_β	compressibility sweep-angle parameter $\left[\tan^{-1} \left(\frac{\tan \Lambda}{\beta}\right)\right]$, degrees
M	Mach number	λ	taper ratio $\left(\frac{\text{tip chord}}{\text{root chord}}\right)$
m	arbitrary number of span stations defined by $\eta = \cos \frac{n\pi}{m+1}$	ϕ	trigonometric spanwise coordinate ($\cos^{-1} \eta$), radians
p	rate of rolling, radians per second	SUBSCRIPTS	
$pb/2V$	wing-tip helix angle, radians	n, v	integers pertaining to specific span stations given by $\eta = \cos \frac{n\pi}{8}$ or $\eta = \cos \frac{v\pi}{8}$
p_{vn}	coefficient depending on wing geometry and indicating the influence of antisymmetric loading at span station n on the downwash angle at span station v	k	pertaining to span station k
q	free-stream dynamic pressure, pounds per square foot	$c.p.$	center of pressure
S	wing area, square feet	a	aileron
t	ratio of aileron chord to wing chord $^3 \left(\frac{c_a}{c}\right)$	t	pertaining to fraction-of-wing-chord ailerons
V	free-stream velocity, feet per second	T	wing tip
w	induced velocity, normal to the lifting surface, positive for downwash, feet per second	R	wing root
y	lateral coordinate measured from the wing root perpendicular to the plane of symmetry, feet	av	average or mean
α_v	section angle of attack at span station v , radians 3	DEVELOPMENT OF METHOD	
$\Delta\alpha_v$	angle of antisymmetric twist of the elastic wing produced by the loading due to rolling, radians 3	The simplified lifting-surface method used herein replaces a lifting surface by a lifting vortex located at the wing one-quarter-chord line. The boundary condition for determining the vortex strength distribution specifies that, along the three-quarter-chord line of the wing, there shall be no flow through the lifting surface. In effect, this specifies that, at the three-quarter-chord line, the ratio of the velocity normal to the mean camber line (induced by the bound and trailing vortices) to the velocity of the free stream shall equal the sine of the angle of attack.	
$\frac{d\alpha}{d\delta}$	rate of change of wing-section angle of attack with control-surface angle for constant section lift coefficient 3		
β	compressibility parameter $(\sqrt{1-M^2})$	Span loadings are theoretically additive. Since the symmetric angle-of-attack distribution contributes only to symmetric loading, it follows that the antisymmetric loading is independent of symmetrically distributed wing twist or camber; hence, to find antisymmetric loading, it is only necessary to consider the loading resulting from the antisymmetric distribution of the angle of attack across the wing span. In the subject case, such a distribution is experienced by the wing as induced angle due to rolling, ⁴ the effective twist due to aileron deflection, or sideslip of the wing with dihedral.	
$\bar{\beta}$	angle of sideslip, radians		
Γ	dihedral angle measured perpendicular to the plane of symmetry, radians		
Γ_c	spanwise circulation, feet squared per second		
δ	angle of deflection of full wing-chord control surface, radians 3		
$\bar{\delta}$	angle of deflection of full-wing-chord control surface, measured perpendicular to the hinge line, radians		
η	dimensionless lateral coordinate $\left(\frac{y}{b/2}\right)$		

³ Measured parallel to the plane of symmetry.

⁴ In considering the case of the angle induced by rolling as equivalent to an antisymmetric distribution of twist, it must be noted that account should be taken of the fact that a rolling wing leaves a twisted vortex trail; whereas a twisted wing does not. The difference in induction effects on the wing of the straight and twisted vortex is considered insignificant here, as has been assumed in other analyses.

For an antisymmetric angle-of-attack distribution, the loading distribution will be equal in absolute magnitude on each semispan, but of opposite sign. The loading therefore needs only to be found over the semispan, and, since the loading is zero at the wing root, only span stations outboard need be considered. The mathematical development of the simplified lifting-surface method for the case of antisymmetric loading is given in appendix A. As shown in appendix A, $(m-1)/2$ linear equations in terms of loading distribution are obtained which satisfy the wing angle-of-attack conditions⁵ at the three-quarter-chord line at m stations n , where m is an arbitrary odd integer. These equations are represented by the summations

$$\alpha_v = \sum_{n=1}^{\frac{m-1}{2}} p_{vn} G_n, \quad v=1, 2, 3, \dots, \frac{m-1}{2} \quad (1)$$

where

α_v antisymmetric angle of attack at wing station v
 p_{vn} coefficients that for a given value of m depend on wing geometry, compressibility, and section lift-curve slope
 G_n loading coefficients at span stations n

The application in appendix A of the present report is with $m=7$. Since the loading at the midspan station is known to be zero, consideration is required of only three stations: $n=1, 2, 3$, equal to wing semispan positions of $\eta = \cos(n\pi/8) = 0.924; 0.707; \text{ and } 0.383$. Equation (1) thus becomes

$$\alpha_v = \sum_{n=1}^3 p_{vn} G_n, \quad v=1, 2, 3 \quad (2)$$

where the integer v pertains to span station $\eta = \cos(v\pi/8)$

To obtain the loading coefficients $G_n = (c_l c/2b)_n$, it remains only to evaluate the coefficients p_{vn} and the spanwise variation of the antisymmetric angle of attack α_v .

EVALUATION OF COEFFICIENTS p_{vn}

Since m is chosen, p_{vn} becomes a function only of wing geometry, compressibility, and section lift-curve slope. The effects of compressibility and section lift-curve slope are equivalent to a change in wing plan form⁶ and can be accounted for by a proper adjustment of the p_{vn} values. As

shown in appendix B, p_{vn} can be conveniently presented as a function of two parameters, namely, a compressible-sweep-angle parameter defined as $\Lambda_\beta = \tan^{-1}(\tan \Lambda/\beta)$ and a parameter H_v involving the ratio of wing span to wing chord and variable section lift-curve slope, defined by

$$H_v = d_v \left(\frac{1}{\kappa_v} \right) \left(\frac{b}{c_v/\beta} \right) \quad (3)$$

where

κ_v ratio of experimental section lift-curve slope at span station v to the theoretical value of $2\pi/\beta$, both at the same Mach number

c_v wing chord at span station v

The value d_v is a scale factor given by

$$\left. \begin{aligned} d_v &= 0.061 \text{ for } v=1 \\ &= 0.234 \text{ for } v=2 \\ &= 0.381 \text{ for } v=3 \end{aligned} \right\} \quad (4)$$

Equation (3) can be written in alternative form that gives H_v in terms of wing geometry parameters that are more significant; thus

$$H_v = d_v \left(\frac{\beta A}{\kappa_{av}} \right) \left[\frac{1}{(\kappa_v/\kappa_{av})(c_v/c_{av})} \right] \quad (5)$$

where

κ_{av} ratio of average section lift-curve slope to $2\pi/\beta$ both at the same Mach number
 κ_v/κ_{av} spanwise distribution of section lift-curve slope for a given Mach number
 c_v/c_{av} spanwise distribution of the wing chord
 $(\beta A/\kappa_{av})$ compressible aspect ratio and average section lift-curve-slope parameter

The term $\frac{1}{(\kappa_v/\kappa_{av})(c_v/c_{av})}$ of equation (5) gives an effective aerodynamic taper of a wing. The distribution of κ_v/κ_{av} may vary with Mach number, particularly at transonic speeds (e. g., due to spanwise variation of airfoil section). However, since the distribution contributes to taper effect, the loading distribution and not the total loading will be appreciably affected.

With H_v determined from equations (3) or (5) and (4), the values of p_{vn} , nine in all, are presented in figure 1 where p_{vn} is given as a function of H_v for various values of Λ_β .

⁵ The reader should note that the boundary condition is given by $w_s = V \sin \alpha$, from which $(w/V)_s$ is seen to equal $\sin \alpha$. The substitution of α_v for $\sin \alpha$, has the effect of increasing the value of loading on the wing above that necessary to satisfy the boundary condition. However, the boundary condition was fixed assuming that the shed vortices moved downstream in the extended chord plane. A more realistic picture is obtained if the vortices are assumed to move downstream in a horizontal plane from the wing trailing edge. It can be seen readily that, if this occurs, the normal component of velocity induced by the trails at the three-quarter-chord line is reduced and, if the boundary condition is to continue to be satisfied, the strength of the bound vortex must increase. It follows that substitution of α_v for $\sin \alpha$, then has the effect of accounting for the bending up of the trailing vortices. It is not known how exact the correction is, but the calculations and experimental verification show it to be of the correct order.

⁶ Compressibility and section lift-curve slope are discussed in the section "Discussion" and in the appendix B.

FIGURE 2.—Variation of the geometric parameter $\frac{\kappa_v}{\kappa_{av}} \frac{H_v}{\beta A}$ with taper ratio λ for straight-tapered wings.

For the case of straight-tapered wings with arbitrary section lift-curve-slope distribution for which the chord distribution is specified by taper ratio, evaluation of equation (5) is given in figure 2 where $\frac{(\kappa_v/\kappa_{av})H_v}{(\beta A/\kappa_{av})}$ for each of the three span stations is shown as a function of taper ratio.

EVALUATION OF ANTISYMMETRIC ANGLE-OF-ATTACK DISTRIBUTION α_v

The antisymmetric angle-of-attack distributions most commonly encountered are those resulting from rolling wings, aileron deflection, and sideslip of wings with dihedral. Evaluation of the angle-of-attack distributions for these various cases is outlined in the sections immediately following.

Rolling wings.—For the case of the rigid wing, the induced velocity normal to the wing surface is equal to the upwash velocity experienced by the rolling wing. Thus, at span station v

$$\alpha_v = \frac{w_v}{V} = -\left(\frac{pb}{2V}\right) \eta_v \quad (6)$$

where $pb/2V$ is the tip helix angle. It should be noted that the relation given by equation (6) assumes the wing structure to be rigid in that the distribution of α_v is completely defined by the linear distribution of helix angle. In the case of flexible wings, however, the expression for α_v must be modified to account for the streamwise angle-of-attack change which may occur due to bending or torsional deflections. In this case,

$$\alpha_v = -\left(\frac{pb}{2V}\right) \eta_v + \Delta\alpha_v \quad (7)$$

where $\Delta\alpha_v$ represents the modifying influence of flexibility. Normally, $\Delta\alpha_v$ is not considered for straight wings since only the effect of torsion (which is usually small) is involved. On swept wings, however, the effect of bending can cause $\Delta\alpha_v$ to be quite large so that the α_v distribution may be affected considerably. Due to the interaction existing between the aerodynamic and structural forces, $\Delta\alpha_v$ cannot be determined directly, but must be found through equations of equilibrium or by iteration. With the loading for the rigid wing provided, however, the iteration procedure becomes relatively easy to apply. The first approximation of α_v is found from the loading of the rigid wing and further refinements of α_v may be found utilizing the successive loadings for the flexible wing as determined.

Deflected ailerons.—Where the spanwise distribution of the angle α_v is to be considered equivalent to antisymmetric aileron deflection, it must suffer a discontinuity at the spanwise end of the control surface. The loading when such a discontinuity is present can be duplicated by a proper distribution of antisymmetric twist. In appendix C, the antisymmetric twist distribution required by the present theory to give accurate span loading distribution due to ailerons is found with the aid of zero-aspect-ratio wing theory given by reference 4. To minimize the computation involved, it is convenient to consider both the case of outboard and inboard ailerons.

1. **Outboard ailerons.**—With $m=7$, three different aileron spans can be conveniently defined for the outboard ailerons. For the aileron spans η_a , measured from the wing tip inboard, the antisymmetric twist distribution required per unit deflection of full-wing-chord ailerons, α_v/δ , is given by

Case.	I	II	III
η_a	0.169	0.444	0.805
$\frac{\alpha_1}{\delta}$	1.003	0.971	0.998
$\frac{\alpha_2}{\delta}$	.017	.996	.991
$\frac{\alpha_3}{\delta}$	.006	.014	.978

(8)

Inboard ailerons.—With $m=7$, three different aileron spans can be conveniently defined for the inboard ailerons. For the aileron spans η_a measured from the wing midspan outboard, the antisymmetric twist distribution required per unit deflection of full-wing-chord ailerons, α_v/δ , is given by

Case	IV	V	VI
η_a	0.556	0.831	1.000
$\frac{\alpha_1}{\delta}$	0.044	0.013	1.016
$\frac{\alpha_2}{\delta}$	-.017	.961	.979
$\frac{\alpha_3}{\delta}$	1.087	1.095	1.101

(9)

Sideslip of wings with dihedral.—For calculating the rolling moment caused by dihedral angle for the sideslipping wing, the effect of the skewness of the vortex field in altering the effects of the dihedral angle will be assumed to be small (as assumed in reference 3). The problem then simplifies to

finding the rolling moment due to antisymmetric angle of attack with the unskewed vortex field. The solution to this problem is the same as for the ailerons which has already been solved.

The antisymmetric distribution of angle of attack for the sideslipping wing with dihedral is given by

$$\alpha_v = \bar{\beta} \Gamma \quad (10)$$

where

- α_v effective angle-of-attack distribution
- $\bar{\beta}$ angle of sideslip measured positive in the counterclockwise direction from the plane of symmetry
- Γ dihedral angle

The wing parameter Γ is not affected by compressibility. Equation (10) is approximate for small values of $\bar{\beta}$ and Γ .

For unit $\bar{\beta} \Gamma$ over the span of the ailerons considered,

$$\bar{\beta} \Gamma = \delta \quad (11)$$

can be substituted for δ in equations (8) and (9).

APPLICATION OF METHOD

For the cases of antisymmetric angle-of-attack distributions resulting from rolling, aileron deflection, or sideslip with dihedral, it is possible to present a set of simultaneous equations which are required for the solution of the load distribution for an arbitrary plan form. With the loading known, integration formulas can be given to determine aerodynamic coefficients.

The loading-distribution coefficient G_n determined from the solutions of the simultaneous equations, are functions of p_{rn} which has been shown in a preceding section to be a function of wing geometry, compressibility, and section lift-curve slope. The aerodynamic coefficients are integrations of the load distribution and, therefore, will also be a function of wing geometry, compressibility, and section lift-curve-slope parameters. Application of the method to the general solution for arbitrary chord distribution is outlined and solutions are presented for the case of straight taper.

GENERAL SOLUTION

Aerodynamic characteristics due to rolling.—The solutions for the aerodynamic effects due to the rolling wing will be found and loading, rolling moment, spanwise center of pressure, and induced drag will be obtained.

1. *Simultaneous loading equations.*—The p_{rn} values are obtained from figure 1 and table I⁷ with values of H , given by equations (3) or (5).

The simultaneous equations (2), for the rigid and flexible wing, respectively, become:

$$\left. \begin{aligned} -0.924 &= p_{11} \bar{G}_1 + p_{12} \bar{G}_2 + p_{13} \bar{G}_3 \\ -0.707 &= p_{21} \bar{G}_1 + p_{22} \bar{G}_2 + p_{23} \bar{G}_3 \\ -0.383 &= p_{31} \bar{G}_1 + p_{32} \bar{G}_2 + p_{33} \bar{G}_3 \end{aligned} \right\} \quad (12)$$

where

$$\bar{G}_n = \frac{G_n}{pb/2V}$$

and

$$\left. \begin{aligned} -0.924 + \frac{\Delta \alpha_1}{pb/2V} &= p_{11} \bar{G}_1 + p_{12} \bar{G}_2 + p_{13} \bar{G}_3 \\ -0.707 + \frac{\Delta \alpha_2}{pb/2V} &= p_{21} \bar{G}_1 + p_{22} \bar{G}_2 + p_{23} \bar{G}_3 \\ -0.383 + \frac{\Delta \alpha_3}{pb/2V} &= p_{31} \bar{G}_1 + p_{32} \bar{G}_2 + p_{33} \bar{G}_3 \end{aligned} \right\} \quad (13)$$

where $\bar{G}_n = \frac{G_n}{pb/2V}$ and $\Delta \alpha_v$ is the incremental angle of attack due to aeroelastic effects.

2. *Loading distribution.*—The loading-distribution coefficient is given by $G = c_l c / 2b$. Other forms of the loading coefficient are given by the identities

$$G = \frac{1}{2A} \frac{c_l c}{c_{av}} = \frac{C_l}{2A} \frac{c_l c}{C_l c_{av}} \quad (14)$$

The loading is known to be zero at $\eta = 0$ and 1 and is determined at three intermediate span stations. Values of loading at other span stations can be obtained from a loading function derived in appendix B or, with equations (B23) or (B24) of appendix B, the loading can be found at span positions $\eta = 0.981, 0.831, 0.556$, and 0.195.

3. *Rolling moment.*—The damping-in-roll derivative for the solutions of equations (12) or (13) is derived in appendix B and given by

$$\frac{\beta C_{lp}}{\kappa_{av}} = \frac{\pi}{16} \left(\frac{\beta A}{\kappa_{av}} \right) [\bar{G}_2 + 0.707 (\bar{G}_1 + \bar{G}_3)] \quad (15)$$

4. *Spanwise center of pressure.*—The equation giving center of pressure on the wing semispan is shown in appendix B to be

$$\eta_{c.p.} = \frac{\beta C_l / \kappa_{av}}{\frac{\beta A}{\kappa_{av}} (0.163 \bar{G}_1 + 0.248 \bar{G}_2 + 0.430 \bar{G}_3)} = \frac{1}{0.082 \left(\frac{c_l c}{C_l c_{av}} \right)_1 + 0.124 \left(\frac{c_l c}{C_l c_{av}} \right)_2 + 0.215 \left(\frac{c_l c}{C_l c_{av}} \right)_3} \quad (16)$$

5. *Induced drag.*—The induced drag is derived in appendix B and given by

$$\frac{\beta C_{Di}}{\kappa_{av}} = \frac{\pi}{2} \left(\frac{\beta A}{\kappa_{av}} \right) \left[G_1^2 + G_2^2 + G_3^2 - \frac{\sqrt{2}}{2} G_2 (G_1 + G_3) \right] \quad (17)$$

Aerodynamic characteristics due to aileron deflection.—The solutions for the aerodynamic effects due to ailerons will be found for three different spans of outboard and inboard ailerons. Cross plots of these data provide curves for arbitrary aileron spans.

1. *Simultaneous loading equations.*—The p_{rn} values are obtained from figure 1 and table I with values of H , given by equations (3) or (5).

(a) *Deflected outboard ailerons.*—The aileron spans measured from the wing tip inboard are given by η_a . The simultaneous solution for antisymmetric spanwise loading due to

⁷ Values of p_{rn} beyond the scope of figure 1 are included in table I. For values of H larger than those included in figure 1 and table I, the p_{rn} curves can be obtained from equation (BS) which gives the linear asymptotes of the p_{rn} function.

deflection of any of the three following aileron spans can be obtained from the appropriate set of the following equations:

Case	I	II	III
η_a	0.169	0.444	0.805
$\frac{\alpha_1}{\delta}$	1.003	0.971	0.998
$\frac{\alpha_2}{\delta}$	.017	.996	.991
$\frac{\alpha_3}{\delta}$	.006	.014	.978

$$\begin{aligned}
 &= p_{11}\bar{G}_1 + p_{12}\bar{G}_2 + p_{13}\bar{G}_3 \\
 &= p_{21}\bar{G}_1 + p_{22}\bar{G}_2 + p_{23}\bar{G}_3 \quad (18) \\
 &= p_{31}\bar{G}_1 + p_{32}\bar{G}_2 + p_{33}\bar{G}_3
 \end{aligned}$$

where $\bar{G}_n = G_n/\delta$.

(b) *Deflected inboard ailerons.*—The aileron spans measured from the wing midspan outboard are given by η_a . The simultaneous solution for antisymmetric spanwise loading due to deflection of any of the three following aileron spans can be obtained from the appropriate set of the following equations:

Case	IV	V	VI
η_a	0.556	0.831	1.000
$\frac{\alpha_1}{\delta}$	0.044	0.013	1.016
$\frac{\alpha_2}{\delta}$	-.017	.961	.979
$\frac{\alpha_3}{\delta}$	1.087	1.095	1.101

$$\begin{aligned}
 &= p_{11}\bar{G}_1 + p_{12}\bar{G}_2 + p_{13}\bar{G}_3 \\
 &= p_{21}\bar{G}_1 + p_{22}\bar{G}_2 + p_{23}\bar{G}_3 \quad (19) \\
 &= p_{31}\bar{G}_1 + p_{32}\bar{G}_2 + p_{33}\bar{G}_3
 \end{aligned}$$

where $\bar{G}_n = G_n/\delta$.

2. *Loading distribution.*—The spanwise loading distributions due to various aileron configurations include:

(a) *Full-wing-chord ailerons.*—The loading is known to be zero at $\eta=0$ and 1, and is determined at three intermediate span stations. With equation (C13) and tables C6, B1, and C7, the loading can be found at span stations $\eta=0.981$, 0.831, 0.556, and 0.195 for each of the aileron spans considered. With these given points and the knowledge that the slope of the loading distribution curve is theoretically infinite at the point of angle-of-attack discontinuity (aileron spanwise end), the loading distribution can be faired.

(b) *Constant fraction of wing-chord ailerons.*—The spanwise loading of constant fraction of wing-chord ailerons is equal to the product of the loading due to full-wing-chord ailerons and the effective change of angle of attack with aileron angle,⁵ $d\alpha/d\delta$. The factor $d\alpha/d\delta$ is a function of the ratio of aileron chord to wing chord $t=c_a/c$. The change of section angle of attack with aileron angle $d\alpha/d\delta$ is presented in figure 3, which is reproduced from figure 18 of reference 5.

Although figure 3 taken from reference 5 limits the Mach number range to Mach numbers less than 0.2, this limitation is believed to be unwarranted since theory indicates that $d\alpha/d\delta$ is unaffected by compressibility for the two-dimensional wing. However, as indicated in reference 4, $d\alpha/d\delta$ is strongly affected by low aspect ratio and will change appreciably if the parameter βA becomes much less than two; hence, the values of $d\alpha/d\delta$ from figure 3 appear to be valid for $\beta A > 2$.

⁵ In using $d\alpha/d\delta$ here, it should be noted that the assumption is made that the effective airfoil section is taken as being parallel to the plane of symmetry and that the section approaches a two-dimensional section. The validity of this assumption can be questioned; however, limited checks with experiment show it to be at least approximately correct.

FIGURE 3.—Variation of lift-effectiveness parameter with aileron chord ratio, $t = \frac{c_a}{c}$. Average trailing-edge angle about 10° ; $M \leq 0.2$. Curves from reference 5.

(c) *Arbitrary spanwise distribution of aileron chord.*—The aileron can be divided into several spans with constant $d\alpha/d\delta$, then the total loading is the sum of the products of the full-wing-chord loading of each span and its respective $d\alpha/d\delta$.

3. *Rolling moment.*—The rolling moment can be found for the following aileron configurations:

(a) *Full-wing-chord ailerons.*—The spanwise loading due to aileron deflection cannot be integrated with sufficient accuracy with equation (15). In appendix C, a similar integration formula is developed that applies to each given aileron span. Equation (C10) and table C5 give

$$\frac{\beta C_{l_{\delta}}}{\kappa_{av}} = \left(\frac{\beta A}{\kappa_{av}} \right) (h_1 \bar{G}_1 + h_2 \bar{G}_2 + h_3 \bar{G}_3) \quad (20)$$

where for each of the cases of equations (18) and (19) the h_n values are given by

Case	I	II	III	IV	V	VI
h_1	0.140	0.139	0.138	0.146	0.141	0.140
h_2	.199	.196	.196	.200	.197	.198
h_3	.145	.139	.138	.140	.139	.140

(b) *Constant fraction of wing-chord ailerons.*—For constant fraction of wing-chord ailerons with aileron angle measured parallel to the plane of symmetry, the aileron effectiveness is given by

$$\frac{\beta C_{l_{\delta}}}{\kappa_{av}} = \frac{d\alpha}{d\delta} \left(\frac{\beta C_{l_{\delta}}}{\kappa_{av}} \right) \quad (21)$$

(c) *Arbitrary spanwise distribution of aileron chord.*—The deflection of ailerons for which t varies spanwise on the wing can be considered as an equivalent wing-twist distribution. The effective antisymmetric twist of the wing is given by

$$\alpha_r = \frac{d\alpha}{d\delta} \delta_i \quad (22)$$

wise, the rolling moment can be obtained by integration as in equation (23). The integral becomes

$$\frac{\beta C_{l_{\bar{\beta}}}}{\kappa_{av}} = \int_0^1 \Gamma(\eta) \frac{d(\beta C_{l_{\bar{\beta}}}/\kappa_{av} \Gamma)}{d\eta} d\eta \quad (29)$$

where $\frac{d(\beta C_{l_{\bar{\beta}}}/\kappa_{av} \Gamma)}{d\eta}$ is the slope of the curve described in part (b) above.

SOLUTION FOR STRAIGHT-TAPERED WINGS

Charts of aerodynamic characteristics for straight-tapered wings can be presented in terms of geometric, compressibility, and average section lift-curve-slope parameters. These charts provide a ready means of obtaining data directly.

Aerodynamic characteristics due to rolling.—The application of equation (12) for a constant value of section lift-curve slope⁹ provides the spanwise loadings at span stations 0.383, 0.707, and 0.924 which are presented in figure 4 for a wide range of plan forms. The interpolation formula of equation (B24) will give values of loading due to rolling at span stations other than those presented. With equation (15), the damping-in-roll coefficients $\beta C_{l_{\bar{\beta}}}/\kappa_{av}$ can be obtained and are presented in figure 5 for a wide range of plan forms.

Aerodynamic characteristics due to aileron deflection.—

The application of equation (19), case III of equation (18), and equation (20) provide aileron effectiveness in the coefficient form $\beta C_{l_{\bar{\beta}}}/\kappa_{av}$ for several aileron spans. In figure 6, $\beta C_{l_{\bar{\beta}}}/\kappa_{av}$ is plotted against extent of unit antisymmetric angle of attack from the wing semispan root outboard for a range of wing parameters.

As presented, figure 6 gives directly the effectiveness of full-wing-chord inboard ailerons for aileron spans measured from the plane of symmetry outboard. The effectiveness of full-wing-chord outboard ailerons for aileron spans measured from the wing tip inboard is given by figure 6 directly by the relations of equation (24). For full-wing-chord ailerons located arbitrarily on the wing semispan, the aileron effectiveness can be obtained directly from figure 6 as indicated in the following example sketch.

With the full-wing-chord values given above, the effectiveness of constant fraction of wing-chord ailerons or ailerons of arbitrary spanwise chord distribution can be found through use of equations (21) or (23) with the $d\alpha/d\delta$ values of figure 3.

⁹ Throughout the figures, κ_{av} is the constant spanwise section lift curve slope or the average of a small variation. For large spanwise variations of κ that follow the function given by equation (B11) developed in appendix B, the parameters $\beta A/\kappa_{av}$ and λ can be replaced by the parameters $\frac{\beta A}{(\kappa_R + \kappa_T \lambda)/(1 + \lambda)}$ and $\frac{\kappa_T}{\kappa_R} \lambda$, respectively. For large spanwise variations of κ that do not follow the curve of equation (B11), the simultaneous equations for the general solution can be solved for arbitrary distributions of κ . The H_s values can be obtained from figure 2.

(a) $\eta = 0.3827$.

FIGURE 4.—Variation of loading due to rolling coefficient $\frac{c_l c}{C_{l_{\bar{\beta}} \kappa_{av}}}$ with compressible sweep parameter Δ_β , degrees, for straight-tapered wings.

(b) $\eta = 0.7071$.

FIGURE 4.—Continued.

Aerodynamic characteristics due to sideslip of wings with dihedral.—The application of equation (19), case III of equation (18), but with $\delta = \bar{\beta} \Gamma$, and $\bar{G} = G/\bar{\beta} \Gamma$, and the use of equation (28) provides rolling moments due to dihedral angle for the wing in sideslip. These rolling moments are given in the coefficient form $\beta C_{l_{\bar{\beta}}}/\kappa_{av} \Gamma$ which is the same function of η as $\beta C_{l_{\bar{\beta}}}/\kappa_{av}$ and is presented with $\beta C_{l_{\bar{\beta}}}/\kappa_{av}$ in figure 6. Figure 6 with equation (29) will provide the rolling moment

(c) $\eta = 0.9239$.

FIGURE 4.—Concluded.

due sideslip for any symmetric spanwise distribution of dihedral angle.

For dihedral angle constant spanwise, the rolling moment is given by the value at $\eta = 1$ in figure 6. These values for constant spanwise dihedral angle are presented in figure 7 as a function of aspect ratio for various values of sweep angle and taper ratio.

DISCUSSION

Effects of plan-form parameters on aerodynamic characteristics for straight-tapered wings are shown by plots against the various parameters. Compressibility is discussed and formulas given for a range of plan forms at sonic speeds. Theoretical considerations and experimental comparisons indicate the order of reliability of the present theoretical results.

STRAIGHT-TAPERED WINGS

The spanwise loading distribution due to rolling for several plan forms is presented in figure 8. These curves are the result of applying figure 4 and the loading interpolation formula of appendix B. The loading coefficient is given as $\frac{\eta_{c.p.}}{(\eta_{c.p.})_{A=0}} \left(\frac{c_l c}{C_l c_{av}} \right)$ to make the total loading on the semispan constant and thus show more clearly the changes of distribution due to sweep and taper ratio. Figure 8 shows large changes in loading distribution for the zero tapered wing. The effects of sweep are generally as expected, namely, that sweepback shifts the loading outboard.

Effects of plan form on the rolling moment due to rolling is shown from cross plots of figure 5 which are presented in figures 9 and 10. For higher aspect ratio, figures 4, 9, and 10 show the marked lowering of rolling moment due to sweep. Figure

(a) $\lambda = 0$.(b) $\lambda = 0.25$.

FIGURE 5.—Variation of damping-in-roll parameter $\frac{\beta C_{l_p}}{\kappa_{av}}$ with compressible sweep parameter Δ_β , degrees, for straight-tapered wings.

9 indicates that for low aspect ratio, the rolling moment becomes essentially independent of sweep and taper. The taper effects on rolling moment as seen in figure 10 are small except for values of taper ratio less than 0.25.

Typical spanwise loading distributions due to full-wing-chord aileron deflection are shown in figure 11. These curves were faired with the aid of the loading interpolation function of appendix C and, at the aileron spanwise end, care was taken to make the slope large.

Wing geometry effects on aileron effectiveness for full-chord outboard partial-span ailerons (with aileron angle measured parallel to the plane of symmetry) are given in figure 12. The geometry effects on $\beta C_{l_p} / \kappa_{av}$ are similar to those on the damping-in-roll coefficient. Comparison of figure 12 (a) with figure 9 shows that C_{l_p} approaches the zero-aspect-ratio value in the same manner as does C_{l_p} . Figure 13 gives comparative effectiveness of inboard and outboard ailerons for swept wings. As sweep increases, the difference of effectiveness between inboard and out-

(c) $\lambda = 0.50$.(d) $\lambda = 1.0$.

FIGURE 5.—Continued.

board ailerons decreases showing that inboard ailerons for highly swept-back wings approach the effectiveness of outboard ailerons. Since $d\alpha/d\delta$ becomes large rapidly at small values of t (fig. 3), then, for a given aileron area, narrow full-span ailerons for swept-back wings may be more desirable than larger-chord outboard ailerons. The relative effects of figures 12 and 13 apply equally well for constant fraction of chord ailerons, since the data would differ only by a constant factor $d\alpha/d\delta$.

COMPRESSIBILITY

From the three-dimensional linearized-compressible-flow equation, it can be shown that the effects of compressibility will be properly taken into account if the longitudinal com-

FIGURE 6.—Aileron rolling-moment parameter $\frac{\beta C_{l_p}}{K_{av}}$, per radian, and rolling moment due to sideslip with dihedral $\frac{\beta C_{l_\beta}}{K_{av}^2}$, per radian squared, for extent of unit antisymmetric angle of attack from the wing root outboard.

(b) $\lambda = 0.5$.

FIGURE 6.—Continued.

ponents of a wing plan form are increased by the factor $1/\beta$. Or, alternatively, if the linearized compressible flow equation be divided through by β^2 , then the lateral and vertical components of a plan form are decreased by the factor β . In both cases, the incompressible local lift is increased by the factor $1/\beta$ and the compressible local lift coefficient can be written as the parameter βc_l .

With these relations known, an incompressible theory can be made into a compressible theory subject to the limitations of the linearized compressible flow equation. The geometric parameters of a wing are simply substituted by βA , $\Lambda_{\beta} = \tan^{-1} \frac{\tan \Lambda}{\beta}$ and βb . With local lift coefficient given by βc_l , the dimensionless loading becomes $G = \frac{\beta c_l c}{2\beta b} = \frac{c_l c}{2b}$. The wing-chord distribution remains unaltered.

The sonic speed results of reference 4 can be used as a limit point in the present theory for a curve of the variation of antisymmetric aerodynamic characteristics with Mach number. The following equations apply at the speed of sound to plan forms with all points of the trailing edge at or behind the upstream line of maximum wing span:

$$C_{l_p} = \frac{-\pi A}{32}$$

(c) $\lambda = 1.0$.

FIGURE 6.—Concluded.

For outboard ailerons,

$$C_{l_s} = \frac{A}{6} \sin^3 \theta, \text{ where } \eta_a = 1 - \cos \theta$$

For inboard ailerons,

$$C_{l_s} = \frac{A}{6} (1 - \sin^3 \theta), \text{ where } \eta_a = \cos \theta$$

Reference 4 shows that aileron effectiveness at the speed of sound is independent of the chordwise location of the aileron hinge line, provided the hinge line remains ahead of all points of the trailing edge.

ACCURACY OF THE SEVEN-POINT SOLUTION FOR AILERONS

The prediction of aileron effectiveness for given aileron spans with wing twist determined by zero-aspect-ratio theory at only seven span points to satisfy the boundary conditions has been theoretically shown to be sufficient by comparing results with the computation of a typical 3.5 aspect ratio, 45° swept wing with 15 span points satisfying the boundary conditions. The process of finding aileron spans for the 15-point method was the same as that in appendix C. The curves showing the variation of C_{l_s} with aileron span for the 7- and 15-point computations were identical.

The solution for the angle-of-attack distribution that includes a discontinuity can be compared with the solution

for the continuous angle-of-attack distribution by considering an aileron such that the angle-of-attack distribution is equivalent to that of the rolling wing. The damping-in-roll coefficient then can be found by use of equation (23) which reduces to the form

$$C_l = \int_0^1 \alpha \frac{dC_{l_s}}{d\eta} d\eta$$

for $\alpha = -\left(\frac{pb}{2V}\right)_\eta$, and integrating by parts

$$C_{l_p} = \int_0^1 C_{l_s} d\eta - C_{l_s}_{\eta=1}$$

This relation states that C_{l_p} is equal to the area between a curve of figure 6 and the line of C_{l_s} for $\eta=1$. The curves of figure 6 were found by the simplified lifting-surface theory with antisymmetric twist determined by zero-aspect-ratio theory. The values of C_{l_p} obtained in this manner from figure 6 were identical to the C_{l_p} values given by simplified lifting-surface theory for continuous linear antisymmetric-twist distribution.

As further theoretical check, the values of rolling moment due to constant spanwise dihedral angle are obtained from 15-point computations in reference 3 for taper ratio equal to one, with which the present theory for the 7-point method is in exact agreement.

FIGURE 7.—Rolling moment due to sideslip of wing with dihedral $\frac{\beta C_{l_p}}{\kappa_{av} A}$, per radian squared, for unit constant spanwise dihedral angle for straight-tapered wings.

FIGURE 8.—Spanwise loading due to rolling of wings with various taper-ratio and sweep-angle parameters of aspect-ratio parameter $\frac{\beta A}{\kappa_{av}} = 4$. The curve for $A=0$ serves as a basis for comparison and the factor $\frac{\eta_{cp}}{\eta_{cp(A=0)}}$ gives the curves constant area equal to 3.454.

COMPARISON OF THEORETICAL AND EXPERIMENTAL RESULTS

The electro-magnetic analogy method of reference 6 provides damping-in-roll coefficients for an aspect-ratio range of unswept, tapered wings. The results of the present theory and those of reference 8 are compared in figure 14. Except for the taper ratio effects on C_{lp} , the comparison is good. The rounded-wing-tip values of C_{lp} given by NACA Rep. 635 (reference 1) are included in figure 14. Since rounded wing tips generally give values of C_{lp} about 6 percent lower than straight wing tips, the values of NACA Rep. 635 appear to be appreciably too high for lower-aspect-ratio wings. The present theory and the theory of refer-

FIGURE 9.—Variation of the damping-in-roll parameter $\frac{\beta C_{lp}}{\kappa_{av}}$ with aspect-ratio parameter $\frac{\beta A}{\kappa_{av}}$ for various sweep angles and taper ratios.

FIGURE 10.—Variation of the damping-in-roll parameter $\frac{\beta C_{lp}}{\kappa_{av}}$ with taper ratio for wings with various aspect-ratio and sweep-angle parameters.

ence 6 approach the value given by the zero-aspect-ratio theory of reference 4 quite satisfactorily. The results of the present theory may be further assessed by the comparison with the results of low-speed experiment as given in figure 15 for the range of plan forms presented. For further experimental verification of the accuracy with which C_{lp} can be determined by the present theory, the reader is referred to reference 3 which supports the theory as well or better than figure 15 of the present report.

FIGURE 14.—Comparison of damping-in-roll coefficient C_{lr} of the present theory with those of the theories of references 1, 4, and 6.

The loading distributions due to rolling as given by the present theory are compared in figure 16 with low-speed experimental results for a range of swept wings. The sweep angle seems to have considerably more influence on loading distribution as given by experiment than the theory indicates. The experimental pressure data, however, were very erratic and no firm conclusion can be made.

Experimental values of rolling effectiveness due to aileron deflection are compared with theoretically predicted values in a correlation diagram given by figure 17. Included are the results of a wide range of plan forms which do not vary consistently with any geometric parameter or aileron configuration. Sketches of the plan forms and ailerons are drawn about the points of correlation. The theory makes use of the curve of figure 3 giving $d\alpha/d\delta$ for a sealed-gap aileron over a range of deflection of $\pm 10^\circ$. Experimental results for aileron deflections greater than 15° measured perpendicular to the hinge line were not included. The correlation points of figure 17 scatter appreciably; however, the mean line of the points does approximate the line of perfect correlation.

Figure 17 does not account for effective plan-form change due to $d\alpha/d\delta$. Only the effectiveness of the low-aspect-ratio triangular wing of figure 17 is exceedingly in error, which is the result of neglecting plan-form change.

The plan-form change due to $d\alpha/d\delta$ can, in part, be considered analogous to that due to section lift-curve-slope change. Thus, the total section lift of a wing, the chord of which is reduced by $d\alpha/d\delta$ and which is at an angle of attack δ , is equal to the lift of the wing-aileron section for which the aileron only is deflected at the angle δ . This change in plan form, unlike the section lift-curve-slope change for

which the chordwise loading remains constant, does not account for a large change in chordwise loading. If the lifting line is considered to be at the chordwise center of pressure, then, for partial-wing-span ailerons, the lifting line is in effect broken at the aileron spanwise end and the present theory becomes invalid. For the case of full-wing-span ailerons, the lifting line in effect remains unbroken and lies along the center of chordwise pressure. For this case the wing chord can be reduced by $d\alpha/d\delta$ to account for plan-form change; however, although in the limit of zero aspect ratio the results are the same as those of reference 4, this procedure does not with sufficient accuracy account for the chordwise loading shifting aft at intermediate aspect ratios. For control surfaces, the effective plan-form change due to $d\alpha/d\delta$ is appreciable for the low-aspect-ratio wings such that in the limit of zero aspect ratio the spanwise loading is independent of the ratio of aileron chord to wing chord (reference 4). However, for moderate aspect ratios, $d\alpha/d\delta$ can be used without accounting for plan-form changes as comparison with experiment indicates.

Experimental values of C_{lr}/Γ are not compared with the present theory since reference 3 gives ample support of the theory.

CONCLUDING REMARKS

The determination of antisymmetric loading for arbitrary wings is shown to be easily obtained by the solution of three simultaneous equations. The coefficients of the simultaneous equations are presented in charts of parameters that include wing geometry, compressibility, and section lift-curve slope as arbitrary quantities. Thus the loading for an arbitrary antisymmetric angle-of-attack distribution can be simply found once the angle-of-attack distribution is chosen.

For the important cases of antisymmetric loading, roll, and aileron deflection, the angle-of-attack distribution is given and the simultaneous equations are formed. Loading for these cases can be found by simply obtaining from charts the coefficients corresponding to the wing geometry, Mach number, and lift-curve slope, inserting in the appropriate equations and solving.

Integration formulas for the loading distributions are given which enable the aerodynamic coefficients C_{lr} and C_{ls} to be found. The rolling moment due to sideslip of a wing with dihedral is shown to be equivalent to that of aileron deflection and a procedure for determining its value is given.

For the special case of straight-tapered wings, the loading distributions and values of C_{lr} and C_{ls} are given in the chart form for a range of wing plan forms.

Experimental and theoretical verification of the theory is shown to be good. The theory is applicable for large aerodynamic angles, provided the flow remains unseparated. The compressibility considerations are reliable to the speed of sound subject to the limitations of the linearized compressible-flow equation.

APPENDIX A

EQUATIONS FOR THE DETERMINATION OF ANTISYMMETRIC LOADING

UNSYMMETRIC LOADING

From NACA Rep. 921 (reference 2), the aerodynamic loading is obtained by solution of linear simultaneous equations

$$\alpha_v = \left(\frac{w}{V} \right)_v = \sum_{n=1}^m A_{vn} G_n, \quad v = 1, 2, \dots, m \quad (A1)$$

where

$$G = \frac{\Gamma_c}{bV} \quad (A2)$$

$$\left. \begin{aligned} A_{vn} &= 2b_{vv} + \left(\frac{b}{c_v} \right) g_{vv} \text{ for } n=v \\ &= -2b_{vn} + \left(\frac{b}{c_v} \right) g_{vn} \text{ for } n \neq v \end{aligned} \right\} \quad (A3)$$

for $\bar{\eta}_\mu \geq 0$ or $\mu \leq \frac{M+1}{2}$.

$$L(v, \mu) = \left\{ \frac{\sqrt{\left[1 + \left(\frac{b}{c_v} \right) \tan \Lambda (|\eta_v| - \bar{\eta}_\mu) \right]^2 + \left(\frac{b}{c_v} \right)^2 (\eta_v - \bar{\eta}_\mu)^2}}{1 + \left(\frac{b}{c_v} \right) (|\eta_v| - \eta_v) \tan \Lambda} - 1 \right\} \frac{1}{\left(\frac{b}{c_v} \right) (\eta_v - \bar{\eta}_\mu)}$$

and

or $\bar{\eta}_\mu \leq 0$ or $\mu \geq \frac{M+1}{2}$

$$\left. \begin{aligned} L(v, \mu) &= \left\{ \frac{\sqrt{\left[1 + \left(\frac{b}{c_v} \right) \tan \Lambda (|\eta_v| + \bar{\eta}_\mu) \right]^2 + \left(\frac{b}{c_v} \right)^2 (\eta_v - \bar{\eta}_\mu)^2}}{1 + \left(\frac{b}{c_v} \right) (|\eta_v| + \eta_v) \tan \Lambda} - 1 \right\} \frac{1}{\left(\frac{b}{c_v} \right) (\eta_v - \bar{\eta}_\mu)} + \\ &\quad \frac{2 \tan \Lambda \sqrt{\left[1 + |\eta_v| \left(\frac{b}{c_v} \right) \tan \Lambda \right]^2 + \left(\frac{b}{c_v} \right)^2 \eta_v^2}}{\left[1 + \left(\frac{b}{c_v} \right) (|\eta_v| - \eta_v) \tan \Lambda \right] \left[1 + \left(\frac{b}{c_v} \right) (|\eta_v| + \eta_v) \tan \Lambda \right]} \end{aligned} \right\} \quad (A5)$$

where

$\eta_v = \cos \frac{v\pi}{m+1}$ spanwise position at which downwash is computed

$\bar{\eta}_\mu = \cos \frac{\mu\pi}{M+1}$ spanwise position of incremental loading at the one-quarter-chord line.

The above equations involve computations over the entire wing. However, if the loading is assumed to be symmetric or antisymmetric, the computations can be reduced to less than half the work. The case of symmetric loading is developed in reference 2 and the antisymmetric case is developed in the following section.

ANTISYMMETRIC LOADING

For antisymmetric loading, the loading on each side of the wing has the same magnitude and distribution but with opposite sign, or

$$\left. \begin{aligned} \alpha_v &= -\alpha_{m+1-v} \\ G_v &= -G_{m+1-v}, \text{ or } G_n = -G_{m+1-n} \end{aligned} \right\} \quad (A6)$$

b_{vv} and b_{vn} are coefficients independent of plan form.

$$g_{vn} = \frac{-1}{2(M+1)} \left[\frac{L(v, 0)f_{no} + L(v, M+1)f_{n,M+1} + \sum_{\mu=1}^M L(v, \mu)f_{n\mu}}{2} \right] \quad (A4)$$

where

$f_{n\mu}$ are coefficients independent of plan form.

The $L(v, \mu)$ functions, which can have η_v negative to find unsymmetrical loading, are given by

Equation (A1) can then be written as

$$\alpha_v = \sum_{n=1}^{\frac{m-1}{2}} (A_{vn} - A_{v, m+1-n}) G_n \quad (A7)$$

where the summation is only to $\frac{m-1}{2}$, since $G_{\frac{m+1}{2}} = 0$ for antisymmetric loading.

With equations (A3), equation (A7) becomes

$$\alpha_v = \left[2(b_{vv} - b_{v, m+1-v}) + \left(\frac{b}{c_v} \right) (g_{vv} - g_{v, m+1-v}) \right] G_v - \sum_{n=1}^{\frac{m-1}{2}} \left[2(b_{vn} - b_{v, m+1-n}) - \left(\frac{b}{c_v} \right) (g_{vn} - g_{v, m+1-n}) \right] G_n \quad (A8)$$

(The prime indicates the value for $n=\nu$ is not summed.)
Now, from equation (A4)

$$g_{\nu n} + g_{\nu, m+1-n} = \frac{-1}{2(M+1)} \left[\frac{L(\nu, 0)(f_{n0} - f_{m+1-n, 0})}{2} + \frac{L(\nu, M+1)(f_{n, M+1} - f_{m+1-n, M+1})}{2} + \sum_{\mu=1}^M L(\nu, \mu)(f_{n\mu} - f_{m+1-n, \mu}) \right] \quad (A9)$$

where

$$f_{n\mu} = \frac{2}{m+1} \sum_{\mu_1=1}^m \mu_1 \sin \mu_1 \phi_n \cos \mu_1 \phi_\mu \quad (A10)$$

and

$$\phi_n = \frac{n\pi}{m+1}, \quad \phi_\mu = \frac{\mu\pi}{M+1}$$

From equation (A9), $f_{n\mu} - f_{m+1-n, \mu}$ can be defined as

$$f_{n\mu}^* = f_{n\mu} - f_{m+1-n, \mu}$$

then, using equation (A10),

$$\begin{aligned} f_{n\mu}^* &= \frac{2}{m+1} \sum_{\mu_1=1}^m \mu_1 \cos \mu_1 \phi_\mu (\sin \mu_1 \phi_n - \sin \mu_1 \phi_{m+1-n}) \\ &= \frac{2}{m+1} \sum_{\mu_1=1}^m \mu_1 \cos \mu_1 \phi_\mu \sin \mu_1 \phi_n (1 + \cos \mu_1 \pi) \end{aligned}$$

and, since the terms of the summation for odd μ_1 vanish,

$$f_{n\mu}^* = \frac{4}{m+1} \sum_{\mu_1=2, 4, 6, \dots, \text{even}}^m \mu_1 \sin \mu_1 \phi_n \cos \mu_1 \phi_\mu \quad (A11)$$

From equation (A11),

$$f_{n\mu}^* = f_{n, M+1-\mu}^* \quad (A12)$$

Combining equation (A9) with (A12) and defining

$$g_{\nu n}^* = g_{\nu n} - g_{\nu, m+1-n}$$

then

$$g_{\nu n}^* = \frac{-1}{2(M+1)} \sum_{\mu=0}^{\frac{M+1}{2}} [L(\nu, \mu) + L(\nu, M+1-\mu)] f_{n\mu}^* \quad (A13)$$

where for $\mu=0$ and $\frac{M+1}{2}$, $f_{n\mu}^*$ is equal to half the values given by equation (A11) in order that the products can be fitted into the summation. With equation (A13), equation (A8) can be written as

$$\begin{aligned} \alpha_\nu &= \left(2C_\nu + \frac{b}{c_\nu} g_{\nu\nu}^* \right) G_\nu - \sum_{n=1}^{\frac{m-1}{2}} \left(2C_{\nu n} - \frac{b}{c_\nu} g_{\nu n}^* \right) G_n \quad (A14) \\ \nu &= 1, 2, 3, \dots, \frac{m-1}{2} \end{aligned}$$

where

$$C_\nu = b_{\nu\nu} - b_{\nu, m+1-\nu}$$

$$C_{\nu n} = b_{\nu n} - b_{\nu, m+1-n}$$

From reference 2,

$$b_m = \frac{\sin \phi_n}{(\cos \phi_n - \cos \phi_\nu)^2} \left[\frac{1 - (-1)^{n-\nu}}{2(m+1)} \right]$$

which gives zero values for $b_{\nu n}$ for even $(n-\nu)$ values. Then, since m is odd,

$$b_{\nu, m+1-\nu} = 0$$

and

$$C_\nu = b_{\nu\nu}$$

It should be noted that $L(\nu, \mu)$ simplifies somewhat for the antisymmetrically loaded wing since η now is only positive in equation (A5). If only positive values of $\bar{\eta}$ are used, then equation (A5) can be written as

$$\begin{aligned} L^*(\nu, \mu) &= L^*_{\nu\mu} = L(\eta, \bar{\eta}) + L(\eta, -\bar{\eta}) \\ &= L(\nu, \mu) + L(\nu, M+1-\mu) \end{aligned}$$

In summary, the foregoing analysis for the antisymmetrically loaded wing gives

$$\alpha_\nu = \sum_{n=1}^{\frac{m-1}{2}} p_{\nu n} G_n \quad (A15)$$

$$\nu = 1, 2, 3, \dots, \frac{m-1}{2}$$

where

$$p_{\nu n} = 2b_{\nu\nu} + \frac{b}{c_\nu} g_{\nu\nu}^* \text{ for } n=\nu \quad (A16)$$

$$= -2C_{\nu n} + \frac{b}{c_\nu} g_{\nu n}^* \text{ for } n \neq \nu$$

$$C_{\nu n} = b_{\nu n} - b_{\nu, m+1-n}$$

$$b_{\nu\nu} = \frac{m+1}{4 \sin \phi_\nu}$$

$$b_{\nu n} = \frac{\sin \phi_n}{(\cos \phi_n - \cos \phi_\nu)^2} \left[\frac{1 - (-1)^{n-\nu}}{2(m+1)} \right]$$

$$g_{\nu\nu}^* = g_{\nu\nu}^* \text{ for } n=\nu$$

$$g_{\nu n}^* = -\frac{1}{2(M+1)} \sum_{\mu=0}^{\frac{M+1}{2}} L^*_{\nu\mu} f_{n\mu}^*$$

$$f_{n\mu}^* = \frac{4}{m+1} \sum_{\mu_1=\text{even}}^m \mu_1 \sin \mu_1 \phi_n \cos \mu_1 \phi_\mu$$

$$f_{n0}^* = \frac{f_{n\mu}^*}{2} \text{ for } \mu=0$$

$$f_{n, \frac{M+1}{2}}^* = \frac{f_{n\mu}^*}{2} \text{ for } \mu = \frac{M+1}{2}$$

APPENDIX B

DERIVATION OF RELATIONS USED IN THE METHOD

APPLICATION OF APPENDIX A

With appendix A, the antisymmetrical loading on a plan form for any antisymmetrical distribution of α_v can be found. The principal work in the computations is to obtain the coefficients of the simultaneous equations (A15). These coefficients can be presented in charts for the complete range of geometric plan-form parameters into which are introduced the effects of compressibility and section lift-curve slope. With the loading due to rolling known, the coefficients and derivatives are obtained by integration formulas.

Section lift-curve-slope effect.—For a two-dimensional wing with the loaded line at the quarter-chord position, the position x aft of the loaded line where the induced downwash equals the angle of attack of the wing can be obtained by the Biot Savart Law as

$$w = \frac{\Gamma_c}{2\pi x} \text{ where } \Gamma_c = \frac{c_l c V}{2}$$

or

$$\frac{w}{V} = \frac{c_l c}{4\pi x} = \alpha$$

or

$$\frac{dc_l}{d\alpha} = \frac{4\pi x}{c}$$

then

$$x = \left(\frac{c}{4\pi} \right) \frac{dc_l}{d\alpha}$$

where $dc_l/d\alpha$ is the section lift-curve slope. Two dimensional section compressibility effects that do not follow the Prandtl-Glauert rule can be given consideration by taking the ratio of $(dc_l/d\alpha)_{\text{compressible}}$ at a Mach number to $2\pi/\beta$. Let κ be the ratio of the section lift-curve slope at a given Mach number to $2\pi/\beta$ or $(dc_l/d\alpha)_{\text{compressible}} = 2\pi\kappa/\beta$, then

$$x = \kappa(c/2)$$

Then the induced angle, $\kappa(c/2)$ aft of the loaded line, is equal to the angle of attack of the wing. For $\kappa=1$, this is at the three-quarter-chord line. For section lift-curve slope less than 2π , κ is less than one and the downwash is equal to the angle of attack at some point between the one-quarter- and three-quarter-chord line.

To take into account the section lift-curve-slope variation in the present theory, the downwash must be found at a distance $\kappa(c/2)$ aft of the loaded line. From the formulas of the summation in appendix A, b/c_v should be taken as $b/\kappa_v c_v$, where κ_v is the ratio of section lift-curve slope for a given Mach number at span station v , to $2\pi/\beta$.

Derivation of parameters for p_{vn} .—The p_{vn} coefficients, as defined by equation (A16) in appendix A, depend on plan-

form geometry in the $(b/c_v)L_{vn}^*$ functions only, or p_{vn} is a function of b/c_v and sweep angle. As previously shown, b/c_v is also a function of the spanwise variation of section lift-curve slope and is effectively equivalent to $b/\kappa_v c_v$, where κ_v is the ratio of section lift-curve slope for a given Mach number at span station v to $2\pi/\beta$. The p_{vn} coefficients can be plotted against $b/\kappa_v c_v$ with sweep angle as a parameter; however, $b/\kappa_v c_v$ will vary from zero to very large values for a range of plan-form geometry, and the plots become unwieldy. For a range of aspect ratio, the values of $b/\kappa_v c_v$ are a maximum for the zero tapered wings when $\eta_v \geq 0.5$ (provided plan-form edges are not concave) and a maximum for the inverse-tapered wings for $\eta_v \leq 0.5$. The ratio of $b/\kappa_v c_v$ for $\eta_v \geq 0.5$ for any plan form to those of the zero tapered wing or the ratio of $b/\kappa_v c_v$ for $\eta_v \leq 0.5$ for any plan form to those of the inverse-tapered wing gives a geometric parameter for any plan form that has maximum values that depend only on aspect ratio.

The chord distribution for straight-tapered wings is given by

$$\frac{b}{c_v} = \frac{A(1+\lambda)}{2[1-|\eta_v|(1-\lambda)]} \quad (B1)$$

Then, for $\lambda=0$,

$$\frac{b}{Ac_v} = \frac{1}{2(1-|\eta_v|)} \quad (B2)$$

and for $\lambda=1.5$

$$\frac{b}{Ac_v} = \frac{5}{2(2+|\eta_v|)} \quad (B3)$$

The ratio of $b/\kappa_v c_v$ to equations (B2) and (B3) gives, respectively, a geometric parameter as

$$\left. \begin{aligned} \frac{b/\kappa_v c_v}{(b/Ac_v)_{\lambda=0}} &= 2(1-\eta_v) \left(\frac{b}{\kappa_v c_v} \right) \text{ for } 0.5 \leq \eta_v < 1 \\ \frac{b/\kappa_v c_v}{(b/Ac_v)_{\lambda=1.5}} &= \frac{2(2+\eta_v)}{5} \left(\frac{b}{\kappa_v c_v} \right) \text{ for } 0 \leq \eta_v \leq 0.5 \end{aligned} \right\} \quad (B4)$$

Let H_v be defined as two-fifths times the values of equation (B4) (the fraction two-fifths is introduced to give H_v the approximate values of p_{vn} to simplify plotting procedures), then adding effects of compressibility (see Discussion section)

$$H_v = d_v \left(\frac{\beta b}{\kappa_v c_v} \right) \quad (B5)$$

where

$$\begin{aligned} d_v &= \frac{4(1-\eta_v)}{5} \text{ for } 0.5 \leq \eta_v < 1 \\ &= \frac{4(2+\eta_v)}{25} \text{ for } 0 \leq \eta_v \leq 0.5 \end{aligned}$$

For $M=m$, $f_{n\mu}^*$ simplifies to

$$f_{n\mu}^* = \left[\frac{2(-1)^{n+\mu} \sin 2\phi_n}{\cos 2\phi_n - \cos 2\phi_\mu} \right]_{\mu \neq n} = \left(\frac{-\sin 4\phi_n}{1 - \cos 4\phi_n} \right)_{n=\mu}$$

$$f_{no}^* = \frac{f_{nu}^*}{2} \text{ for } \mu=0$$

$$f_{n \frac{m+1}{2}}^* = \frac{f_{n\mu}^*}{2} \text{ for } \mu = \frac{m+1}{2}$$

$$L_{\nu\mu}^* = \frac{1}{\left(\frac{b}{c_\nu}\right)(\eta_\nu - \bar{\eta}_\mu)}$$

$$\left\{ \sqrt{\left[1 + \left(\frac{b}{c_\nu}\right)(\eta_\nu - \bar{\eta}_\mu) \tan \Lambda \right]^2 + \left(\frac{b}{c_\nu}\right)^2 (\eta_\nu - \bar{\eta}_\mu)^2} - 1 \right\} +$$

$$\frac{1}{\left(\frac{b}{c_\nu}\right)(\eta_\nu + \bar{\eta}_\mu)}$$

$$\left\{ \frac{\sqrt{\left[1 + \left(\frac{b}{c_\nu}\right)(\eta_\nu - \bar{\eta}_\mu) \tan \Lambda \right]^2 + \left(\frac{b}{c_\nu}\right)^2 (\eta_\nu + \bar{\eta}_\mu)^2}}{1 + 2 \left(\frac{b}{c_\nu}\right) \eta_\nu \tan \Lambda} - 1 \right\} +$$

$$\frac{2 \tan \Lambda \sqrt{\left[1 + \left(\frac{b}{c_\nu}\right) \eta_\nu \tan \Lambda \right]^2 + \left(\frac{b}{c_\nu}\right)^2 \eta_\nu^2}}{1 + 2 \left(\frac{b}{c_\nu}\right) \eta_\nu \tan \Lambda}$$

$$\eta_\nu = \cos \phi_\nu \text{ where } \phi_\nu = \frac{\nu \pi}{m+1}$$

$$\bar{\eta}_\mu = \cos \phi_\mu \text{ where } \phi_\mu = \frac{\mu \pi}{M+1}$$

$$\bar{\eta}_n = \cos \phi_n \text{ where } \phi_n = \frac{n \pi}{m+1}$$

For a discussion of the relative accuracies obtained for a choice of values of M and m , see reference 7. The most favorable application is with $M=m$.

For tapered wings, H_v simplifies to

$$\left. \begin{aligned} H_v &= \frac{2(1-\eta_v)(1+\lambda)}{5[1-\eta_v(1-\lambda)]} \left(\frac{\beta A}{\kappa_v} \right) \text{ for } 0.5 \leq \eta_v < 1 \\ &= \frac{2(2+\eta_v)(1+\lambda)}{25[1-\eta_v(1-\lambda)]} \left(\frac{\beta A}{\kappa_v} \right) \text{ for } 0 \leq \eta_v \leq 0.5 \end{aligned} \right\} \quad (\text{B6})$$

Plots of p_{vn} against H_v in the range of $H_v=0$ to 4 will give p_{vn} coefficients for wings of any chord distribution for aspect ratios up to 10 or 12.

Linear asymptotes of p_{vn} .—For large values of H_v , the p_{vn} functions become linearly proportional to H_v . Since this linear characteristic appears at relatively low values of H_v , the simple linear relation between p_{vn} and H_v is quite usable.

The L^*_{vn} function of appendix A is multiplied by b/c_v and the product is linearized.

$$\left. \begin{aligned} \left(\frac{b}{c_v} \right) L^*_{vn} &= \frac{2}{\cos \Lambda} \left(\frac{b}{c_v} \right) - \frac{2\eta}{\eta^2 - \bar{\eta}^2} + \left(\frac{1}{|\eta - \bar{\eta}|} + \frac{1}{\eta} \right) \sin \Lambda - \\ &\quad \frac{1}{2\eta} \tan \frac{\Lambda}{2} - \\ &\quad \frac{1}{2\eta} \left[\frac{1 - \sqrt{1 + \left(\frac{\eta - \bar{\eta}}{\eta + \bar{\eta}} \tan \Lambda \right)^2}}{\tan \Lambda} \right] \dots \text{for } \bar{\eta} < \eta \\ &= \frac{-2\eta}{\eta^2 - \bar{\eta}^2} + \left(\frac{1}{|\eta - \bar{\eta}|} + \frac{1}{\eta} \right) \sin \Lambda - \frac{1}{2\eta} \tan \frac{\Lambda}{2} - \\ &\quad \frac{1}{2\eta} \left[\frac{1 - \sqrt{1 + \left(\frac{\eta - \bar{\eta}}{\eta + \bar{\eta}} \tan \Lambda \right)^2}}{\tan \Lambda} \right] \dots \text{for } \bar{\eta} > \eta \\ &= \left(\frac{1}{\cos \Lambda} + \tan \Lambda \right) \left(\frac{b}{c_v} \right) - \frac{1}{2\eta} + \frac{1}{\eta} \sin \Lambda - \\ &\quad \frac{1}{2\eta} \tan \frac{\Lambda}{2} \dots \text{for } \bar{\eta} = \eta \\ &= \frac{2}{\cos \Lambda} \left(\frac{b}{c_v} \right) - \frac{2}{\eta} + \frac{2 \sin \Lambda}{\eta} \dots \text{for } \bar{\eta} = 0 \end{aligned} \right\} \quad (\text{B7})$$

With the values of equation (B7) substituted into equation (A16) the values of p_{vn} for arbitrary sweep angle are obtained. Thus, for $m=7$, the following equation (B8) gives values for p_{vn} as

$$\begin{aligned} p_{11} &= \left(\frac{3.928}{\cos \Lambda} + 1.026 \tan \Lambda \right) H_1 + 7.968 - 1.494 \sin \Lambda + \\ &\quad 0.014 \tan \frac{\Lambda}{2} + 0.082 \left(\frac{1 - \sqrt{1 + 0.0016 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &\quad 0.068 \left(\frac{1 - \sqrt{1 + 0.0177 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &\quad 0.034 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{12} &= \left(\frac{0.851}{\cos \Lambda} - 2.901 \tan \Lambda \right) H_1 - 3.138 + 1.080 \sin \Lambda - \end{aligned}$$

$$\begin{aligned} &0.034 \tan \frac{\Lambda}{2} - 0.034 \left(\frac{1 - \sqrt{1 + 0.0016 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.096 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{13} &= \left(\frac{-0.176}{\cos \Lambda} + 1.026 \tan \Lambda \right) H_1 + 0.129 - 0.869 \sin \Lambda + \\ &0.082 \tan \frac{\Lambda}{2} + 0.014 \left(\frac{1 - \sqrt{1 + 0.0016 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &0.068 \left(\frac{1 - \sqrt{1 + 0.0177 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &0.034 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{21} &= \left(\frac{0.221}{\cos \Lambda} + 0.534 \tan \Lambda \right) H_2 - 2.088 - 0.383 \sin \Lambda - \\ &0.018 \tan \frac{\Lambda}{2} - 0.088 \left(\frac{1 - \sqrt{1 + 0.0177 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.044 \left(\frac{1 - \sqrt{1 + 0.0294 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.037 \left(\frac{1 - \sqrt{1 + 0.0886 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{22} &= \frac{0.975}{\cos \Lambda} H_2 + 4.596 - 0.146 \sin \Lambda - 0.044 \tan \frac{\Lambda}{2} + \\ &0.125 \left(\frac{1 - \sqrt{1 + 0.0177 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.044 \left(\frac{1 - \sqrt{1 + 0.0294 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.125 \left(\frac{1 - \sqrt{1 + 0.0886 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{23} &= \left(\frac{0.221}{\cos \Lambda} - 0.534 \tan \Lambda \right) H_2 - 1.912 + 0.221 \sin \Lambda + \\ &0.107 \tan \frac{\Lambda}{2} - 0.044 \left(\frac{1 - \sqrt{1 + 0.0177 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &0.018 \left(\frac{1 - \sqrt{1 + 0.0294 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &0.044 \left(\frac{1 - \sqrt{1 + 0.0886 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{31} &= \left(\frac{-0.028}{\cos \Lambda} - 0.164 \tan \Lambda \right) H_3 + 0.149 + 0.324 \sin \Lambda + \\ &0.034 \tan \frac{\Lambda}{2} - 0.082 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\ &0.163 \left(\frac{1 - \sqrt{1 + 0.0886 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\ &0.197 \left(\frac{1 - \sqrt{1 + 0.1993 \tan^2 \Lambda}}{\tan \Lambda} \right) \\ p_{32} &= \left(\frac{0.136}{\cos \Lambda} + 0.464 \tan \Lambda \right) H_3 - 1.570 - 0.389 \sin \Lambda - \end{aligned}$$

$$\begin{aligned}
& 0.082 \tan \frac{\Lambda}{2} + 0.231 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) - \\
& 0.082 \left(\frac{1 - \sqrt{1 + 0.1993 \tan^2 \Lambda}}{\tan \Lambda} \right) \\
p_{33} = & \left(\frac{0.628}{\cos \Lambda} - 0.164 \tan \Lambda \right) H_3 + 3.417 + 0.083 \sin \Lambda + \\
& 0.197 \tan \frac{\Lambda}{2} - 0.082 \left(\frac{1 - \sqrt{1 + 0.1717 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\
& 0.163 \left(\frac{1 - \sqrt{1 + 0.0886 \tan^2 \Lambda}}{\tan \Lambda} \right) + \\
& 0.034 \left(\frac{1 - \sqrt{1 + 0.1993 \tan^2 \Lambda}}{\tan \Lambda} \right) \quad (B8)
\end{aligned}$$

Linear spanwise distribution of $(\kappa c)_v/(\kappa c)_{av}$.—With the condition that the product of section lift-curve slope and wing chord varies linearly spanwise, then

$$\kappa c = \frac{2b}{A_* [1 + (\kappa_T/\kappa_R)\lambda]} \{1 - \eta_v [1 - (\kappa_T/\kappa_R)\lambda]\}$$

and equation (3) becomes

$$H_v = d_v (\beta A_*) \frac{1 + (\kappa_T/\kappa_R)\lambda}{2 \{1 - \eta_v [1 - (\kappa_T/\kappa_R)\lambda]\}} \quad (B9)$$

where A_* is the aspect ratio based on the wing chord equal to κc . In equation (B9), H_v is reduced to terms of two parameters. Expressions of A_* in terms of aspect ratio for straight-tapered wings and the distribution of section lift-curve slope can be found.

For straight-tapered wings

$$A = \frac{2b}{c_R (1 + \lambda)}$$

and since κc is linear

$$A_* = \frac{2b}{\kappa_R c_R [1 + (\kappa_T/\kappa_R)\lambda]}$$

then

$$A_* = \frac{A}{(\kappa_R + \kappa_T \lambda)/(1 + \lambda)}$$

and equation (B9) becomes

$$H_v = d_v \left[\frac{\beta A}{(\kappa_R + \kappa_T \lambda)/(1 + \lambda)} \right] \frac{1 + (\kappa_T/\kappa_R)\lambda}{2 \{1 - \eta_v [1 - (\kappa_T/\kappa_R)\lambda]\}} \quad (B10)$$

The distribution of κ for straight-tapered wings is given by

$$\kappa_v = \frac{(\kappa c)_v}{c_v} = \kappa_R \frac{1 - \eta_v [1 - (\kappa_T/\kappa_R)\lambda]}{1 - \eta_v (1 - \lambda)} \quad (B11)$$

Equation (B10) is in terms of two parameters given by $\left[\frac{\beta A}{(\kappa_R + \kappa_T \lambda)/(1 + \lambda)} \right]$ and $(\kappa_T/\kappa_R)\lambda$. Solutions for spanwise loading in terms of these two parameters and Λ_β are valid for the distribution of section lift-curve slope given by equation (B11). Equation (B11) indicates that at $\lambda=1$, κ_v is a linear function and at $\lambda=0$, κ_v is a constant. For values of λ

between 0 and 1, κ_v is a curve in the region between the linear function and a constant.

Equation (B10) is given by figure 2 for $m=7$, but with the ordinate given by the parameter $\frac{H_v}{\beta A/[(\kappa_R + \kappa_T \lambda)/(1 + \lambda)]}$ and the abscissa by $(\kappa_T/\kappa_R)\lambda$.

For the case of linear distribution of $(\kappa c)_v$ and straight-tapered wings for which the chord and section lift-curve slope can be specified in three parameters, the loading and associated aerodynamic characteristics can be presented for a range of the parameters Λ_β , $\beta A/[(\kappa_R + \kappa_T \lambda)/(1 + \lambda)]$, and $(\kappa_T/\kappa_R)\lambda$.

INTEGRATION OF ANTISYMMETRIC LOADING

Rolling-moment coefficient and derivatives.—Rolling-moment coefficient is given by

$$\beta C_l = \frac{\beta A}{2} \int_{-1}^1 G(\bar{\eta}) \bar{\eta} d\bar{\eta} \quad (B12)$$

where

$$\bar{\eta} = \cos \phi$$

which, by an integration formula,

$$\int_{-1}^1 f(\bar{\eta}) d\bar{\eta} = \frac{\pi}{m+1} \sum_{n=1}^m f(\bar{\eta}_n) \sin \phi_n \quad (B13)$$

becomes

$$\begin{aligned}
\beta C_l &= \frac{\pi \beta A}{2(m+1)} \sum_{n=1}^m G_n \cos \phi_n \sin \phi_n \\
&= \frac{\pi \beta A}{4(m+1)} \sum_{n=1}^m G_n \sin 2\phi_n
\end{aligned}$$

Since the loading is antisymmetric, $\frac{G_{m+1}}{2} = 0$, and

$$\beta C_l = \frac{\pi \beta A}{2(m+1)} \sum_{n=1}^{\frac{m-1}{2}} G_n \sin 2\phi_n \quad (B14)$$

For spanwise loading due to rolling, the loading is found as a function of $pb/2V$, then equation (B14) divided by $pb/2V$ gives

$$\beta C_{l_p} = \frac{\pi \beta A}{2(m+1)} \sum_{n=1}^{\frac{m-1}{2}} \bar{G}_n \sin 2\phi_n \quad (B15)$$

where

$$\bar{G} = G/(pb/2V)$$

The rolling moment due to ailerons will be found in appendix C.

Induced drag.—The induced drag coefficient is, with equation (B13), given by

$$\beta C_{D_i} = \beta A \int_{-1}^1 \alpha_i G d\eta = \frac{\pi \beta A}{m+1} \sum_{n=1}^m G_n \alpha_i \sin \phi_n$$

where α_i is one-half the induced angle of the wing wake given by equation (A14) for $c_v = \infty$, then for antisymmetric loading

$$\beta C_{D_i} = \frac{2\pi \beta A}{m+1} \sum_{n=1}^{\frac{m-1}{2}} \left(b_n G_n^2 - G_n \sum_{n=1}^{\frac{m-1}{2}} C_{vn} G_n \right) \sin \phi_n \quad (B16)$$

where the prime indicates the value of $n=\nu$ is not summed.

Spanwise center of pressure.—The center of pressure on the wing half panel is given by

$$\eta_{c.p.} = \frac{\int_0^1 G \bar{\eta} d\bar{\eta}}{\int_0^1 G d\bar{\eta}}$$

The numerator is equal to $\beta C_l / \beta A$. If the Fourier series for loading is assumed,

$G(\phi) = \sum_{\mu_1=\text{even}}^m a_{\mu_1} \sin \mu_1 \phi$, the denominator becomes

$$\sum_{\mu_1=\text{even}}^m a_{\mu_1} \int_0^{\pi/2} \sin \phi \sin \mu_1 \phi d\phi = \sum_{\mu_1=\text{even}}^m -a_{\mu_1} (-1)^{\frac{\mu_1}{2}} \left(\frac{\mu_1}{\mu_1^2 - 1} \right)$$

then

$$\eta_{c.p.} = \frac{\beta C_l}{-\beta A \sum_{\mu_1=\text{even}}^m a_{\mu_1} (-1)^{\frac{\mu_1}{2}} \left(\frac{\mu_1}{\mu_1^2 - 1} \right)} \quad (\text{B17})$$

where a_{μ_1} are the Fourier coefficients.

Loading-due-to-rolling function and interpolation table.—The Fourier series that approximates the antisymmetric loading with only a few terms is given by

$$G(\phi) = \sum_{\mu_1=\text{even}}^m a_{\mu_1} \sin \mu_1 \phi \quad (\text{B18})$$

The loading G_n is determined at span positions of $\bar{\eta} = \cos \phi_n$

where $\phi_n = \frac{n\pi}{m+1}$. The a_{μ_1} are given by

$$a_{\mu_1} = \frac{2}{\pi} \int_0^\pi G(\phi) \sin \mu_1 \phi d\phi \quad (\text{B19})$$

With the quadrature formula of equation (B13), equation (B19) becomes, for antisymmetric loading,

$$a_{\mu_1} = \frac{4}{m+1} \sum_{n=1}^{\frac{m-1}{2}} G_n \sin \mu_1 \phi_n \quad (\text{B20})$$

For $m=7$, the a_{μ_1} coefficients are equal to (for even μ_1)

$$\left. \begin{aligned} a_2 &= \frac{1}{2} \left(\frac{\sqrt{2}}{2} G_1 + G_2 + \frac{\sqrt{2}}{2} G_3 \right) \\ a_4 &= \frac{1}{2} (G_1 - G_3) \\ a_6 &= \frac{1}{2} \left(\frac{\sqrt{2}}{2} G_1 - G_2 + \frac{\sqrt{2}}{2} G_3 \right) \end{aligned} \right\} \quad (\text{B21})$$

Equation (B18) with (B21) can be arranged to give

$$\left. \begin{aligned} G(\phi) &= \frac{1}{2} \left(\frac{\sqrt{2}}{2} \sin 2\phi + \sin 4\phi + \frac{\sqrt{2}}{2} \sin 6\phi \right) G_1 + \\ &\quad \frac{1}{2} (\sin 2\phi - \sin 6\phi) G_2 + \\ &\quad \frac{1}{2} \left(\frac{\sqrt{2}}{2} \sin 2\phi - \sin 4\phi + \frac{\sqrt{2}}{2} \sin 6\phi \right) G_3 \end{aligned} \right\} \quad (\text{B22})$$

With equation (B22) the loading due to rolling can be determined at any span position. Letting $\phi = \phi_k = \frac{k\pi}{8}$ and tabulating the factors of G_n as e_{nk} , an interpolation table may be obtained to determine loading at span station k .

TABLE B1, e_{nk}
[$m=7$]

η_k	0.981	0.831	0.556	0.195
k				
n	1/2	3/2	5/2	7/2
1.....	0.8155	0.5449	-0.1622	0.1684
2.....	-.2706	.6533	.6533	-.2706
3.....	.1084	-.1622	.5449	.8155

$$G_k = \sum_{n=1}^3 e_{nk} G_n \quad (\text{B23})$$

Equation (B23) may be used for interpolation of any form of loading coefficient, thus

$$\left(\frac{c_l c}{c_l c_{av}} \right)_k = \sum_{n=1}^3 e_{nk} \left(\frac{c_l c}{c_l c_{av}} \right)_n \quad (\text{B24})$$

APPENDIX C

DETERMINATION OF ANTISYMMETRIC WING TWIST FOR FINDING SPANWISE LOADING DUE TO AILERON DEFLECTION

WING TWIST FOR A GIVEN AILERON SPAN

The determination of loading for an angle-of-attack distribution that contains a discontinuity by a method which satisfies the boundary conditions at a finite number of points can be made by increasing the number of points until the solutions become sufficiently accurate. For the method as given in appendix A, the number of points that satisfy the boundary conditions is given by m . For the large value of m required for accurate results, the computations become exceedingly laborious; however, a procedure using a moderate value of m can be determined by use of a low-aspect-ratio theory with which a wing twist can be found that duplicates the results of the discontinuous angle-of-attack distribution.

A theoretical but relatively simple method of finding spanwise loading due to inboard and outboard ailerons for wings of low aspect ratio is given by reference 4. In the present theory, as aspect ratio approaches zero, g^*_{vn} values of appendix A become zero and the p_{vn} coefficients given by equation (A16) become constant or independent of plan-form shape and equal to

$$\left. \begin{aligned} p_{vn} &= -2C_{vn} \\ p_{vv} &= 2b_{vv} \end{aligned} \right\} \quad (C1)$$

These coefficients are given by the relations under equation (A15) and p_{vn} can be tabulated.

TABLE C1.— p_{vn}

[For $m=7$ and $A=0$]

$n \backslash v$	1	2	3
1	10.4524	-2.0000	0
2	-3.6954	5.6568	-1.5308
3	0	-2.0060	4.3296

With equation (A15), antisymmetric loading can be found for zero-aspect-ratio wings. As a comment on the accuracy of the present theory for $m=7$, the solution of equation (A15), with the $A=0$ p_{vn} values for loading due to rolling gave the same values at the three semispan stations as does reference 4, namely, $G(\phi) = -\frac{(\dot{p}b/2V) \sin 2\phi}{4}$.

The zero-aspect-ratio theory of reference 4 shows that all span loading characteristics are independent of plan-form shape for zero aspect ratio. This independence makes that theory ideal for obtaining the boundary conditions of the present theory for zero aspect ratio, which should apply with the present theory for higher aspect ratios for which plan-form shape has an effect on spanwise loading. The boundary conditions of the present theory are given by the antisymmetric values of α_v in equation (A15). The problem is to find what antisymmetrical distribution of α_v is required for the present theory to duplicate the exact loading

distribution given by reference 4 for a given aileron span.

The aileron spans are arbitrarily chosen for the present theory as the mean value of the spanwise trigonometric coordinate of the downwash point at a section angle of attack equal to zero. For $m=7$, three aileron spans can be defined for both outboard and inboard ailerons. Let η_a be the aileron span, and θ the spanwise point of the end of the aileron, then

$$\eta_a = 1 - \cos \theta \text{ for outboard ailerons}$$

$$\eta_a = \cos \theta \text{ for inboard ailerons}$$

For the present theory, the aileron spans defined are tabulated as follows:

TABLE C2

Case	Outboard			Inboard		
	I	II	III	IV	V	VI
θ	$\frac{3\pi}{16}$	$\frac{5\pi}{16}$	$\frac{7\pi}{16}$	$\frac{5\pi}{16}$	$\frac{3\pi}{16}$	0
η_a	0.1685	0.4444	0.8049	0.5556	0.8315	1.0000

For the aileron spans listed in table C2, the exact span loading distribution can be found from reference 4. With the p_{vn} values listed in table C1 and the exact values of G_1 , G_2 , and G_3 from reference 4, equation (A15) gives the twist required for the present theory to give the loading distribution for each case listed in table C2 or

$$\left. \begin{aligned} \frac{\alpha_1}{\delta} &= 10.4524 \left(\frac{G_1}{\delta} \right) - 3.6954 \left(\frac{G_2}{\delta} \right) \\ \frac{\alpha_2}{\delta} &= -2 \left(\frac{G_1}{\delta} \right) + 5.6568 \left(\frac{G_2}{\delta} \right) - 2 \left(\frac{G_3}{\delta} \right) \\ \frac{\alpha_3}{\delta} &= -1.5308 \left(\frac{G_2}{\delta} \right) + 4.3296 \left(\frac{G_3}{\delta} \right) \end{aligned} \right\} \quad (C2)$$

The spanwise loading distribution from reference 4 for outboard ailerons is given by

$$\left[\frac{G(\phi)}{\delta} \right]_{\text{outboard}} = \frac{1}{\pi} \left[(\cos \phi - \cos \theta) \ln \left| \frac{\sin \frac{\theta + \phi}{2}}{\sin \frac{\theta - \phi}{2}} \right| - (\cos \phi + \cos \theta) \ln \left| \frac{\cos \frac{\theta + \phi}{2}}{\cos \frac{\theta - \phi}{2}} \right| \right] \quad (C3)$$

For the full-wing-span aileron, $\theta = \frac{\pi}{2}$ or $\eta_a = 1$

$$\left[\frac{G(\phi)}{\delta} \right]_{\eta_a=1} = \frac{2}{\pi} \cos \phi \ln \left| \frac{1 + \sin \phi}{\cos \phi} \right| \quad (C4)$$

For inboard ailerons, with the same value of θ

$$\left[\frac{G(\phi)}{\delta} \right]_{\text{inboard}} = \left[\frac{G(\phi)}{\delta} \right]_{\eta_a=1} - \left[\frac{G(\phi)}{\delta} \right]_{\text{outboard}} \quad (C5)$$

With equations (C3), (C4), and (C5), the spanwise loading G_1 , G_2 , and G_3 at span stations $\phi = \pi/8$, $\pi/4$, and $3\pi/8$, or $\eta = 0.9239$, 0.7071 , and 0.3827 can be tabulated for each of the cases given in table C2.

TABLE C3

$\frac{G_n}{\delta}$	Case I	II	III	IV	V	VI
$\frac{G_1}{\delta}$	0.1136	0.1919	0.2316	0.0454	0.1237	0.2373
$\frac{G_2}{\delta}$	0.0500	.2800	.3851	.1164	.3464	.3964
$\frac{G_3}{\delta}$	.0190	.1022	.3620	.2922	.3754	.3944

The twist distribution required for each case is obtained with equation (C2) and table C3, tabulating

TABLE C4

$\frac{\alpha}{\delta}$	Case I	II	III	IV	V	VI
$\frac{\alpha_1}{\delta}$	1.0029	0.9713	0.9979	0.0444	0.0128	1.0157
$\frac{\alpha_2}{\delta}$	.0174	.9957	.9913	-.0169	.9614	.9788
$\frac{\alpha_3}{\delta}$	.0056	.0139	.9777	1.0868	1.0951	1.1007

With the twist distribution given by table C4, equation (A15) can be used to solve for spanwise loading due to ailerons for any of the six cases.

ROLLING MOMENT DUE TO AILERON DEFLECTION

The rolling moment is given by

$$C_l = \frac{A}{4} \int_0^\pi G(\phi) \sin 2\phi d\phi \quad (C6)$$

For span loading due to ailerons, the loading distribution is distorted sufficiently such that the quadrature formula given by equation (B13) is not sufficiently accurate for $m=7$ to integrate equation (C6). With equation (B18)

$$C_l = \frac{\pi A}{8} a_2 \quad (C7)$$

Expanding equation (B18) for $\phi = \pi/8$, $\pi/4$, and $3\pi/8$, or obtaining G_1 , G_2 , and G_3 in series of a 's, the sum of the G 's gives

$$a = \frac{1}{2} (0.7071G_1 + G_2 + 0.7071G_3) + a_{14} - a_{18} + a_{30} - a_{34} \quad (C8)$$

The higher harmonic coefficients can be put as factors of the G_n . The rolling-moment coefficient becomes

$$C_l = A \left\{ \frac{0.7071\pi}{16} \left[1 + \frac{(a_{14} - a_{18} + a_{30} - a_{34})}{1.2071G_1} \right] G_1 + \frac{\pi}{16} \left[1 + \frac{(a_{14} - a_{18} + a_{30} - a_{34})}{1.2071G_2} \right] G_2 + \frac{0.7071\pi}{16} \left[1 + \frac{(a_{14} - a_{18} + a_{30} - a_{34})}{1.2071G_3} \right] G_3 \right\} \quad (C9)$$

When h_n is defined as the coefficients of G_n

$$C_l = A (h_1 G_1 + h_2 G_2 + h_3 G_3) \quad (C10)$$

The ratio of $(a_{14} - a_{18} + a_{30} - a_{34})$ to G_n can be evaluated by the zero-aspect-ratio theory. It is expected this ratio will not vary appreciably with aspect ratio. From reference 4, the loading series expansion gives for equation (B18)

$$\left. \begin{aligned} \left(\frac{a_{\mu_1}}{\delta} \right)_{\text{outboard}} &= \frac{4}{\pi \mu_1 (\mu_1^2 - 1)} (\cos \theta \sin \mu_1 \theta - \mu_1 \sin \theta \cos \mu_1 \theta) \\ \left(\frac{a_{\mu_1}}{\delta} \right)_{\eta_a=1} &= \frac{-(-1)^{\frac{\mu_1}{2}}}{\mu_1^2 - 1} \\ \left(\frac{a_{\mu_1}}{\delta} \right)_{\text{inboard}} &= \left(\frac{a_{\mu_1}}{\delta} \right)_{\eta_a=1} - \left(\frac{a_{\mu_1}}{\delta} \right)_{\text{outboard}} \end{aligned} \right\} \quad (C11)$$

These high harmonic coefficients are small, but are not negligible for loading due to ailerons. The h_n are tabulated for each of the cases

TABLE C5

h_n	Case I	II	III	IV	V	VI
h_1	0.1398	0.1388	0.1379	0.1462	0.1407	0.1402
h_2	.1994	.1963	.1955	.2004	.1973	.1975
h_3	.1446	.1388	.1382	.1400	.1394	.1397

SPANWISE LOADING DISTRIBUTION

The spanwise loading distributions due to the twist distributions of table C4 are found at three span stations, and, since these loadings are not completely defined by a few terms of the assumed loading series, the values of loading at other span stations cannot be found accurately by direct use of equation (B23) and table B1. For zero-aspect-ratio wings, the spanwise loading distribution due to aileron deflection is given to all span stations by equation (C3). The loading distribution for other than zero-aspect-ratio wings will fluctuate about the value given by equation (C3) in a manner similar to the manner that loading due to rolling varies about the function $\sin 2\phi$ of zero-aspect-ratio theory. Since the interpolation table of equation (B23) applies only to loadings that vary about the function $\sin 2\phi$ the loading due to aileron deflection can be divided by the ratio of equation (C3) to $\sin 2\phi$ and the resulting loading will be approximately given by $\sin 2\phi$.

The zero-aspect-ratio values of equation (C3) can be tabulated as ratios of $\frac{G(\phi)/\delta}{\sin 2\phi}$. Define

$$R_n = \frac{G(\phi_n)/\delta}{\sin 2\phi_n} \quad (C12)$$

The zero-aspect-ratio values of R_n can be tabulated for each aileron-span case considered.

TABLE C6.— R_n

Case	Outboard			Inboard		
	I	II	III	IV	V	VI
η_a	0.1685	0.4444	0.8049	0.5556	0.8315	1.0000
1.....	0.1607	0.2714	0.3275	0.0642	0.1749	0.3358
2.....	.0500	.2800	.3851	.1164	.3464	.3964
3.....	.0269	.1445	.5119	.4132	.5309	.5578

The interpolation series of equation (B23) becomes

$$\left(\frac{\bar{G}}{\bar{R}}\right)_k = \sum_{n=1}^3 e_{nk} \left(\frac{\bar{G}}{\bar{R}}\right)_n \quad (C13)$$

where $\bar{G} = \frac{G}{\delta}$ and e_{nk} are given by table B1. With R_k tabulated, values of loading at span stations $\eta_k = \cos \frac{k\pi}{8}$ are obtained.

TABLE C7.— R_k

η_k	Case k	I	II	III	IV	V	VI

REPORT 1057

ANALYSIS OF THE EFFECTS OF BOUNDARY-LAYER CONTROL ON THE TAKE-OFF AND POWER-OFF LANDING PERFORMANCE CHARACTERISTICS OF A LIAISON TYPE OF AIRPLANE¹

By ELMER A. HORTON, LAURENCE K. LOFTIN, Jr., STANLEY F. RACISZ, and JOHN H. QUINN, Jr.

SUMMARY

A performance analysis has been made to determine whether boundary-layer control by suction might reduce the minimum take-off and landing distances of a four-place or five-place airplane or a liaison type of airplane below those obtainable with conventional high-lift devices. The airplane was assumed to have a cruise duration of 5 hours at 60-percent power and to be operating from airstrips having a ground friction coefficient of 0.2 or a combined ground and braking coefficient of 0.4. The payload was fixed at 1500 pounds, the wing span was varied from 25 to 100 feet, the aspect ratio was varied from 5 to 15, and the power was varied from 300 to 1300 horsepower. Maximum lift coefficients of 5.0 and 2.8 were assumed for the airplanes with and without boundary-layer control, respectively. A conservative estimate of the boundary-layer-control-equipment weight was included. The effects of the boundary-layer control on total take-off distance, total power-off landing distance, landing and take-off ground run, stalling speed, sinking speed, and gliding speed were determined.

The more important results of the analysis can be summarized as follows: The absolute minimum total take-off distance which was obtained with an airplane having a low wing loading and a moderately low aspect ratio is not reduced by the addition of boundary-layer control. The effectiveness of boundary-layer control in reducing the total take-off distance for a given maximum speed improves with increasing aspect ratio, and, for wing loadings of 10 pounds per square foot or more and an aspect ratio of 10 or more, the addition of boundary-layer control results in a decrease in the total take-off distance of as much as 14 percent. The total landing distance for a given maximum speed is reduced for all configurations by the use of boundary-layer control. The reduction varies from 25 to 40 percent depending on the wing loading.

The reduction in ground run for take-off was negligible for an aspect ratio of 5 but was of the order of 10 to 30 percent for aspect ratios of 10 and 15; whereas, the reduction in ground run for landing was from 25 to 40 percent for all configurations. The stalling speed for a given maximum speed was reduced 20 to 25 percent for all configurations by the application of boundary-layer control.

For the landing condition, boundary-layer control also reduced the gliding speed but resulted in a slightly higher sinking speed, or vertical velocity, than that for the conventional airplane having the same wing span.

INTRODUCTION

The design of a new airplane usually involves a compromise between several desired high-speed performance characteristics and the practical necessity for operating the airplane in and out of airports of reasonable size. The degree of necessary compromise has been reduced by the use of high-lift devices to increase the maximum lift coefficient. Such devices as leading- and trailing-edge flaps which are now in use on operational aircraft permit the attainment of maximum airplane lift coefficients, power-off, of the order of 2.8 (reference 1). In the belief that much higher airplane maximum lift coefficients would be desirable, numerous wind-tunnel investigations have been made of the effectiveness of boundary-layer control as a means for obtaining high maximum lift coefficients. Airfoil-section maximum lift coefficients as high as 5.5 have been obtained in wind-tunnel tests (see, for example, reference 2), and in a limited flight investigation airplane lift coefficients of 4.2 were obtained (reference 3).

There is, however, some question as to the exact benefits to be derived from the use of the high lift coefficients available with boundary-layer control. In an effort to obtain some idea of the extent to which the high lift coefficients available with boundary-layer control might be useful, an analytical investigation has been made of the effect of lift coefficient on the distance required for a four or five place or liaison type of airplane to take off and land over a 50-foot obstacle.

A liaison type of airplane was selected for the analysis since such an airplane might be expected to operate from small or makeshift airports where take-off and landing distances would be of primary importance. A 1,500-pound payload and sufficient fuel for a 5-hour flight were assumed. The power, wing span, and aspect ratio of the airplane configurations investigated were varied over a wide range.

¹ Supersedes NACA TN 1597, "Analysis of the Effects of Boundary-Layer Control on the Take-Off Performance Characteristics of a Liaison-Type Airplane" by Elmer A. Horton and John H. Quinn, Jr., 1948, and NACA TN 2143, "Analysis of the Effects of Boundary-Layer Control on the Power-Off Landing Performance Characteristics of a Liaison-Type Airplane" by Elmer A. Horton, Laurence K. Loftin, Jr., and Stanley F. Racisz, 1950.

Allowances were made for changes in the gross weight resulting from changes in the airplane configuration and for the weight of the boundary-layer-control equipment. A maximum lift coefficient of 2.8 was assumed for the airplanes without boundary-layer control and a value of 5.0 was assumed to be the highest maximum lift coefficient available with boundary-layer control.

In addition to calculations of the distance required to land and take off over a 50-foot obstacle, the ground-run distance corresponding to landing and take-off, stalling speed, gliding speed, and sinking speed were calculated for all the airplanes. The maximum speed of each airplane configuration was also calculated in order to provide some indication of the relation between high-speed performance and landing and take-off performance. The landing maneuver was assumed to be executed without the use of power.

SYMBOLS

W	airplane gross weight, pounds
w	weight of airplane components, pounds
g	acceleration due to gravity (assumed equal to 32.2), feet per second per second
T	thrust, pounds
T_0	static thrust, pounds
$T_{V_{max}}$	thrust at maximum velocity, pounds
S	wing area, square feet
θ	angle of flight path with respect to ground, degrees
V	velocity, feet per second
$\bar{V}$	average flight velocity during transition arc, feet per second $\left(\frac{V_G + V_s}{2}\right)$
D	total drag, pounds
C_D	airplane drag coefficient (D/qS)
D_0	wing profile drag, pounds
C_{D_0}	wing profile-drag coefficient (D_0/qS)
C_{Di}	induced drag coefficient ($C_L^2/\pi Ae$)
L	total lift, pounds
C_L	airplane lift coefficient (L/qS)
C_{LT}	lift coefficient that would be required for steady level flight at speed $\bar{V}$
$\Delta C_L = C_{L_{max}} - C_{LT}$	
s	horizontal distance, feet
s_i	total take-off distance over 50-foot obstacle, feet
s_L	landing distance from 50-foot obstacle, feet
R	radius of transition arc, feet
q	dynamic pressure, pounds per square foot $\left(\frac{1}{2} \rho V^2\right)$
H	total pressure, pounds per square foot
C_P	pressure coefficient $\left(\frac{H_0 - H_d}{q_0}\right)$
Q	quantity rate of flow, cubic feet per second
C_Q	quantity rate of flow coefficient (Q/SV_0)
P	brake horsepower

A	aspect ratio (b^2/S)
h	altitude at which flare is started, feet
b	span, feet
e	wing efficiency factor based on variation of spanwise loading from an elliptical loading with no ground effect (assumed equal to 0.9)
$A_P = \frac{T_0}{P}$	constants for calculating propeller thrust
$B = \frac{2(T - T_0)}{P \rho V^2}$	
$C = \frac{T_{V_{max}}}{P}$	
η	efficiency factor of blower (assumed equal to 0.9)
μ	ground or braking friction coefficient or both
ρ	mass density of air, slugs per cubic foot
γ	ratio of specific heats at constant volume and constant pressure (1.4 for air)
τ	time, seconds
Subscripts:	
c	conventional airplane
BLC	boundary-layer-control airplane
0	free-stream conditions
d	conditions in boundary-layer-control duct
L	conditions at point of ground contact on landing
max	maximum
u	pay load
G	glide
F	float
g	ground conditions for take-off
1	conditions during ground run of airplane for take-off
B	ground conditions for landing
t	conditions at take-off of airplane
T	transition
s	stalling
opt	optimum conditions

METHOD OF ANALYSIS

In calculating the take-off and landing performance characteristics for the various airplanes, a number of basic assumptions were made concerning the airplane configurations, the aerodynamic characteristics of the wing both with and without boundary-layer control, the method of estimating the weight of the airplane and the auxiliary boundary-layer-control equipment, and the method used in performing the take-off and landing maneuvers. The final comparative results should be unaffected by these assumptions inasmuch as the same assumptions were used for both the conventional and boundary-layer-control airplanes, except for the assumptions concerning the weight of the boundary-layer-control equipment which, in this instance, are believed to be conservative. In general, the assumptions were compatible with data from existing airplanes.

AIRPLANE CONFIGURATION

The airplane was assumed to have a cantilever semimonocoque wing, rectangular in plan form, with airfoil sections tapering from a thickness-chord ratio of 0.18 at the root to 0.12 at the tip. The empennage area was considered to be $0.25S$. The fuselage frontal area F for the constant payload w_u of 1,500 pounds was determined from the following equation obtained from reference 4:

$$F = 0.15w_u^{2/3}$$

The dimensions of the fuselage and landing gear remained constant.

The propeller was considered to be fully automatic in order that maximum engine speed and power could be obtained at all airspeeds. The fuel and oil supplies were assumed sufficient for 5 hours of cruising at 60 percent of maximum power with a specific fuel consumption of 0.50 pound per brake horsepower per hour.

It was assumed that an auxiliary engine and a blower were used to apply suction through the duct provided by the internal space of the semimonocoque wing to the boundary-layer-control slots. The boundary-layer-control apparatus was assumed to have a fuel supply sufficient for the duration of the flight.

AERODYNAMIC CHARACTERISTICS

The variation of wing profile-drag coefficient with lift coefficient, shown in figure 1, was determined from section data contained in references 5 to 8. The data are for the smooth-surface condition of the wings with and without boundary-layer control. The use of boundary-layer suction is seen to cause only relatively small changes in the profile drag in the range of lift coefficients from 0 to 1.6. On a wing provided with suction slots to improve the maximum lift, however, suction through these slots must be maintained in the cruising range of lift coefficients in order that the profile drag will not be increased by outflow through the slots. For

FIGURE 1.—Assumed profile-drag coefficient of the wing with and without boundary-layer control.

this reason, the previously mentioned provision of enough fuel to operate the boundary-layer-control apparatus continuously during the 5-hour flight was considered necessary. The use of a drag polar based on airfoil-section data for the rough-surface condition might represent a more realistic appraisal of the high-speed characteristics of the airplane configurations investigated. Enough data were not available, however, to permit the determination of the drag polar for the rough-surface condition. The assumed empennage drag coefficient based on the empennage area was 0.01 and the assumed fuselage and landing-gear drag coefficients were 0.20 and 0.05, respectively, based on the fuselage frontal area (reference 9). The induced drag coefficients were calculated from the equation

$$C_{D_i} = \frac{C_L^2}{\pi A e}$$

where the value of e was assumed to be 0.9. The maximum attainable lift coefficients were assumed to be 2.8 and 5.0 for the airplane without and with boundary-layer control, respectively.

WEIGHT ANALYSIS

It was found convenient to express the gross weight of the airplane in terms of the wing span, aspect ratio, and power. The relation expressing the gross weight as a function of these variables was found by determining the weights of various airplane components as functions of one or more of the variables. The airplane components are designated by the following subscripts:

m	engine
p	propeller, hub, and engine auxiliaries
g	gasoline and oil
F	fuselage
L	landing gear
E	empennage
w	wing
b	blower
bm	blower engine

The following empirical relations giving the weights of engine, engine auxiliaries, propeller, and hub were determined from an analysis of 65 airplanes and 225 engines ranging from 50 to 2,000 horsepower (references 9 and 10):

$$w_m = P \left(\frac{192}{P-30} + 1.1 \right) \quad (1)$$

$$w_p = P \left(\frac{4.58}{P^{0.68}} + 0.48 \right) \quad (2)$$

The airplane was assumed to have a cruising duration of 5 hours at 60-percent full power with a specific fuel consumption of 0.5 pound per horsepower per hour and an oil requirement of 1 gallon per 16 gallons of gasoline (reference 9). Thus, the weight of gasoline and oil is

$$w_g = 1.62P \quad (3)$$

The empirical relations giving the weight of fuselage, landing gear, empennage, and wing are from reference 9 and are as follows:

$$w_F = 0.172 W^{0.94} \quad (4)$$

$$w_L = 0.067 W^{0.98} \quad (5)$$

$$w_E = 0.25S \quad (6)$$

$$w_w = 0.046 S A^{0.47} \left(\frac{W}{b} \right)^{0.53} \left(\frac{b}{t} \right)^{0.115} \quad (7)$$

For the analysis, a value of $\frac{b}{t} = 35$, which is a representative value for the type airplane considered, was assumed in evaluating equation (7). The ratio of span to root thickness b/t enters in the wing weight equation to the 0.115 power and, since the wing weight is only approximately 15 percent of the gross weight, this ratio could vary appreciably without causing a change in the gross-weight estimate of more than 1 to 2 percent.

A summation of equations 1 to 7 plus the assumed pay load of 1,500 pounds results in the following empirical relation giving the gross weight of the conventional airplane as a function of span, aspect ratio, and horsepower:

$$W_c = P \left(\frac{192}{P-30} + \frac{4.58}{P^{0.68}} + 3.20 \right) + 1500 + 0.172 W^{0.94} + 0.067 W^{0.98} + S \left[0.25 + 0.07 A^{0.47} \left(\frac{W}{b} \right)^{0.53} \right] \quad (8)$$

The gross weight of the boundary-layer-control airplane is then the gross weight of the conventional airplane plus the gross weight of the blower engine w_{bm} and blower w_b ; that is,

$$W_{BLC} = W_c + w_{bm} + w_b \quad (9)$$

The estimate of the blower-engine power was made in terms of the compression ratio, quantity flow, absolute entrance pressure, and blower efficiency by the following expression for an adiabatic gas flow:

$$P_{bm} = \frac{\gamma}{\gamma-1} \frac{H_a Q}{550 \eta} \left[\left(\frac{H_0}{H_a} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right] \quad (10)$$

Reference 2 indicated that sufficient boundary-layer control for a maximum lift coefficient of 5.0 could be obtained with a flow coefficient $C_Q = 0.03$ and a pressure coefficient $C_P = 4.0$. However, in order to make a conservative estimate of the weight of the boundary-layer-control equipment, a flow coefficient of 0.04 and a pressure coefficient of 15.0 (reference 11) were used and, by substitution, equation (10) becomes, for $\eta = 0.9$,

$$P_{bm} = 0.00367 \left(H_0 - 3 \frac{W}{S} \right) \sqrt{WS} \left[\left(\frac{H_0}{H_0 - 3 \frac{W}{S}} \right)^{0.286} - 1 \right] \quad (11)$$

The blower-engine weight was then obtained by assuming an engine weight of 2.5 pounds per horsepower and a flight duration of 5 hours at 60-percent power with a specific fuel consumption of 0.5 pound per horsepower per hour. With these assumptions, the blower-engine weight, including fuel, is

$$w_{bm} = 4 P_{bm} = 0.0147 \left(H_0 - 3 \frac{W}{S} \right) \sqrt{WS} \left[\left(\frac{H_0}{H_0 - 3 \frac{W}{S}} \right)^{0.286} - 1 \right] \quad (12)$$

The weight of the blower was obtained by assuming an axial-flow stator-rotor type constructed of aluminum alloy having a hub-to-tip ratio of 0.6 and an axial velocity of 400 feet per second. The outer casing was assumed to be 0.125 inch thick and 48 inches long, the rotor, blades, and shaft, to be equivalent to a disk 2 inches thick with a diameter 0.8 of the tip diameter, and the stator vanes, to be equivalent to a disk 0.25 inch thick with the same diameter as the complete rotor. With these assumptions, the blower-weight equation was developed and is as follows:

$$w_b = 0.044 \sqrt{WS} + 1.13 (WS)^{0.25} \quad (13)$$

TAKE-OFF PERFORMANCE ANALYSIS

Take-off maneuver.—The take-offs were assumed to be made at full power, with no head wind, and to consist of three phases: (1) an accelerated run on the ground at the attitude for least total resistance until the speed for take-off was reached; (2) the transition arc or period of change of the flight path from ground run to steady climb; and (3) steady climb to an altitude of 50 feet where take-off is considered complete. A sketch illustrating the assumed maneuver is presented in figure 2.

Equations for total take-off distance.—The following equation for the total take-off distance was obtained from reference 12 by combining the expressions giving the distance

FIGURE 2.—Illustration of assumed maneuver to clear a 50-foot obstacle on take-off.

required for ground run, transition arc, and climb:

$$s_t = \frac{W/S}{\rho g} \left\{ \frac{1}{(\mu C_{L_1} - C_{D_1}) - B \frac{W/S}{W/P}} \log_e \left[1 + \frac{(\mu C_{L_1} - C_{D_1}) - B \frac{W/S}{W/P}}{\left(\frac{A_P}{W/P} - \mu \right) C_{L_1}} \right] + \frac{2 \tan \frac{\theta}{2}}{C_{L_{max}} - C_{L_1}} + \frac{\rho g h}{S \tan \theta} \right\} \quad (14)$$

where

$$\theta = \sin^{-1} \left[\frac{A_P}{W/P} - \left(B \frac{W/S}{W/P} + C_{D_1} \right) \frac{1}{C_{L_1}} \right] \quad (15)$$

and

$$C_{L_1} = 0.9 C_{L_{max}}$$

which is the usual value assumed for C_{L_1} in an analysis of this nature.

The attitude of least air and ground resistance during the ground run, as shown in reference 13, is defined by the expression:

$$C_{L_1} = \frac{1}{2} \mu \pi A e \quad (16)$$

In using equation (16) in the analysis, the profile-drag variation is neglected. The assumed ground friction coefficient $\mu=0.2$ is equivalent to that of deep grass or sand. A lower value of μ corresponding to that of concrete would reduce the take-off distance of both the conventional and

boundary-layer-control airplanes by approximately the same percentage; thus the comparative results would be equal to those given in this report.

The power constants A_P and B used in equations 14 and 15 were obtained from reference 12 and are reproduced herein as figure 3. Use of figure 3 requires determination of V_{max} as a function of span, which was done by equating thrust to airplane drag as follows:

$$T_{V_{max}} = \frac{1}{2} \rho V_{max}^2 \frac{b^2}{A} C_D \quad (17)$$

where C_D is the summation of the assumed drags of the airplane components in coefficient form. Also, from reference 12,

$$T_{V_{max}} = CP \quad (18)$$

where, from figure 3,

$$C = 3.09 - 0.005 V_{max} \quad (19)$$

equation (17) can then be expressed as

$$P(3.09 - 0.005 V_{max}) = \frac{1}{2} \rho V_{max}^2 \frac{b^2}{A} C_D \quad (20)$$

From this equation V_{max} as a function of span for various powers and aspect ratios was obtained for both the conventional and boundary-layer-control airplane, and the results are given in figures 4 and 5. Once V_{max} is known as a function of span, the power constants A_P and B are obtained for the various spans from figure 3.

FIGURE 3.—Thrust factors as functions of maximum speed for automatic propellers (reference 12).

FIGURE 4.—Maximum speed of assumed airplane without boundary-layer control as a function of span for various powers.

(a) $A=5$.(b) $A=10$.

FIGURE 5.—Maximum speed of assumed airplane with boundary-layer control as a function of span for various powers.

Ground-run distance and stalling speed.—The ground run required for take-off was calculated by use of the following expression from reference 12:

$$s_g = \frac{W/S}{\rho g \left[(\mu C_{L_1} - C_{D_1}) - B \frac{W/S}{W/P} \right]} \log_e \left[1 + \frac{(\mu C_{L_1} - C_{D_1}) - B \frac{W/S}{W/P}}{\left(\frac{A_P}{W/P} - \mu \right) C_{L_1}} \right] \quad (21)$$

The stalling speed V_s was found for each airplane from the relation

$$V_s = \sqrt{\frac{2W}{\rho S C_{L_{max}}}} \quad (22)$$

LANDING PERFORMANCE ANALYSIS

Landing maneuver.—The landing maneuver was considered to consist of four phases: (1) the steady glide, (2) a transition path executed at maximum lift coefficient to bring the airplane from a steady glide to level flight, (3) a floating period of 2 seconds to allow for lag in control response and for the application of brakes (see reference 14), and (4) the ground run. The beginning of the landing was considered as the point at which the altitude was 50 feet; the total landing distance was considered to be the horizontal distance from this point to the end of the ground run. The maneuver was considered to be performed without the use of power—that is, no propeller drag or thrust—and with no wind. A sketch illustrating the assumed maneuver is presented in figure 6.

Basic assumptions.—In calculating the total landing distance, certain simplifying assumptions were made in connection with the manner in which the transition from the steady-glide speed and attitude to level-flight speed and attitude was executed. These assumptions were based on the concept that the horizontal distance covered during the transition period for the type of airplane considered is a relatively small portion of the total landing distance so that a precise determina-

tion of the transition path is not required. The simplifying assumptions were:

1. The airplane was assumed to execute the transition at maximum lift coefficient and the transition path was assumed to be represented by an arc of constant radius. This assumption implies, of course, a constant speed during the transition.

2. Although a constant speed was assumed for the transition arc, it is, of course, obvious that in the actual case the speed during the transition must vary from the steady-glide speed to the landing speed. The constant speed implied by the assumption of a transition arc of constant radius was determined by assuming a linear variation in speed from the steady-glide speed to the stalling speed and taking the constant speed as the arithmetic mean of these two values. This assumption implies a constant decelerating force during the transition.

These assumptions are somewhat similar to those found in approximate methods for calculating the transition path following take-off (reference 12). Such approximate methods for calculating the take-off distance have been found to give good results and, in those cases for which experimental data were available, the method outlined for calculating the landing distance was also found to give good results.

Development of landing equations.—On the basis of assumptions 1 and 2 the following equations for the total landing distance can be derived. The horizontal distance covered during the transition arc s_T is considered first. Reference to figure 6 shows that

$$s_T = R \sin \theta_G \quad (23)$$

where θ_G is the angle of steady glide and R is the radius of the transition arc. The instantaneous radius of curvature during a pull-up at maximum lift is given by the expression

$$R = \frac{2}{\rho g} \frac{W}{S} \frac{1}{C_{L_{max}} - C_{L_T} \cos \theta} \quad (24)$$

where C_{L_T} in this equation corresponds to the lift coefficient for unaccelerated level flight at the velocity at which the pull-up is being executed and θ is the instantaneous flight-path angle. If the cosine of the glide-path angle is assumed to be 1.0, equation (24) can be written as follows:

$$R = \frac{2}{\rho g} \frac{W}{S} \frac{1}{\Delta C_L} \quad (25)$$

where ΔC_L is the difference between the maximum lift coefficient and the lift coefficient corresponding to the previously defined mean speed used during the transition. Since the stalling speed is known, the value of the steady-glide speed V_G is all that is required for the determination of R and the horizontal distance covered during the transition. The value of V_G must be chosen in such a way that the time required for the velocity to decrease from V_G to V_L is the same as the time required for the airplane to traverse the distance s_T . The tangential forces acting on the airplane during the transition arc are composed of the drag which is a decelerating force and the component of weight along the flight path which is an accelerating force. The mean decelerating drag force

FIGURE 6.—Illustration of assumed maneuver to clear a 50-foot obstacle in landing.

D_T is determined from the drag coefficient at the maximum lift coefficient and the mean speed $\bar{V}$.

There is, however, an accelerating force which may be determined in the following manner. At the end of the steady glide the following relation holds:

$$D_G = W \sin \theta_G$$

where D_G is the drag in the steady glide. Since the glide angle θ_G is usually small, θ varies in a nearly linear manner with s_T during the transition, and since $\sin \theta$ also varies in a nearly linear manner with θ for small values of θ , the mean accelerating force during the transition may be written as

$$\frac{W \sin \theta}{2} = \frac{D_G}{2}$$

Therefore, the time required for the airplane to decelerate from the steady-glide speed V_G to the landing speed V_L is then given by the following expression:

$$\tau = \frac{W}{g} \frac{V_G - V_L}{D_T - \frac{D_G}{2}} \quad (26)$$

If the cosine of the flight-path angle is considered to be unity, the time required to traverse the distance s_T is

$$\tau = \frac{s_T}{\bar{V}} \quad (27)$$

where $\bar{V}$ is the mean speed. Since the two intervals of time expressed by equations (26) and (27) must be equal, the distance s_T may be expressed in the following form:

$$s_T = \frac{2\bar{V}(V_G - V_L)W}{g(2D_T - D_G)} \quad (28)$$

If

$$\sin \theta_G = \sin \tan^{-1} \left(\frac{C_D}{C_L} \right)_G = \left(\frac{C_D}{C_L} \right)_G$$

the distance s_T as given by equations (23) and (25) may be written

$$s_T = \frac{2}{\rho g} \frac{W}{S} \frac{1}{\Delta C_L} \left(\frac{C_D}{C_L} \right)_G \quad (29)$$

A simultaneous solution of equations (28) and (29) gives, after some algebraic manipulation, the following equation:

$$\begin{aligned} & \left[\left(\frac{C_D}{C_L} \right)_L \left(\frac{C_D}{C_L} \right)_G - 6 \right] \left(\frac{V_L}{V_G} \right)^3 + \left[3 \left(\frac{C_D}{C_L} \right)_G \left(\frac{C_D}{C_L} \right)_L + 10 \right] \left(\frac{V_L}{V_G} \right)^2 + \\ & \left[\left(3 - 2 \frac{C_{D_G}}{C_{D_L}} \right) \left(\frac{C_D}{C_L} \right)_G \left(\frac{C_D}{C_L} \right)_L - 2 \right] \left(\frac{V_L}{V_G} \right) + \\ & \left[\left(1 - 2 \frac{C_{D_G}}{C_{D_L}} \right) \left(\frac{C_D}{C_L} \right)_G \left(\frac{C_D}{C_L} \right)_L - 2 \right] = 0 \end{aligned} \quad (30)$$

An exact solution of equation (30) for $\frac{V_L}{V_G}$ requires additional analytic expressions relating $\left(\frac{C_D}{C_L} \right)_G$ and $\frac{C_{D_G}}{C_{D_L}}$ to $\frac{V_L}{V_G}$. Such relations can, of course, be found by expressing the drag polars for the various airplanes in analytic form. It was found more convenient, however, to perform a simultaneous solution of equations (28) and (29) by a trial and error process. Once the correct value of V_G is determined from equations (28) and (29), the horizontal distance covered in the transition arc is easily calculated for a particular airplane from equation (29).

The horizontal distance s_G , covered in the steady glide from a height of 50 feet to the height h at which the transition is begun, can be calculated by the following equations (see fig. 6):

$$s_G = \frac{50 - h}{\tan \theta_G} = \frac{50 - h}{\left(\frac{C_D}{C_L} \right)_G}$$

However,

$$h = R(1 - \cos \theta_G)$$

so that

$$s_G = \frac{50 - R \left[1 - \cos \tan^{-1} \left(\frac{C_D}{C_L} \right)_G \right]}{\left(\frac{C_D}{C_L} \right)_G} \quad (31)$$

The values of R and $\left(\frac{C_D}{C_L} \right)_G$ are already known from the previous calculations of the transition path so that s_G may be readily determined. The distance covered during the floating period is merely

$$s_F = 2 V_L = 2 \sqrt{\frac{2W}{\rho S C_{L_{max}}}} \quad (32)$$

The equation for determining the ground run or braking distance, obtained from reference 15, is

$$s_B = \frac{V_L^2}{2g \left(\frac{C_D}{C_L} - \mu \right)} \log_e \left(\frac{C_D/C_L}{\mu} \right) \quad (33)$$

where $\frac{C_D}{C_L}$ is the lift-drag ratio for the maximum-lift condition and V_L corresponds to the stalling speed. The combined ground and braking friction coefficient was assumed to be 0.4. This value of the friction coefficient can be obtained with cinders on ice. (See reference 14.) The ground effect on the induced drag was neglected. The total landing distance is obtained from a summation of the horizontal distances covered during the four phases of the maneuver:

$$s_L = s_G + s_T + s_F + s_B \quad (34)$$

where these four components are calculated by means of equations (31), (29), (32), and (33), respectively.

SCOPE OF CALCULATIONS

The landing and take-off performance characteristics calculated included the total landing and take-off distances, the ground run corresponding to landing and take-off, the stalling speed, the gliding speed, and the sinking speed. The airplanes for which the landing and take-off performances were calculated had wing spans varying from 25 feet to 100 feet, engine brake horsepower varying from 300 to 1,300, and aspect ratios of 5, 10, and 15. As previously stated, the wing span, aspect ratio, and power determine the weight of an airplane and the airplane configuration. The actual values of the engine horsepower for which calculations were made were somewhat different for the landing and take-off analysis; however, the range of horsepower covered in the two analyses was the same. The landing and take-off performances were calculated for each airplane with and without boundary-layer control. The highest attainable value of the maximum lift coefficient was assumed to be 2.8 for the airplanes without boundary-layer control and, 5.0 for the airplanes with boundary-layer control. The landing performance calculations were made only for lift coefficients of 2.8 and 5.0. The take-off performance calculations, however, were made for a number of lift coefficients in order to determine the optimum value for each configuration. The effect of the additional weight of the boundary-layer-control equipment on the take-off performance characteristics was isolated by calculating the take-off performance characteristics of the boundary-layer-control airplane with and without the additional weight of the boundary-layer-control equipment included in the gross-weight estimate. This calculation was made for wings of aspect ratio 10 only inasmuch as the effect would be relatively the same for other aspect ratios.

Data defining the range of airplane configurations for which the performance calculations were made are presented in figures 7 and 8 for the airplanes without and with boundary-layer control, respectively. These data were obtained by cross-plotting the data derived from equations 8, 12, and 13, examples of which are given in figures 9 and 10 for the aspect-ratio-10 configuration. From figures 7 and 8 it is seen that the wing loading of the airplanes investigated varied from about 4 pounds per square foot to 160 pounds per square foot without boundary-layer control and, from 4 pounds per square foot to 180 pounds per square foot with boundary-layer control.

The maximum velocity of the different airplane configurations without and with boundary-layer control was calculated in order to provide a basis of comparison for the high- and low-speed performances and is given in figures 4 and 5. From figures 4 and 5 it is seen that for a given wing span, aspect ratio, and brake horsepower of the main propulsive unit the maximum velocities of the airplanes with and without boundary-layer control are nearly the same. The slight variation in speed is due to the additional weight of the boundary-layer-control equipment which increases the wing loading and thus the lift and drag coefficient for any given speed and also the small extent to which the drag polars of

the airplanes with and without boundary-layer control differ in the low lift-coefficient range (fig. 1).

RESULTS AND DISCUSSION

The discussion is intended to show the effects of increasing the maximum lift coefficient by boundary-layer control upon the landing and take-off performance characteristics and upon the relation between high-speed performance and the take-off and landing performance as the airplane configuration is varied. The pertinent take-off and landing performance characteristics are presented in terms of the wing span, power, and aspect ratio for the airplanes with and without boundary-layer control. The choice of variables employed in presenting the data was arbitrary to some extent. Although other parameters could have been employed, span, aspect ratio, and power were chosen because these variables indicate the physical size and practicability of the airplane. In some cases, the performance parameters were plotted against wing loading or power loading as well as wing span because their use tended to clarify the results. The effect upon the take-off characteristics of increasing the maximum lift coefficient by boundary-layer control is discussed first.

TAKE-OFF CHARACTERISTICS

The take-off characteristics to be discussed are:

- (1) The total take-off distance
- (2) The ground run and stalling speeds

TOTAL TAKE-OFF CHARACTERISTICS

Examples of the variations of total take-off distance of the boundary-layer-control airplane with maximum lift coefficient for various spans and horsepower at an aspect ratio of 10 are presented in figure 11. For a given aspect ratio, the lift coefficient for minimum take-off distance increases as the span decreases and the wing loading increases. These results were cross-plotted in figure 12 to show the variation of optimum C_L with wing loading for the various aspect ratios and horsepower. The figure shows that at an aspect ratio of 5, regardless of wing loadings, the optimum lift coefficient is less or slightly greater than that available with conventional high-lift devices. For aspect ratios of 10 and 15 and wing loadings of less than 10 pounds per square foot, although the optimum maximum lift coefficient for take-off exceeds the maximum lift coefficient attainable without boundary-layer control, the use of lift coefficients greater than 2.8 will decrease the take-off distance very little. (See fig. 11.) For the larger wing loadings, however, the rate of change of the take-off distance with lift coefficient is large and the use of the optimum lift coefficient offers a considerable decrease in take-off distance.

Throughout the remainder of the analysis, the effects of other variables on total take-off distance are discussed for the optimum lift coefficient unless it exceeds 5.0, in which case the take-off distance was calculated for a maximum lift coefficient of 5.0.

FIGURE 8.—Wing loading of assumed airplane with boundary-layer control as a function of span for various powers.

FIGURE 9.—Gross weight of conventional airplane as a function of span for various powers. $A=10$.

Effect of boundary-layer control on take-off.—The variation of take-off distance with span for various horsepowers is presented for aspect ratios of 5, 10, and 15 in figures 13 and 14 for the conventional and boundary-layer-control airplanes, respectively. The effect of the weight of the boundary-layer-control equipment on the take-off characteristics was found for an aspect ratio of 10 by assuming that no weight was added by the auxiliary blower and motor. These data are presented in figure 15.

The effect of boundary-layer control on the total take-off distance of the airplane may be seen in figure 16, which shows the total take-off distance as a function of maximum speed for both the conventional and boundary-layer-control airplanes with varying aspect ratio and horsepower. Figure 16 shows that for a given maximum speed and an aspect ratio of 5, regardless of span, the boundary-layer-control airplane generally requires more distance for take-off than the conventional airplane. As the aspect ratio increases, however, boundary-layer control becomes more effective, and for an aspect ratio of 10 or more with a wing loading of 10 pounds per square foot or more the addition of boundary-layer control decreases the total take-off distance. It follows that, for a given take-off distance, the boundary-layer-control airplane would have a greater maximum speed.

The effect of the weight of the boundary-layer-control equipment on the total take-off distance is shown in figure 16 (b) for aspect ratio of 10. This figure shows that the total take-off distance may be decreased appreciably by decreasing the weight; therefore, every effort should be made to decrease the weight of the boundary-layer-control equipment.

Figure 16 also shows that the absolute minimum total take-off distance obtained with a low wing loading and moderately low aspect ratio is not decreased by the addition of boundary-layer control.

FIGURE 12.—Optimum maximum lift coefficient for minimum total take-off distance of an airplane with boundary-layer control as a function of wing loading for various aspect ratios and powers.

Effect of power loading on take-off distance.—The power loading is shown as a function of take-off distance for various wing loadings and aspect ratios in figures 17 and 18 for the conventional and boundary-layer-control airplanes, respectively. As is shown, the optimum power loading, which is nearly independent of wing loading and aspect ratio, is approximately 8.5 and 9.0 pounds per horsepower for the conventional airplane and the boundary-layer-control airplane, respectively. It should be noted that increasing the horsepower above the optimum value increases the take-off distance. This result is due to the accompanying change in engine, fuel, and structural weight.

GROUND-RUN AND STALLING-SPEED CHARACTERISTICS

In order to obtain the minimum ground run, which is given in figures 19 and 20, the calculations were made by considering the ground run completed when a speed was reached corresponding to a flying speed at 0.9 of the assumed maximum lift coefficient. During the analysis, it was found that, because the induced drags were large for aspect ratio of 5 of the boundary-layer-control airplane, the power was insufficient to maintain level flight at lift coefficients greater than 3.8; therefore, the ground run for an aspect ratio of 5 was calculated for a maximum lift coefficient of 3.8. The variation of ground run with span for various horsepower and aspect ratios is shown in figures 19 and 20 for the conventional and boundary-layer-control airplanes, respectively, and in figure 21 for the airplane with boundary-layer control but with the weight of the additional equipment disregarded. These data are compared in figure 22 where the ground run has been plotted as a function of V_{max} for various horsepower and aspect ratios.

The boundary-layer-control airplane had shorter ground runs than the conventional airplane for all configurations considered. The reduction was negligible for an aspect ratio of 5 and a maximum lift coefficient of 3.8. At aspect ratios of 10 and 15 and maximum lift coefficient of 5.0, however, the ground run was decreased 10 to 30 percent by the addition of boundary-layer control. The beneficial effect of reducing the boundary-layer-control-equipment weight, as previously noted for the total take-off distance, was again observed for the case of the ground run (fig. 22 (b)).

This reduced ground run produced by use of high maximum lift coefficients associated with boundary-layer control may prove to be most advantageous for carrier-based airplanes or seaplanes.

The stalling speed V_s is presented as a function of maximum speed in figure 23 for various aspect ratios and horsepower. The stalling speed was 20 to 25 percent less for the boundary-layer-control airplane than for the conventional airplane for all configurations considered.

POWER-OFF LANDING CHARACTERISTICS

The power-off landing characteristics to be discussed are

- (1) The total landing distance
- (2) The ground-run distance
- (3) The speed at which the different phases of the landing maneuver are executed

Total landing distance.—The total landing distance is presented as a function of wing span in figure 24 with power as the parameter. The data are for aspect ratios of 5, 10, and 15 and are for the airplanes with and without boundary-layer control. An examination of the data of figure 24 indicates that, for a given engine power and aspect ratio, the landing distance decreases rapidly with increasing span over a certain range of spans, after which further increases in span have little effect. This is a result of the manner in which the wing loading varies with span. (See figs. 7 and 8.) For a given wing span, the landing distance is seen to increase with increasing engine power. In all cases, increasing the aspect ratio for a fixed span and power increases the total landing distance. For any given aspect ratio, the shortest landing distance is obtained for the airplane with largest span and lowest power. These trends are evident in the data for all configurations investigated. The effect of boundary-layer control on the total landing distance can best be seen in figure 25. In this figure the ratio of the total landing distance with boundary-layer control to the total distance without boundary-layer control is plotted as a function of span. The data clearly indicate that, regardless of engine power or aspect ratio, the use of maximum lift coefficients of the order of 5.0 which can be obtained with boundary-layer control as compared with lift coefficients of 2.8 which can be obtained without boundary-layer control results in decreases in the total landing distance which vary between 25 and 40 percent.

The data of figure 26 show that, for a constant wing loading, the use of boundary-layer control results in reductions

of the total landing distance which vary from about 27 to 43 percent. The slightly more favorable effect of boundary-layer control when the comparison is based on a constant wing loading rather than on a constant span is explained by the fact that the addition of boundary-layer control to the airplane of constant span increases the wing loading by a small amount which has an adverse effect on the landing distance. For a constant wing loading, variations in the engine power have a negligible effect upon the landing distance (fig. 26); hence, the relatively large adverse effect of increasing the power upon the landing distance of an airplane of constant span, shown by the data of figure 24, results from the effect of engine power on wing loading. It might also be thought that the adverse effect upon the landing distance of increasing the aspect ratio for a given span and power (fig. 24) could be attributed entirely to an increase in wing loading. The data of figure 26, however, show that for a given wing loading, increasing the aspect ratio also causes some increase in the landing distance. This unfavorable effect of increasing aspect ratio on the landing distance results from the fact that as the aspect ratio is increased the airplane lift-drag ratio is also increased so that there results a flatter glide and, hence, a greater horizontal distance from the 50-foot obstacle to the point of ground contact. The proper application of a spoiler or air brake might, therefore, reduce or eliminate the unfavorable effect of increasing aspect ratio on the total landing distance.

FIGURE 24.—Landing distance of an airplane with and without boundary-layer control as a function of span for various powers.

FIGURE 24.—Concluded.

FIGURE 25.—Landing distance of airplane with boundary-layer control as a fraction of landing distance of same airplane without boundary-layer control.

FIGURE 26.—Landing distance of an airplane with and without boundary-layer control as a function of wing loading.

The over-all conclusion to be drawn from the data of figures 24 to 26 is that boundary-layer control causes a substantial reduction in the total landing distance of all the airplane configurations investigated. The minimum landing distance for the configurations investigated was obtained for the airplane configuration having boundary-layer control and the lowest wing loading and aspect ratio—that is, a wing loading of 4 pounds per square foot and an aspect ratio of 5.

As previously pointed out, the application of boundary-layer control does not have any appreciable effect upon the maximum speed. Consequently, the reductions in landing

distance resulting from boundary-layer control (figs. 24 to 26) can be obtained without any sacrifice in maximum speed in most cases. In order to show this effect more clearly, the total landing distance has been plotted against maximum speed in figure 27 for the airplanes with and without boundary-layer control. Figure 27 shows that for a given maximum speed the use of boundary-layer control results in a 25 to 40 percent decrease in the landing distance. The wing spans of the different airplanes are indicated by symbols on these curves. It is interesting to note that for most cases large increases in the maximum speed can be obtained with no increase in the landing distance by the use of boundary-layer control along with reduction in span. The unfavorable effect of increasing aspect ratio on the landing distance for a given maximum speed is, as previously pointed out, a result of the higher lift-drag ratio of the airplanes of high aspect ratio. The fact that boundary-layer control does not have a favorable effect upon the landing distance for the highest maximum speeds obtainable with a given power is explained by the data of figures 4 and 5 which show that the highest possible speed for a given power is slightly higher for the airplane without boundary-layer control than for the airplane with boundary-layer control. This is due to the increased wing loading of the boundary-layer-control airplane.

The data presented in figures 24 to 27 lead to the conclusion that the high lift coefficients available with boundary-layer control are very effective in reducing the landing distance of the type of airplane considered in this investigation. A somewhat different conclusion was reached with respect to the effect on the total take-off distance of the increased lift coefficients available with boundary-layer control. The data of figure 16 showed that there was no appreciable decrease in the total take-off distance due to boundary-layer control for a given maximum speed unless the aspect ratio was of the order of 15. Even for the higher aspect ratios, the relative effect of boundary-layer control on the total take-off distance is small as compared with its effect on the landing distance.

Ground-run distance.—The ground-run distance is plotted against wing span for different aspect ratios and engine horse-powers in figure 28 and against maximum speed in figure 29. The data of figure 28 indicate that the use of boundary-layer control results in reductions of the ground-run distance which vary from 30 to 40 percent depending upon the configuration. The use of the lowest possible wing loading—that is, low aspect ratio and engine of low power—gives the the shortest ground-run distance for a given span.

The data of figure 29 indicate that, for nearly all configurations, reductions in the ground-run distance of 35 to 40 percent can be obtained by the use of boundary-layer control without compromising the maximum speed. In comparison with the trends of figure 29, the data of figure 22 indicated that boundary-layer control has an important effect upon the ground run to take-off for a given maximum speed only if the aspect ratio is of the order of 10 to 15 and that the ground run for take-off is generally longer than that for landing.

(a) $A=5$.

FIGURE 27.—Landing distance of an airplane with and without boundary-layer control as a function of velocity for various powers.

(b) $A=10$.

FIGURE 27.—Continued.

FIGURE 29.—Ground-run distance of an airplane with and without boundary-layer control as a function of maximum velocity.

Landing speeds.—The speeds with which the various phases of the landing maneuver are executed are of some importance as an indication of the piloting skill required to land a particular airplane. For this reason, data are given in figures 30 and 31 pertaining to the effect of boundary-layer control on the vertical or sinking speed in the steady glide and steady-glide speed.

The effect of boundary-layer control on the sinking speed is shown in figure 30 where the vertical velocity is plotted against wing span for various horsepower and aspect ratios for the airplanes with and without boundary-layer control. The data show that boundary-layer control has only a relatively small effect on the sinking speed in all cases. For all the airplanes both with and without boundary-layer control, reducing the span for a given aspect ratio and engine power is seen to increase the sinking speed.

In figure 31 the velocity in the steady glide is plotted against wing span for the airplanes of different aspect ratio and power both with and without boundary-layer control. In all cases, the use of boundary-layer control is seen to reduce the speed in the steady glide by 20 to 25 percent. As would be expected, the steady-glide speed increases with

decreasing span for a fixed power and aspect ratio in all cases. Increasing the aspect ratio for a given span and power also increases the gliding speed because of the associated increase in wing loading and wing lift-drag ratio.

EFFECT OF ASSUMPTIONS ON RESULTS

As was previously pointed out, most of the many assumptions employed in the analysis would not be expected to have any large effect on the landing and take-off performances of the boundary-layer-control airplane as compared with the airplane without boundary-layer control. Three assumptions were made, however, which should be considered in comparing the performance characteristics of the conventional and boundary-layer-control airplanes. These assumptions are

- (1) No head wind
- (2) No ground effect
- (3) A ratio of span to root thickness of 35 and a thickness to chord ratio of 0.18 at the root and 0.12 at the tip

These three assumptions would probably have a greater effect on the boundary-layer-control airplane than on the conventional airplane for the following reasons.

(a) $A=5$.
(b) $A=10$.
(c) $A=15$.
FIGURE 30.—Vertical velocity as a function of span for an airplane with and without boundary-layer control.

FIGURE 31.—Velocity during glide for an airplane with and without boundary-layer control as a function of span.

Head wind.—Because the maximum lift coefficients of the boundary-layer-control airplanes were greater than those of the conventional airplanes, the horizontal speed during the landing or take-off maneuver was less for the boundary-layer-control airplane than for the conventional airplane. Given a uniform head wind, the airspeeds of the two airplanes would remain unchanged, but the horizontal speed with respect to the ground of the slower airplane would be reduced by a greater percentage than that of the faster airplane. Therefore, the horizontal distance required to land from or take off and climb to a given altitude would be decreased in a head wind by a greater percentage for the boundary-layer-control airplane than for the conventional airplane.

Ground effect.—The effect of proximity to the ground is mainly that of increasing the effective aspect ratio. The greater aspect ratio would result in proportionately greater decreases in induced drag for the boundary-layer-control airplane with its high maximum lift coefficient than for the conventional airplane; therefore, the take-off distance for the boundary-layer-control airplane would be decreased by a greater percentage than that for the conventional airplane. For a more thorough treatment of this subject, see reference 16.

Wing thickness-chord ratios.—If the ratio of wing span to root thickness were maintained at 35, the root thickness-chord ratios of the wing would greatly exceed 0.18 for the larger spans and aspect ratios. The wing profile drag of the

conventional airplane would, therefore, be considerably greater than the values used because of the large profile drags associated with airfoil sections having thickness ratios greater than 0.21 (reference 17). With boundary-layer control, however, it is possible to use the thicker airfoil sections without greatly increasing the profile drag as experimental results have indicated that, when separated flow exists, the drag of an airfoil section, including the boundary-layer-control power, may be less than the drag without boundary-layer control (references 2, 7, and 8).

CONCLUSIONS

An analysis was made to determine the effect of boundary-layer control on the take-off and power-off landing performance characteristics of a liaison type of airplane having aspect ratios ranging from 5 to 15, wing spans ranging from 25 to 100 feet, and engine brake horsepower ranging from 300 to 1,300. The airplanes were assumed to have a 1,500-pound pay load and a cruising duration at 60-percent power of 5 hours. The results of the analysis indicate the following conclusions:

1. The addition of boundary-layer control does not reduce the absolute minimum total take-off distance which is obtained with a low wing loading and a moderately low aspect ratio.
2. The effectiveness of boundary-layer control in reducing the total take-off distance for a given maximum speed improves with increasing aspect ratio and, for wing loadings of 10 pounds per square foot or more and an aspect ratio of 10 or more, the addition of boundary-layer control results in a decrease in the total take-off distance of as much as 14 percent.
3. For a given maximum speed the ground-run distance for take-off was reduced for all configurations by the use of boundary-layer control. This reduction was negligible for an aspect ratio of 5 but was from 10 to 30 percent for aspect ratios of 10 and 15.
4. For a given maximum speed, the use of boundary-layer control resulted in a reduction in stalling speed of 20 to 25 percent for all configurations.
5. A reduction in the weight of the boundary-layer-control equipment would result in an appreciable decrease in the total take-off distance and ground-run distance for take-off, but its effect on the stalling speed would be negligible.
6. The optimum horsepower loading for minimum take-off distance was found to be approximately 8.5 and 9.0 pounds per horsepower for the conventional and boundary-layer-control airplanes, respectively.
7. For a specified airplane maximum speed, the total landing distance was reduced from 25 to 40 percent and the landing ground-run distance was reduced 30 to 40 percent by the use of boundary-layer control.

8. The gliding speeds were 20 to 25 percent lower for most of the airplanes with boundary-layer control than those for the airplanes without boundary-layer control.

9. For a fixed wing span, the sinking speed, or vertical velocity for the landing condition was slightly higher for the airplane with boundary-layer control than that for the conventional airplane.

REPORT 1058

INFLUENCE OF CHEMICAL COMPOSITION ON RUPTURE PROPERTIES AT 1200° F OF FORGED CHROMIUM-COBALT-NICKEL-IRON BASE ALLOYS IN SOLUTION-TREATED AND AGED CONDITION¹

By E. E. REYNOLDS, J. W. FREEMAN, and A. E. WHITE

SUMMARY

The influence of systematic variations of chemical composition on rupture properties at 1200° F was determined for 62 modifications of a basic alloy containing 20 percent chromium, 20 percent nickel, 20 percent cobalt, 3 percent molybdenum, 2 percent tungsten, 1 percent columbium, 0.15 percent carbon, 1.7 percent manganese, 0.5 percent silicon, 0.12 percent nitrogen, and the balance iron. These modifications included individual variations of each of 10 elements present and simultaneous variations of molybdenum, tungsten, and columbium. Laboratory induction furnace heats were hot-forged to round bar stock, solution-treated at 2200° F, and aged at 1400° F. The melting and fabrication conditions were carefully controlled in order to minimize all variable effects on properties except chemical composition.

For the limited number of composition variables studied the range in 100-hour rupture strengths was from 26,000 to 52,000 psi. Major strengthening effects resulted from additions of molybdenum, tungsten, and columbium, individually or simultaneously. The lowest-strength alloy contained none of these elements. Chromium also had a major strengthening influence. However, no alloy was obtained which had properties which were outstanding compared with those of the basic analysis.

Carbon (varied from 0.08 to 0.60 percent), nitrogen (0.08 to 0.18 percent), manganese (0.30 to 2.5 percent), nickel (10 to 20 percent), cobalt (20 to 32 percent), and columbium (2 to 4 percent) had little influence on rupture properties. Nitrogen (0.004 to 0.08 percent), chromium (10 to 30 percent), nickel (0 to 10 percent), cobalt (0 to 20 percent), molybdenum (0 to 4 percent), tungsten (0 to 4 percent), and columbium (0 to 1 percent) increased strength appreciably. Silicon (0.5 to 1.6 percent) and nickel (20 to 30 percent) had a weakening influence. Columbium had a marked influence on increasing total elongation to fracture.

Rupture strengths varied directly with a measure of the resistance to creep of the alloys with total elongation to fracture as a parameter. This indicated that rupture strengths were a function of the effect of the composition modifications on both the inherent creep resistance and the amount of deformation the alloys would tolerate before fracture.

Interpretation of the results on the basis of microstructural studies indicated that molybdenum and tungsten improved creep resistance by entering solid solution. Nickel and cobalt, two elements forming part of the matrix solid solution, appeared to improve strength by increasing the solubility of molybdenum

and tungsten. Chromium improved creep resistance, at least in part, as a result of an aging reaction. Columbium did not appreciably affect creep resistance but improved rupture strength by increasing the elongation to fracture.

Information is presented which indicates that melting and hot-working conditions play an important role in high-temperature properties of alloys of the type investigated.

INTRODUCTION

This investigation had as its object a study of the influence of systematic variations of chemical composition on the 1200° F rupture properties of forged alloys in the solution-treated and aged condition in which the composition was varied from the following basic analysis:

Chemical composition (percent)

Carbon, C	0.15	Cobalt, Co	20
Manganese, Mn	1.7	Molybdenum, Mo	3
Silicon, Si	0.5	Tungsten, W	2
Chromium, Cr	20	Columbium, Cb	1
Nickel, Ni	20	Nitrogen, N	0.12
		Iron, Fe	32

Sixty-two modifications of this alloy were studied in which each of 10 elements was systematically varied individually and Mo, W, and Cb were varied simultaneously.

The investigation was prompted by the fact that at present there are no published data which make possible a correlation between systematic variations in chemical composition and the high-temperature properties of forged Cr-Ni-Co-Fe-Mo-W-Cb alloys of the type investigated. Past research has shown that close control over processing of alloys is necessary to reproduce high-temperature properties between different heats of the same analysis. Lack of such control of processing variables has resulted in the failure of attempts to correlate the published high-temperature data on these types of alloys. Such correlations are needed to provide a basis for establishing optimum chemical compositions for heat-resistant alloys, for reducing the required alloy content while retaining worth-while properties, and for determining the fundamental mechanisms by which alloying elements influence properties at high temperatures.

As an initial approach to the solution of a large problem, the investigation was necessarily limited in scope. The

¹ Supersedes NACA TN 2449, "Investigation of Influence of Chemical Composition on Forged Modified Low-Carbon N-155 Alloys in Solution-Treated and Aged Condition as Related to Rupture Properties at 1200° F" by E. E. Reynolds, J. W. Freeman, and A. E. White, 1951.

number of compositions studied, the use of only one condition of processing, the evaluation of high-temperature characteristics only by rupture properties for 100 hours at 1200° F, and the use of only microstructural and hardness data to provide interpretation of results were the major limitations placed on the investigation.

This work was conducted at the University of Michigan under the sponsorship and with the financial assistance of the National Advisory Committee for Aeronautics.

EXPERIMENTAL PROCEDURE

The basic analysis selected for study of the influence of systematic variations in chemical composition on rupture properties at 1200° F was that of a commercial alloy which has the following nominal composition:

Chemical composition (percent)			
Carbon.....	0.15	Cobalt.....	20
Manganese.....	1.7	Molybdenum.....	3
Silicon.....	0.5	Tungsten.....	2
Chromium.....	20	Columbium.....	1
Nickel.....	20	Nitrogen.....	0.12
		Iron.....	32

The influence of composition was evaluated on 62 modifications of this alloy with the following composition variables:

(1) Individual variations of the elements in the basic analysis:

C, percent.....	0.08, 0.40, 0.60
Mn, percent.....	0, 0.30, 0.50, 1.0, 2.5
Si, percent.....	1.2, 1.6
Cr, percent.....	10, 30
Ni, percent.....	0, 10, 30
Co, percent.....	0, 10, 32
Mo, percent.....	0, 1, 2, 5, 7
W, percent.....	0, 1, 5, 7
Cb, percent.....	0, 2, 4, 6
N, percent.....	0.004, 0.08, 0.18

(2) Simultaneous variations, in steps of 2 percent, of Mo, W, and Cb from 0 to 4 percent

In all cases Fe variations compensated for the variations of total alloy content.

The first step in the investigation was the development of melting, forging, and heat-treatment procedures which would minimize all variable effects on properties except chemical composition. This work was done on the basic alloy with the reproducibility of 1200° F rupture properties from heat to heat being the main criterion for final adoption of preparation procedures. Six heats were prepared to develop melting practice. Three additional heats were prepared using varying deoxidation practices. The forging procedure was developed on six additional heats of the basic alloy.

The work on procedure development and detailed descriptions of the final procedures adopted are summarized in the subsequent section "Preparation of Experimental Alloys." Briefly these consisted of melting the alloys as 9-pound induction-furnace heats, hot-forging the ingots between 2200° and 1800° F to bar stock, heat-treating at 2200° F for 1 hour, and water-quenching followed by aging at 1400° F for 24 hours.

All alloys were chemically analyzed for the modified element while complete analyses were made only on spot heats

within a group after it was established that melting practice was yielding the desired compositions.

Metallographic examinations were made of all the alloys in the as-cast, hot-forged, solution-treated, aged, and rupture-tested conditions. Vickers hardness tests were made on bar stock in the solution-treated and the aged conditions.

The high-temperature load-carrying ability of the alloys was evaluated by means of stress-rupture properties at 1200° F. Rupture test specimens, machined from the heat-treated bar stock, were 0.250 inch in diameter with a 1-inch gage length. The stress-rupture tests were made in individual stationary units with the load applied by a simple beam acting through a system of knife edges. At least two and usually three or four tests at various stresses were made on each alloy and were of sufficient duration to establish the 100-hour rupture strengths and to permit at least an estimate of the 1000-hour strengths. Time-elongation data were taken during the rupture tests by the drop-of-the-beam method and also, in the case of many of the longer time tests, by means of modified Martens type extensometers with a sensitivity of 0.00005 inch per inch. There was good agreement between curves from the two types of deformation measurements in all cases where both types were used on the same tests.

PREPARATION OF EXPERIMENTAL ALLOYS

This section discusses the development of techniques for melting, forging, and heat-treating, describes the procedures finally adopted, presents the observed behavior of the alloys during processing, and shows the reproducibility of rupture properties of the basic alloy resulting from the processing procedures used.

MELTING

Preliminary melting experiments.—Six heats were prepared originally to develop and standardize melting practice, particularly to obtain control over final composition from charge calculations and reproducibility from heat to heat. Actual analyses of these heats are given in table I. It was found necessary to make certain minor corrections in the charged materials and the next five heats of the basic alloy had reasonably consistent compositions.

Melting procedure.—The alloys were melted in a 12-pound-capacity induction furnace as 9-pound heats. The heats were poured into 9-inch-long tapered (1½- to 1¼-in.-sq.) cast-iron ingot molds with 2½-inch-square hot tops. The life of the magnesia melting crucible was from 10 to 12 heats.

A typical melting charge and schedule are given in table II. This table shows the various ferroalloys used to make up the charges. The Fe, Cr, Ni, and Co charge was first melted down; Mn and Si were added, followed by Mo, W, and Cb. The heat was then deoxidized with 15 grams of calcium-silicon alloy, power turned off, bath temperature taken with both a Leeds and Northrup optical pyrometer and a platinum, platinum-rhodium immersion thermocouple, and the metal poured. The calibration of the immersion thermocouple was checked periodically.

Immediately after pouring, a Chromel-Alumel thermocouple was immersed into the molten metal in the hot top and the cooling curve determined by readings at 5-second intervals on a Leeds and Northrup portable potentiometer.

In a subsequent study of the effect of deoxidation on properties, three heats of the basic alloy were prepared using deoxidation practices varying from the normal use of 15 grams of calcium-silicon alloy. The three variations were: No deoxidation (alloy 74); 15 grams of zirconium-silicon-iron alloy (75); and melting under a lime-fluorspar slag (76).

Melting characteristics.—Table I gives the chemical compositions of the experimental alloys. The intended modifications from the basic alloy are given along with actual values where chemical analyses were made. In general, the actual analyses were consistently close to the desired composition.

Table III gives bath temperatures just prior to pouring the alloys. There was a fair agreement and no consistent difference between the optical pyrometer and the immersion thermocouple readings. Cleanness of the bath surface was found to be of importance in the pyrometer readings. The agreement between the two methods in so many cases indicates that the temperatures given are reliable.

A macrographic section of the ingot cross section was taken from each heat from just below the hot top to determine if pipe or porosity existed. All of the heats actually tested were sound. The ingot grain structure was well-defined on these sections, a typical example of which is shown in figure 1 for several heats. In general the various ingot macrostructures reflected the relative pouring temperatures rather than variations in chemical composition. The higher the pouring temperature, the greater was the total area covered by the columnar grains and, the greater the size, the less the total area covered by the equiaxed grains at the center.

FIGURE 1.—Typical macrostructures of ingots. Etchant, Marble's reagent.

The cooling curves obtained on the metal in the ingot hot tops were similar in that, in all cases when readings were begun early enough to determine it, they had a definite halt in temperature within what seemed to be the solidification range for the alloys. Usually these halts were preceded on the curve by what appeared to be an undercooling effect. The time of the constant temperature halt varied for the alloys from 10 to 60 seconds. After these halts the cooling curves were smooth with a gradual decrease in cooling rate as the temperature decreased. The last column in table III contains the temperatures of halts in the cooling curves during solidification. In cases where temperature readings were not started early enough the halt temperature is indicated as being greater than that at which the cooling curve was started.

The over-all temperature range of the halts was from about 2420° to 2610° F and they varied consistently with systematic chemical-composition variations. Alloying additions tended to lower the temperature of the halt, with Cb having the greatest effect. The exact physical significance of the temperature halts, beyond an indication of the temperatures at which the major portion of the alloy solidified, is uncertain.

FORGING

Preliminary forging experiments.—There was available for the forging work a Nazel air forging hammer (size 3, type B) which is approximately equivalent to a 400-pound steam hammer. This hammer was fitted with 3½- by 8-inch flat dies.

Preliminary forging to determine the forging temperature range for the alloys was done on ¾-inch-square bar stock of the basic alloy, reducing it to 0.43-inch squares from 2100°, 2200°, 2300°, and 2400° F. The plasticity increased with temperature, but burning, which resulted in forging cracks, occurred at 2400° F. Further experiments on a 0.55-percent-C heat (alloy 5) indicated that burning could occur at 2300° F in this alloy. Since the alloy was quite difficult to forge with an initial temperature of 2100° F it was decided to use 2200° F as the initial forging temperature. Subsequent work on the heats with variable composition showed that all the alloys were forgeable from this temperature, the forgeability, however, varying with the composition.

Finishing forging temperatures were kept at 1800° F or above as judged by color, in order to minimize hot-cold-work, which is known to influence the properties of these alloys.

Several ingots were forged to ½-inch-square bars between the flat dies, a reduction of approximately 90 percent. Microstructural examination of these forged bars showed a nonuniformity of grain size in the cross section. A diagonal "X," distinctly visible on visual examination of the etched cross section, was present in all the bars. The grains were appreciably finer along these diagonal planes than in the triangles, under the flat surfaces of the bar, formed between these planes.

A number of different methods of forging were tried in order to determine the cause of and in an effort to eliminate this grain size nonuniformity. The methods used and their results were:

(1) Forging at a 45° angle to the original square of the ingot resulted in the same diagonal "X" from the corners of the final square indicating that the ingot structure bore no relation to this characteristic.

(2) Upset forging prior to final reduction to a square showed no advantage of the added working on the structural uniformity.

(3) Finishing as an octagon between flat dies yielded areas of fine grains originating at all eight corners of the bar.

(4) Forging wholly between a flat top die and bottom "V" dies to an octagon appeared to abuse the metal more than any other method used. It was difficult to draw the metal out, the cross section merely being changed back and forth. This tended to open up the center of the bar.

(5) Forging to approximately 1 inch square and finishing to ½ inch round between hand swages in four steps gave the best structural uniformity. A narrow band of fine grains was sometimes present near the surfaces of the round bars but the over-all grain size was quite uniform.

The above experiments showed that the forging "X" in the square bars was the result of the relatively greater amount of hot-work along the diagonal planes. This was further verified by the fact that occasionally in forging the square bars diagonal cracks would form completely through the bars.

As a result of the forging experiments it was decided to fit the hammer with a set of dies with swaging impressions. Subsequent experiments using this method proved satisfactory so it was adopted as the standard forging procedure for the experimental alloys.

Forging procedure.—The general arrangement of the 400-pound-capacity air forging hammer and the heating furnace is shown in figure 2. A picture of the forging operation in swaging dies is shown in figure 3. Figure 4 shows a bar which was forged to indicate the steps in reduction from the ingot to the final round bar. A typical forging record is presented in table IV.

The temperature of the furnace was controlled by an automatic temperature controller through a platinum, platinum-rhodium thermocouple. The temperature of the forg-

ing stock was measured by a Chromel-Alumel thermocouple attached to a small bar placed next to the stock.

The cast ingots were ground to remove all surface defects prior to forging. The ingots were preheated to approximately 1400° F, then placed just inside the door in the coolest region of the furnace, and finally moved to the center of the furnace at 2200° F.

Generally half of an ingot was forged at a time. After holding at least 30 minutes at 2200° F the ingot was forged from approximately 1.4 inches square to slightly over 1 inch square between flat dies with from two to four reheats. A number of the blows in the flat dies were on the corners of the bars to prevent corner cracks and to prepare the piece for the first swage. The bar was reheated and forged to approximately 0.95 inch round in the first swage with from one to three reheats. The second swage reduced the bar to approximately 0.75 inch round with two to four reheats. The forged bar was then cut off the unforged half of the ingot and recharged to the furnace. The third swage reduced the bar to approximately 0.58 inch round with three to six reheats. The bar was then cut in two equal pieces for the final swaging. The last swage finished these bars to 0.40 to 0.50 inch round with from 5 to 10 reheats. The number of blows from the hammer were counted and tabulated. The number of reheats and blows varied depending on the ease of forging of the alloy and the size of the stock. Total reduction of area during forging was approximately 90 percent

FIGURE 2.—Arrangement of forging hammer and furnace.

FIGURE 3.—Forging experimental alloy in swaging dies.

FIGURE 4.—Forged bar showing reduction steps used in swaging experimental alloys from original ingot to final round bar stock.

Reduction in the individual swages was done in steps; that is, after the first reheat only a portion of the bar was reduced to the swage diameter, after the second reheat another portion of the bar was reduced, but in the last reheat or two the whole length of the bar was worked to the final diameter of that swage. In particular, in the finishing swage, the complete length of the bar was given some work during the final two or three operations.

Finishing temperature of forging was judged by the color of the stock by an experienced forger. An attempt was made to hold this temperature above 1800° F.

Forging characteristics.—During forging an effort was made to evaluate the relative forgeability of the experimental alloys. This evaluation consisted of observing the forging characteristics of the alloys—ease of reduction and tendency to form cracks—and of keeping complete records of the number of reheats and blows required to forge each alloy. These methods were at best only very approximate.

Since the small hammer used was taxed to capacity during the initial stages of the breakdown by the rigidity of most of the alloys and since the force of the blows was varied some-

what, depending on the forgeability of the alloys, the method of comparing the required blows was usable only for distinguishing between alloys with wide differences in plasticity. Judging the relative response of the alloys to the blows from the hammer seemed to be the best method to evaluate forgeability. Relative forgeability could be only qualitatively estimated, however, by this method, because only two ingots were forged together and only a few forged in 1 day.

In table V a summary is given of forging data and the estimated forgeability of all the alloys compared with that of the basic alloy. This forgeability is listed merely as "better," "poorer," or the "same" as that of the basic alloy. In cases where the alloys are either poorer or better, remarks are given to explain this rating.

On the basis of these forgeability ratings the following effects of composition on forgeability were evident:

(1) Additions of Si (0.5 to 1.6 percent), Mo (0 to 7 percent), and N (0.004 to 0.18 percent) had no observable effect on forgeability.

(2) It appeared that Mn (0 to 2.5 percent) increased forgeability by lowering the tendency of cracking.

(3) Additions of C (0.08 to 0.60 percent) decreased forgeability by lowering the plasticity and increasing the tendency of cracking.

(4) The elements Ni (0 to 30 percent), Co (0 to 32 percent), and Cr (10 to 30 percent) lowered plasticity and thus forgeability, Cr seemingly having the greatest effect.

(5) Additions of W (0 to 7 percent) lowered plasticity and forgeability.

(6) The effect of Cb (0 to 6 percent) was unique among the elements. Alloys without Cb were subject to severe cracking during the initial breakdown of the ingot between flat dies, the forgeability thus being poorer than that for the basic alloy. Increasing Cb to the 1 percent of the basic alloy seemed completely to alleviate this situation. When it was increased to 4 and 6 percent the material was more difficult to forge as a result of the decreased plasticity.

HEAT TREATMENT

Originally a solution treatment at 2100° F was considered to be a satisfactory condition for testing. This was on the basis that for one heat of the basic alloy previously studied (reference 1), for which the solution-treatment temperature was varied from 1800° to 2300° F, a treatment at 2100° F gave slightly higher rupture strengths than the other conditions. Further work, however, indicated that there was poor agreement between properties of two heats in this condition and the best agreement between heats resulted from a 2200° F solution treatment followed by a 1400° F aging treatment. The variability in properties between heats was attributed to the relative residual effects of the hot-working which had not been removed by the 2100° F solution treatment. It appeared that the 2200° F treatment tended to minimize, but did not completely remove, the residual hot-working effects without excessively coarsening the grain size. It was therefore selected as the solution temperature for the alloys in this investigation.

Previous investigation of the basic alloy had shown that at temperatures of solution treatment above 2050° F the 100-hour rupture test elongation was quite low and decreased

with increasing solution temperatures. Accompanying this low elongation was a tendency for the alloy to be sensitive to stress concentrations at the specimen fillets, fractures occurring in these regions. However, proper aging of the solution-treated alloy eliminated this stress-concentration sensitivity and increased the 100-hour rupture strength slightly while not appreciably affecting 1000-hour strengths. Aging between 1350° and 1500° F did not produce significant changes in properties. A temperature of 1400° F for 24 hours was selected for aging the experimental alloys in this investigation so that variable effects resulting from stress-concentration sensitivity would be minimized and the materials would be in a more stable condition than when only solution-treated.

It is known that the treatment used does not give the highest strengths at high temperatures for the basic alloy and it is not believed that this treatment necessarily would give the best properties for any of the composition modifications studied. But it is believed that use of this treatment, plus the careful control to hold melting and fabrication conditions as constant as possible, has minimized all variable effects on properties except chemical composition in this investigation.

Heat-treatment procedure.—All of the alloys were solution-treated for 1 hour at 2200° F, water-quenched, aged 24 hours at 1400° F, and air-cooled prior to rupture testing. Solution treatments were made in a gas-fired furnace and aging was in an electric resistance furnace.

Heat-treatment observations.—An observation made during heat treatment of the effect of Cb on scaling characteristics of the alloys appeared to be significant. In alloys containing four or more percent of Cb relatively heavy scaling occurred during the 1-hour solution treatment at 2200° F. This scaling effect was greater on these high-Cb alloys than on the alloy containing 10 percent Cr which was expected to have the poorest corrosion resistance of the alloys studied.

REPRODUCIBILITY OF RUPTURE PROPERTIES AT 1200° F OF BASIC ALLOY

The final objective of the work on techniques for preparing the experimental alloys was the development of a condition in which the rupture properties at 1200° F would be reproducible from heat to heat of a given composition. The interpretation of significant property variations with chemical composition depends on the range of this reproducibility.

The rupture test characteristics at 1200° F for six heats of the basic alloy, the alloy used to evaluate the preparation procedures, are given in table VI, for both square and round bar stock. The range of reproducibility of rupture properties indicated for the round stock forged by the finally adopted swaging procedure was as follows:

100-hour rupture strength, psi.....	48,000 to 50,000
1000-hour rupture strength, psi.....	37,000 to 38,000
100-hour rupture elongation, percent.....	19 to 25

These ranges are used in interpreting the significant influences of composition variables for the materials forged as rounds. Properties of alloys with variable C and Mn, forged early in the program as square stock and tested as such, are compared with the wider property range indicated in table VI for square stock of the basic alloy.

The stress and rupture-time data for the six heats are plotted in figure 5 with curves drawn which indicate the range in strengths for the round stock. Figure 6 presents in a similar manner the data for stress against creep rate obtained from curves of elongation against time for the rupture tests. The narrower property ranges for the round stock compared with those of the square stock are noted.

FIGURE 5.—Curves of stress against time for rupture for six heats of basic alloy. Range indicated for round bar stock. Treatment: 2200° F for 1 hour, water-quenched; 1400° F for 24 hours.

FIGURE 6.—Curves of stress against minimum creep rates at 1200° F for six heats of basic alloy. Range indicated for round bar stock. Treatment: 2200° F for 1 hour, water-quenched; 1400° F for 24 hours.

As an example of the narrowing of the range by using the more easily controlled and duplicated swaging procedure, alloy 8 had the lowest (46,500 psi) and alloy 10 the highest (52,000 psi) 100-hour rupture strengths of the 5500-psi over-all range for square bar stock. After forging as rounds these same two heats had 100-hour rupture strengths of 48,500 and 50,000 psi, thus narrowing the over-all range of 100-hour rupture strengths to 1500 psi. The 1000-hour rupture-strength range was narrowed from 2500 to 1000 psi by changing the forging procedure. Similar changes in ranges for squares and rounds are indicated in table VI for stresses at constant creep rates and for the minimum creep rate at constant stress.

Table VI also gives properties of alloys 74 and 75 which indicate that variation in melting deoxidation practice can have a pronounced effect on high-temperature characteristics of alloys of this type.

The influence on rupture test characteristics of changing hot-working and deoxidation procedures indicates that the solution treatment at 2200° F did not completely eliminate variables in prior processing. However, the use of the same deoxidation practice for all the alloys and the control of hot-working resulting from the adoption of the procedure producing rounds rather than squares plus the use of the 2200° F solution treatment are believed to have minimized the effects of variables in processing on the high-temperature properties.

Data for two commercial heats of the basic alloy with the same heat treatment as the experimental alloys have been included in table VI to show the relationship between the experimental alloys and normal commercial properties.

INFLUENCE OF CHEMICAL-COMPOSITION VARIABLES ON ROOM-TEMPERATURE METALLURGICAL CHARACTERISTICS OF MODIFIED ALLOYS

Microstructural studies and hardness tests were made on all the experimental alloys to obtain metallurgical information to aid in interpretation of the influence of chemical composition on rupture properties.

MICROSTRUCTURE

Microstructural studies were made of each of the alloys in the following conditions: As-cast; hot-forged; solution-treated 1 hour at 2200° F and water-quenched; aged 24 hours at 1400° F after solution treatment; and rupture-tested the maximum time at 1200° F. An electrolytic solution of 10 percent chromic acid was used as an etchant.

Effect of treatment on microstructures.—The as-cast structure revealed the amount and distribution of the excess constituents in the cast dendritic pattern. The hot-forged structures were examined for flaws, uniformity of grain size, and distribution of excess constituents. Only limited information is included on the cast and forged structures, the main emphasis being placed on structures of the alloys prior to testing in the heat-treated condition. The solution-treated structure showed the amount of insoluble excess constituents after light etching and the grain size after deep etching. The grain size was much easier to determine in the

aged structures because the grain boundaries were revealed by light etching. The aged structure also revealed the amount and mode of matrix precipitation. From the structure of the maximum-time rupture test any change occurring during testing and the mode of fracture could be observed.

An example of microstructural variation with treatment for the basic alloy is shown in figure 7. The as-cast condition contained a considerable amount of excess constituent. After hot-forging the alloy was uniformly fine-grained and contained excess constituent at the grain boundaries and in the matrix. Solution-treating at 2200° F dissolved the grain boundary constituent but not the matrix constituent. Solution-treating also coarsened the grains considerably as is best shown by the aged structure. Aging caused considerable grain boundary precipitate and some random matrix precipitation. Rupture testing at 1200° F increased the matrix precipitate slightly.

As an example of one extreme to which microstructures varied with composition, figure 8 shows microstructures for the 0Mo-0W-0Cb alloy in the as-cast, solution-treated, aged, and rupture-tested conditions. The structures differed from those of the basic alloy in that: There was much less excess constituent in the as-cast and the solution-treated conditions; grain size after solution treatment was much larger; and aging produced more precipitate near the grain boundaries and a preferred type of matrix precipitate which tended to follow definite crystallographic planes. The two alloys also differed in that the 0Mo-0W-0Cb alloy had a completely intergranular fracture while that of the basic alloy was approximately half intergranular and half transgranular.

FIGURE 8.—Concluded.

The above comparison has pointed out the major similarities and differences in structures which were found for all the alloys. Similarities were:

(1) The amount of excess constituent in the solution-treated condition was proportionate, for any given alloy, to the amount of excess constituent in the as-cast condition. The structures indicate that the rapid cooling of the ingot after solidification effectively solution-treated the material.

(2) All grain boundary constituents were dissolved during solution treatment.

(3) Precipitation occurred during aging at 1400° F.

(4) Very little additional precipitation occurred during rupture testing at 1200° F for any of the alloys with the exception of low-Co modifications.

Major structural differences between the alloys were:

(1) Amount of excess constituent after solution treatment.

(2) Grain size.

(3) Location, type, and amount of aging precipitate.

Classification of microstructures.—In order to condense the description of and to make possible a quick comparison of the changes in microstructure occurring with variation in chemical composition the following classification of microstructures of the solution-treated and the aged materials was devised. Symbols were used to indicate the differences in the basic structural characteristics.

(1) Solution-treated structures

Amount of insoluble constituent:

I—small

II—medium

III—large

IV—very large

(2) Aged structures

A. S. T. M. grain size number:

1 (up to $1\frac{1}{2}$ grains/sq in. at 100X magnification) to 8 (96 grains or more/sq in. at 100X magnification)

Amount of grain boundary precipitate:

x—small

y—medium

z—large

Type of matrix precipitate:

C—precipitate tends to follow crystallographic planes

R—random matrix precipitate

Amount of matrix precipitate:

a—small

b—medium

c—large

d—very large

As an example of how this classification works the structures of the basic alloy (fig. 7) and the 0Mo-0W-0Cb modification (fig. 8) are classified below:

(1) Basic alloy:

Classification—II 5 y Rb

II—medium amount of insoluble constituent

5—number 5 A. S. T. M. average grain size

y—medium amount of precipitate near the grain boundaries

Rb—medium (b) amount of random (R) matrix precipitate

(2) 0Mo-0W-0Cb alloy:

Classification—I 1 : Cb

I—small amount of insoluble constituent

1—number 1 A. S. T. M. average grain size

z—large amount of precipitate near the grain boundaries

Cb—medium (b) amount of matrix precipitate on crystallographic planes (C)

The microstructural classifications are given in table VII for all the experimental alloys arranged for comparative purposes on the basis of the alloying element varied. For the alloys in which simultaneous variations were made in Mo, W, and Cb the classifications are repeated to show the influence of individual variations of these elements.

Influence of alloying elements on microstructure.—The effects on microstructure of variations of the elements will be given on the basis of the classification of table VII, supplemented by photomicrographs showing only the more pronounced effects observed.

Carbon: It is indicated in table VII and by the microstructures in figure 9 that as C was increased from 0.08 to 0.60 percent in the basic alloy the amount of insoluble constituent and matrix precipitate increased considerably and the grain size decreased, while the amount of grain boundary precipitate and the randomness of the matrix precipitate did not change. Figure 10 also shows that the amount of insoluble constituent was not reduced by heating the 0.60-percent-C alloy 10 hours at 2200° F over what it was after 1 hour.

The increase in the amount of soluble and insoluble constituents indicates that C is an important component in both

the soluble and precipitating phases found in the basic alloy and its modifications.

Manganese: There was no apparent effect of Mn on microstructure.

Silicon: As will be shown later, Si was the only element which consistently lowered rupture strength over the complete composition range studied (from 0.5 percent in the basic alloy to 1.6 percent). The microstructures in figure 11 indicate that variation of Si did not change microstructural characteristics except for a smaller grain size for the high-Si alloy.

Chromium: Increasing Cr from 10 percent to the 20 percent of the basic alloy and to 30 percent drastically changed the microstructure as shown by the classification in table VII and the microstructures in figure 12. Increasing Cr caused the following changes: (1) The grain size became larger; (2) the amount of grain boundary precipitate increased between 10 and 20 percent Cr; (3) the matrix precipitate became heavier, especially between 20 and 30 percent Cr; and (4) for the 30-percent-Cr alloy the matrix precipitation occurred on the crystallographic planes rather than having a random pattern as for the lower-Cr alloys.

Nickel: The only pronounced structural variation for the series of Ni alloys was the ferrite-sigma-type phase which was present in the 0-percent-Ni alloy (see fig. 13). In the solution-treated alloy this phase was free from precipitate and the alloy was magnetic. In the aged condition a large amount of precipitation occurred in this phase and the alloy was nonmagnetic, signifying the transformation from the magnetic ferrite-type phase to the nonmagnetic sigma phase.

Upon rupture testing at 1200° F the magnetism increased with testing time, indicating some reversion to the ferrite-type phase. The 0-percent-Ni alloy also had less grain boundary precipitate and less precipitate in the austenite matrix than the higher-Ni alloys. None of the ferrite-type phase was observed in the alloy containing 10 percent Ni or in any of the other alloys studied in this investigation. Alloys containing 10 and 30 percent Ni were very similar in structure to the 20-percent-Ni basic alloy.

Cobalt: Varying Co from 0 to 32 percent produced two marked effects (see table VII and fig. 14). The 0-percent-Co alloy had a large amount of random matrix precipitation in the aged condition. The 10-percent-Co alloy resembled the basic 20-percent-Co alloy having only a medium amount of matrix precipitate. Increasing Co from 20 to 32 percent produced an alloy in which marked germination occurred at the 2200° F solution-treating temperature, resulting in several very massive grains surrounded by grains of normal size across the bar.

Another effect of Co on the structure occurred during rupture testing. Much additional matrix precipitation occurred in the 0-percent-Co alloy during testing; some also occurred in the 10-percent-Co alloy, and there was very little additional precipitate in the 20- and 32-percent alloys.

There was no evidence that Co changed the amount of the insoluble constituent or the grain boundary precipitate in the alloys.

Nitrogen: There was no appreciable influence from N varied from 0.004 to 0.18 percent.

Molybdenum: There were 10 modifications of alloys in which Mo was varied between 0 and 4 percent with 10 different constant ratios of W and Cb.

In the basic composition Mo was varied from 0 to 7 percent (alloys 32 to 36 in table VII). The only apparent effect of Mo was the larger grains at both the lower and the higher percentages.

For the nine other alloy modifications (alloys 43, 45, 46, 53 to 73, and 82 to 84) increases in Mo to 2 and 4 from

FIGURE 17.—Curves of hardness against alloy content for individual element modifications.

0 percent produced only very slight changes in structure except in the alloys containing Cb (particularly 4 percent Cb) in which case the grain size was refined and the amount of matrix precipitation during aging was increased.

Major structural changes between these alloy modifications were the result of variation in Cb.

Tungsten: In the 10 alloy modifications in which W was varied systematically (alloys 37 to 40, 43, 45, 46, 53 to 73, and 82 to 84 in table VII) similar observations to those for the influence of Mo were made. Increases in W slightly refined the grains and increased the matrix precipitation to a small degree in some cases.

Columbium: As shown in table VII for the 10 alloy modifications with variable Cb, this element had a marked influence on all the structural classification variables. A typical example of microstructural changes occurring with Cb additions from 0 to 6 percent to the basic composition is shown in figure 15.

Increasing Cb from 0 to the 1 percent of the basic alloy produced the following structural changes: (1) Increased the insoluble constituent from very little to an appreciable amount; (2) drastically reduced grain size; (3) decreased the concentration of grain boundary precipitation during aging; (4) changed the mode of matrix precipitation from internal

crystallographic planes to a random pattern; and (5) decreased the amount of matrix precipitation during aging.

Increasing Cb from the 1 percent of the basic alloy to 4 percent continued to increase markedly the amount of insoluble constituent, to further gradually reduce grain size, and not to alter appreciably the grain boundary concentration effects or the randomness of precipitation while increasing the amount of matrix precipitation during aging in alloys containing four or more percent of Mo or W.

While Cb did produce major changes in microstructure, it is noted that for the alloys arranged in table VII with Cb as the systematic variable the presence of either or both Mo or W in the alloys increased the tendencies for these changes. This is shown in figure 16 for 4-percent-Cb alloys containing increasing Mo and W contents.

Summary of influence of alloying elements on microstructure.—A summary of the effects of alloying elements on tendencies for microstructural changes is given in table VIII.

Two elements producing major microstructural changes were Cb and C. Both elements increased the amounts of insoluble constituent and aging precipitate and refined the grain size of material solution-treated at 2200° F. In addition, Cb changed the mode of matrix precipitation from

FIGURE 18.—Curves of hardness against molybdenum content for 10 tungsten-columbium modifications.

preferred, when no Cb was present, to random, when the 1 percent of the basic alloy or more was present.

Additions of Mo and W produced little change in microstructure except in alloys containing 4 percent Cb in which case these elements decreased the grain size and increased matrix precipitation.

Between 20 and 30 percent of Cr a pronounced increase occurred in the amount of aging precipitate and the mode of precipitation changed from random to preferred.

Grain size was mildly increased and the amount of aging precipitate decreased by Co.

Additions of Ni (between 10 and 30 percent) produced only minor changes in structure. The 0-percent-Ni alloy contained a ferrite-sigma type of phase which disappeared when Ni was raised to 10 percent.

The only effect of Si, within the limits studied, was to refine grain size slightly. No discernible change in structure was produced by Mn and N.

HARDNESS

Vickers hardness tests at room temperature were made on metallographic specimens of all the experimental alloys in the solution-treated (2200°F , 1 hr, water-quenched) and the aged (1400°F , 24 hr, air-cooled) conditions. Preliminary hardness surveys on several alloys indicated that the forged

bars had uniform hardnesses both in the lengthwise and the crosswise directions.

Hardness test results, representing the average of at least four tests on each sample, are given in table IX and are plotted against composition variables in figures 17 to 20.

There was fair agreement between the hardnesses of five heats of the basic alloy. Additions of C, N, Cr, Mo, W, and Cb tended to increase hardness in both conditions; Ni, particularly from 0 to 10 percent, lowered hardness; and Mn, Si, and Co did not appreciably affect hardness. Perhaps an exception to this was the effect observed for the 1.6-percent-Si alloy, which was the only one of all the alloys studied which did not show hardening as a result of aging. The addition of Cr from 20 to 30 percent markedly increased the age-hardening characteristics of the alloy.

Figure 18 shows the influence of Mo for 10 W-Cb modifications. Additions of Mo, while tending to increase hardness, did not appreciably increase the age-hardening tendency except for the modifications containing more than 4 percent total of W plus Cb. For the 10 Mo-Cb modifications (fig. 19) the effect of W additions was similar to that observed for Mo, although there was less tendency for increasing age hardening with higher alloy contents. In both figures 18 and 19 it is seen that there was a greater difference between the hardness in the solution-treated and the aged conditions

FIGURE 19.—Curves of hardness against tungsten content for 10 molybdenum-columbium modifications.

for the modifications not containing Cb than for the modifications containing Cb. This effect is shown again in figure 20 in that Cb additions from 0 to 2 percent to the 10 Mo-W modifications narrowed the age-hardening range. Additions of Cb from 2 to 4 percent tended to broaden the age-hardening range for modifications containing the larger amounts of Mo and W.

It is recognized that these hardness results are not a true evaluation of the comparative aging effects caused by composition variables. Such an evaluation would necessarily require aging-time-temperature data.

INFLUENCE OF CHEMICAL-COMPOSITION VARIABLES ON RUPTURE TEST CHARACTERISTICS AT 1200° F

The results of rupture tests at 1200° F for all the alloys studied are given in table X. Included in this table are the times for rupture, elongations, reductions of area, and minimum creep rates obtained from the curves of elongation against time for the individual tests. Also included are 100- and 1000-hour rupture strengths obtained from double-logarithmic plots of stress against rupture time (an example

is shown in fig. 5); estimated elongation to rupture in 100 hours; stresses for creep rates of 0.1 and 0.01 percent per hour obtained from double-logarithmic plots of stress against minimum creep rates from the rupture tests (an example is shown in fig. 6); and minimum creep rates at 40,000 psi. The alloys are listed in table X in the approximate order of the element varied in the basic analysis.

Rupture tests of sufficient number and duration were conducted to establish the 100-hour rupture strengths. The 1000-hour rupture strengths were obtained by extrapolation of the double-logarithmic curves of stress against rupture time. Unless the maximum-time rupture test was longer than 500 hours, however, the 1000-hour strengths are listed in table X as estimated and are indicated as such on the curves of strength against chemical composition.

In this evaluation of the influence of variations in chemical composition on the properties most emphasis has been placed on rupture properties at 1200° F. Because the creep data were obtained from the rupture tests, it is emphasized that the rates of deformation were much higher than those usually associated with reported "creep strength."

FIGURE 20.—Curves of hardness against columbium content for 10 molybdenum-tungsten modifications.

100-HOUR RUPTURE PROPERTIES AT 1200° F OF MODIFIED ALLOYS

The 100-hour rupture strengths and elongations for all of the alloys are arranged in order of increasing 100-hour rupture strengths in figure 21. The ranges in properties for the basic alloy heats, forged both as squares and as rounds, are indicated to show the significant variations in properties. The following observations are made:

(1) The over-all 100-hour rupture strength range was from 26,000 to 52,000 psi. The lowest-strength alloy was the one which did not contain Mo, W, and Cb. The two highest-strength alloys were modifications of the basic alloy, one containing 30 percent Cr, the other 7 percent W.

(2) Six alloys had rupture strengths above the range of the basic alloy forged to round bars. None of the alloys, however, were above the range for the basic alloy forged to squares where the practice was not so well controlled.

(3) It appears that all of the elements can be varied individually over relatively wide ranges without appreciably altering rupture strengths. It will be shown, however, that in most cases rupture strengths varied consistently with systematic variations in composition.

(4) Alloys having strengths near the lower end of the range were those containing the smallest amounts of Mo,

W, or Cb added separately or two at a time. Additions of greater amounts of these elements generally yielded rupture strengths which were closer to the strength range of the basic alloy.

(5) Adding 2 percent of either Mo, W, or Cb to the lowest-strength alloy increased the 100-hour rupture strength in the order of 10,000 psi or more.

(6) Strengths in the order of those of the basic alloy were obtained without the presence of Cb. Strengths almost as high were obtained without the presence of Mo or of W.

(7) Low Cr, Co, or Ni and high Si resulted in lower strengths than the range for the basic heats.

(8) Elongation at rupture in 100 hours ranged from 5 to 40 percent.

(9) There was no relationship apparent between rupture elongation and strength. The omission of Cb resulted in consistently low elongation. More Cr or Co than the 20 percent of the basic alloy also lowered elongation.

INDIVIDUAL VARIATIONS OF ELEMENTS

The influence on rupture test characteristics of systematic variations of the individual elements, shown in figures 22 to 31, was as follows:

FIGURE 21.—Influence of chemical-composition modifications on 100-hour rupture properties at 1200° F. Heat treatment: 2200° F for 1 hour, water-quenched; 1400° F for 24 hours.

Carbon.—The effect of C, varied from 0.08 to 0.60 per cent, was only slight. All the rupture strengths fell within close proximity to those of the basic alloy (see fig. 22). The variable C heats were forged as squares and are compared with the property ranges found for similarly forged basic heats. The lowest and the highest C heats had rupture elongations below normal.

Nitrogen.—Variations of N, from 0.004 to 0.18 per cent, tended to increase strength somewhat (see fig. 23). The alloy containing 0.004 per cent N had strengths which were slightly below those of the basic 0.12-percent-N alloy while the 0.08-percent-N alloy was slightly stronger.

Manganese.—Figure 24 shows that Mn variations from 0 to 2.5 per cent had no significant influence on rupture

FIGURE 22.—Curves of rupture test data at 1200° F against carbon content of basic alloy. Horizontal dashed lines indicate property range for five basic heats.

FIGURE 23.—Curves of rupture test data at 1200° F against nitrogen content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

FIGURE 24.—Curves of rupture test data at 1200° F against manganese content of basic alloy. Horizontal dashed lines indicate property range for five basic heats.

properties except a somewhat lower elongation for the low-Mn heat.

Silicon.—Figure 25 shows that increasing Si from the 0.5 percent of the basic alloy to 1.6 percent produced a marked lowering of rupture strength and an increase in elongation. The stresses at constant creep rates were lowered and creep rates at 40,000 psi were noticeably raised in agreement with trends in rupture properties. This was the only case in which the addition of an element consistently lowered strength over the complete composition range studied.

Chromium.—The influence of Cr variations from 10 to 30 percent is shown in figure 26. The 100-hour rupture strengths were increased from 39,000 to 52,000 psi while rupture elongation decreased from 25 to 10 percent. Similar marked

FIGURE 25.—Curves of rupture test data at 1200° F against silicon content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

FIGURE 26.—Curves of rupture test data at 1200° F against chromium content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

increases occurred in 1000-hour rupture strengths and stresses at constant creep rates while the creep rate at 40,000 psi was drastically reduced, particularly between 10 and 20 percent Cr.

Nickel.—Additions of Ni from 0 to 30 percent had little influence on properties as shown in figure 27. The 0- and 30-percent-Ni alloys had slightly lower rupture strengths than the range for the basic 20-percent-Ni heats, producing an apparent maximum in strength between 10 and 20 per-

FIGURE 27.—Curves of rupture test data at 1200° F against nickel content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

cent Ni. A similar slight trend was noted in stresses at constant creep rates while the creep rate at 40,000 psi decreased and then increased with increasing Ni, following the trend of the change in elongation at fracture in 100 hours.

Cobalt.—Figure 28 shows the influence of Co variations from 0 to 32 percent. The 0- and 10-percent-Co alloys had lower rupture strengths than normal with little effect on elongation. The 20- and 32-percent-Co alloys had equal 100-hour rupture strengths at a higher level than those with lower Co. The 1000-hour rupture strengths and stresses at constant creep rates were improved, while the elongation and creep rate were lowered, when Co was increased from the 20 percent of the basic alloy to 32 percent.

FIGURE 28.—Curves of rupture test data at 1200° F against cobalt content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

Molybdenum.—Additions of Mo from 0 to 7 percent improved rupture and creep properties as shown by figure 29. The most marked improvement in rupture strength from Mo was from additions of 1 to 3 percent.

Tungsten.—Figure 30 shows that the improvement in rupture strength with additions of W from 0 to 7 percent was gradual over the entire range, this addition increasing 100-hour strength from 45,000 to 52,000 psi. The stresses at constant creep rates showed a similar trend to rupture strengths while rupture elongation was not at all affected by W.

Columbium.—Figure 31 shows that increasing Cb from 0 to the 1 percent of the basic alloy increased the 100-hour rupture strength from 40,000 to 48,000 psi. Additions of Cb

FIGURE 29.—Curves of rupture test data at 1200° F against molybdenum content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

from 1 to 6 percent produced no further improvement in strength. A similar trend was shown by creep properties. However, the increase of 44,500 to 47,500 psi in the stress for a minimum creep rate of 0.1 percent per hour between 0 and 1 percent Cb was not of the same magnitude as the rupture strength increase. Rupture test elongation was raised from 12 to 22 percent by the addition of 1 percent Cb and tended to increase further with higher Cb.

SIMULTANEOUS VARIATIONS OF MOLYBDENUM, TUNGSTEN, AND COLUMBIUM

In addition to the individual variations of all the elements the effects of simultaneous variations of Mo, W, and Cb in steps of 2 percent from 0 to 4 percent were evaluated. This made possible curves showing the influence on properties of systematic variations of one of these elements for 10 different constant ratios of the other two elements.

FIGURE 30.—Curves of rupture test data at 1200° F against tungsten content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

Molybdenum.—The influence of the Mo variations from 0 to 4 percent on rupture test characteristics of alloy modifications, including the basic alloy, with 10 different constant ratios of W and Cb is shown in figure 32. Curves comparing the relative effect of Mo on the 100-hour rupture strength of the 10 W-Cb modifications are shown in figure 33.

Increasing Mo from 0 to 4 percent tended continuously to increase the 100-hour rupture strength for all the ratios of W and Cb. The relative effect was greatest for the modifications containing neither W nor Cb, the strength increase being from 26,000 to 42,000 psi. In alloys containing W or Cb the strengthening effect of Mo was greatest for the alloys which contained 2 and 4 percent of W and no Cb. This strengthening effect was less for alloys containing 2 and 4 percent Cb and no W and became even less for those containing both Cb and W which had a higher level of initial strength.

FIGURE 31.—Curves of rupture test data at 1200° F against columbium content of basic alloy. Horizontal dashed lines indicate property range for three basic heats.

The 1000-hour-strength trends followed those of the 100-hour strengths. There was a slight tendency for increasing Mo to widen the difference between the 100- and 1000-hour rupture strengths in the modifications containing more than 6 percent total of W plus Cb.

In general Mo tended to improve the 100-hour rupture elongation. It is noted that for the alloys in which Cb was absent the elongation was quite low (5 to 15 percent) as compared with the elongations above 20 percent of the alloys containing 2 and 4 percent Cb.

The stresses causing a minimum creep rate of 0.1 percent per hour followed the trends and were of the same order of magnitude as the 100-hour rupture strengths. The trends

and magnitudes of stresses causing a creep rate of 0.01 percent per hour were somewhat similar to those of the 1000-hour rupture strengths. Creep stresses were consistently higher than rupture strength, however, for the 0-percent-Cb alloys having low rupture elongation and were somewhat lower than rupture strength for the alloys with higher elongation.

Tungsten.—By rearranging the data for alloys involving simultaneous variations of Mo, W, and Cb figures 34 and 35 were obtained. These show the influence of W variations from 0 to 4 percent on rupture test characteristics of alloy modifications with 10 different constant ratios of Mo and Cb.

Additions of W produced an almost linear increase in 100-hour rupture strength. The greatest improvement, 26,000 to 41,000 psi, was for the 0Mo-0Cb modifications, with the relative improvements tapering off for the alloys with higher Mo and Cb to about 4000 psi in the range 46,000 to 50,000 psi for the 4Mo-4Cb modifications. The 1000-hour rupture strengths, although only estimated in many cases, followed a similar, but not quite so pronounced, trend. The trends in creep properties were also, in general, the same as those for the rupture strengths with the additional effect of the level of elongation on the relation between rupture strength and stresses at constant creep rates.

There was a general tendency for W to lower the 100-hour rupture elongation very slightly. The low elongation of the alloys which did not contain Cb was again noted.

Columbium.—The data arranged to define the influence of Cb are shown in figures 36 and 37. The influence of Cb on rupture strengths was significantly different from the influences of Mo and W. Additions of Cb from 0 to 2 percent, in general, increased the 100-hour rupture strength, but there was no significant strength increase with greater additions. This finding, in addition to the observation of the influence of 1 percent as compared with that of 0 percent Cb on the strength of the basic alloy, led to the preparation of an additional alloy (77) containing 0Mo-0W-1Cb which fits into the 0Mo-0W alloy modifications as shown in figure 36. This alloy had as good or better strength properties than the 0Mo-0W-2Cb modification. The addition of Cb to the 4Mo-2W and 4Mo-4W modifications evidently had no effect or a slightly detrimental effect on rupture strength.

One or two percent of Cb markedly improved the rupture elongation. An additional slight improvement was realized with even higher Cb.

The stresses causing a creep rate of 0.1 percent per hour were higher than the 100-hour rupture strengths for 0-percent-Cb alloys but lower than the rupture strengths for alloys containing Cb. Thus the creep stress did not follow the increase in rupture strength with the additions of 1 or 2 percent Cb but either remained constant or decreased. It appeared that the marked increase in elongation with small Cb additions was the factor responsible for the improvement in rupture strength.

It can be concluded that, for the alloy modifications studied, additions of Cb are necessary to produce substantial ductility in the rupture test, but additions of more than 2, or probably 1, percent of Cb add nothing to the rupture properties of the alloys.

FIGURE 37.—Summary of influence of columbium on 100-hour rupture strength at 1200° F of 10 molybdenum-tungsten modifications. Horizontal dashed lines indicate property range for three basic heats.

Comparative influences of molybdenum, tungsten, and columbium.—Figure 38 shows comparative influences of Mo, W, and Cb on the 100-hour rupture properties at 1200° F for three of the alloy modifications in which these elements were varied simultaneously: 0Mo-0W-0Cb, 2Mo-2W-2Cb, and 4Mo-4W-4Cb. Two of the three elements are constant while the third is varied from 0 to 4 percent giving a family of three curves with one common composition. The 100-hour rupture strengths varied from 26,000 to 51,000 psi. Comparative influences of elements on rupture strengths were as follows:

(1) For the family of curves in which there is a common alloy with a composition of 0Mo-0W-0Cb, a Cb addition of 1 percent gave the highest strength; higher Cb lowered the strength. Increasing Mo and W increased strength continuously with Mo having the greatest influence. The strengths of the alloys on this family of curves were at a lower level, 26,000 to 42,000 psi, than those for the other two alloy modifications.

(2) For the 2Mo-2W-2Cb modifications, having strengths between 40,000 and 49,000 psi, Mo had the greatest strengthening influence; Cb was next, but strength dropped off above 2 percent Cb; and W produced a consistent, but the least, over-all strength increase.

(3) The 4Mo-4W-4Cb modifications were at the highest strength level of the three, 45,000 to 51,000 psi. Additions of Mo and W had about the same strengthening influence while Cb tended to lower strength.

The effects of the elements on 100-hour rupture elongations, also shown in figure 38, were the same for all three levels of composition: W tended to lower elongation slightly; Mo raised the elongation slightly; and Cb additions from 0 to 1 or 2 percent markedly raised the elongation from values below 10-percent elongation to 20 percent or higher.

The combined influence on 100-hour rupture strength of Mo, W, and Cb, on a total weight percent basis is shown in figures 39, 40, and 41. Each of these graphs contains the same points plotted to the same coordinates, these points representing all of the alloys in the testing program in which Mo, W, and Cb were varied, the remainder of the basic analysis being constant. The difference between the graphs is in the method of joining the points. In figure 39 the points are joined to give curves showing the effect of Mo varied from 0 to 4 percent for 10 constant ratios of W and Cb. In figure 40 the points are joined to show the effect of W and in figure 41 the curves show the effect of Cb.

FIGURE 38.—Comparative influences of molybdenum, tungsten, and columbium on 100-hour rupture properties at 1200° F of modified alloys. Horizontal dashed lines indicate property range for three basic heats.

FIGURE 39.—Influence of molybdenum additions (0, 2, and 4 percent) on a total weight percent basis of molybdenum, tungsten, and columbium on 100-hour rupture strength at 1200° F of modified alloys. Horizontal dashed lines indicate property range for three basic heats.

FIGURE 40.—Influence of tungsten additions (0, 2, and 4 percent) on a total weight percent basis of molybdenum, tungsten, and columbium on 100-hour rupture strength at 1200° F of modified alloys. Horizontal dashed lines indicate property range for three basic heats.

The array of points in these graphs indicates the general strength increase resulting from increasing the total alloy content of Mo plus W plus Cb from 0 to 12 percent. The main reason for the scatter of the points is evident from comparison of the curves in the three graphs. Both Mo (fig. 39) and W (fig. 40) produce strength increases over the entire composition range, while the Cb curves (fig. 41) above 1 and 2 percent Cb flatten out and cut horizontally across the property range. This emphasizes the unique influence, shown in previous graphs, of Cb on rupture strength.

The comparative influence on 100-hour rupture strength of Cb in relation to the influence of Mo and W is broken down further in the graphs of figure 42. Curves at constant Cb contents of 0, 1, 2, and 4 percent indicate the combined strengthening influence of Mo plus W. Curves represent-

FIGURE 41.—Influence of columbium additions (0, 2, and 4 percent) on a total weight percent basis of molybdenum, tungsten, and columbium on 100-hour rupture strength at 1200° F of modified alloys. Horizontal dashed lines indicate property range for three basic heats.

ing this influence have been drawn and are summarized in the bottom graph in which Cb content is the parameter. The short-dashed curves on the upper four graphs represent the influence of Mo and the long-dashed curves, the influence of W at constant amounts of the other element.

The spread in data in the graphs of figure 42 was much less than that in figures 39, 40, and 41 in which the influence of Cb was not separated. When Mo is added in lower percentages it has the greater strengthening influence and W has the greater influence at higher percentages. These trends cause the curves representing the Mo and W influences to turn toward the center of the range representing the data spread at the higher percentages of these two elements and thus to strengthen the reliability of the single curves representing the data at constant Cb contents.

The summary curves in figure 42 indicate that additions of more than 1 percent of Cb were of no benefit to the alloys. When approximately 8 percent total of Mo plus W was present any addition of Cb was of no benefit to the strength. As has been noted previously, however, Cb additions of 1 percent markedly improved the rupture ductility over that of the 0-percent-Cb alloys, regardless of the influence of Cb on strength.

From the summary curves in figure 42 it is possible to predict the 100-hour rupture strength of alloys with any combination of Mo and W, at the four Cb levels, within the composition range in which these elements were investigated. Such predictions for alloys falling within the range of 0 to 1 percent Cb are not possible because data were not obtained. Based on the data, the largest error in these predictions would be in the vicinity of 2 percent total of Mo plus W. This error could be as much as 2500 psi, which is not large compared with the 2000-psi range in properties found from heat to heat of the basic alloy. Such predictions of course are tempered by the limitations of the investigation, particularly by the limitation of only one condition of preparation and heat treatment.

FIGURE 42.—Influence of molybdenum and tungsten additions on a total weight percent basis on 100-hour rupture strength at 1200° F of columbium modifications.

SUMMARY OF INFLUENCE OF CHEMICAL COMPOSITION ON RUPTURE TEST CHARACTERISTICS

Individual variations of elements.—Figure 43, which summarizes the rupture properties at 1200° F for variations of one element at a time in the basic analysis, indicates the following influences of chemical composition for alloys melted, forged, and heat-treated under the conditions of this investigation:

(1) Variation of C and Mn had no appreciable influence over the ranges examined.

(2) Very low N caused somewhat low rupture strength and intermediate N produced strengths slightly above normal.

(3) The effect of Si was unique in that increasing amounts lowered rupture strength and increased elongation.

(4) Increasing amounts of all other elements resulted in increased rupture strength over the complete range of variation except Ni, Co, and Cb which apparently reached a saturation content for rupture strength at 10, 20, and 1 percent, respectively. Additions of Cb caused a pronounced increase in rupture elongation.

(5) A saturation point for Mo and W was approached at the 3- and 2-percent levels of the basic alloy although improvements were obtained by further additions of these elements. The element Mo increased and W had no effect on elongation.

(6) The rupture strength was markedly increased by additions of Cr from 10 to 30 percent, and rupture elongation was decreased.

(7) Relative magnitudes of 100-hour rupture-strength improvements were: 20 percent Cr increased strength 13,000 psi; 7 percent Mo, 8500 psi; 7 percent W, 7000 psi; and 1 percent Cb, 8500 psi. The addition of 1 percent of Si decreased strength 5000 psi.

The following modifications had strengths appreciably below that of the basic alloy: 1.2 percent Si, 1.6 percent Si, 10 percent Cr, 0 percent Co, 10 percent Co, 0 percent Mo, 1 percent Mo, 2 percent Mo, 0 percent W, 1 percent W, and 0 percent Cb. The only alloys which had appreciably higher strengths than the basic alloy were those with 30 percent Cr and 7 percent W. From this it appears little was done to improve the 1200° F rupture strength of the basic alloy in the single condition of treatment studied, that rather wide individual variations of the elements can be permitted, particularly to higher values than those in the basic analysis, without appreciably altering properties, and that Cr, Co, Mo, W, and Cb are necessary for high strength.

Simultaneous variations of molybdenum, tungsten, and columbium.—The summarized influences on rupture properties at 1200° F of simultaneous variations of Mo, W, and Cb in the basic analysis, shown in figure 42 for the 100-hour rupture strength, serve to emphasize the general findings when these elements were varied individually. These influences are as follows:

(1) The absence of Mo, W, and Cb yielded an alloy with very low rupture strength, 26,000 psi for rupture in 100 hours.

(2) Separate additions of Mo, W, or Cb in amounts up to 4 percent to the 0Mo-0W-0Cb analysis raised the 100-hour rupture strength up to at least 40,000 psi as compared with 49,000 psi for the basic alloy.

(3) Simultaneous additions of the three elements in amounts up to 4 percent at least doubled the strength of the 0Mo-0W-0Cb analysis. Such additions did not, however, yield alloys with properties which were outstandingly better than those of the basic alloy.

FIGURE 43.—Summary of influence of variation of individual alloying elements in basic alloy on 100-hour and 1000-hour rupture strengths and 100-hour rupture elongation at 1200° F. Horizontal dashed lines indicate property range for three basic heats.

(4) Additions of Mo and W to 4 percent raised strength progressively. Additions of more than 1 percent of Cb, however, were not beneficial to strength.

(5) Additions of Mo and W had little effect on rupture test elongation. Alloys containing no Cb had consistently low elongation and additions of 1 to 2 percent Cb markedly increased the elongation.

Relation of rupture and creep properties.—It was noted in table X and in the graphs of properties against composition that the stresses causing a minimum creep rate of 0.1 percent per hour were similar in magnitude to the 100-hour rupture strength. In general it was also noted that changes in rupture strength were accompanied by similar changes in creep properties except for alloys with relatively low rupture elongation, particularly alloys not containing Cb, where total elongation appeared to have relatively greater influence on fracture time.

It appears, therefore, that the rupture strengths of the alloys were controlled by their inherent resistance to creep, as measured by the stresses based on minimum creep rates obtained during the rupture test and their total elongation to fracture.

DISCUSSION OF RESULTS

The results indicate that by careful control of processing conditions the high-temperature characteristics of forged Cr-Ni-Co-Fe-Mo-W-Cb alloys can be related to systematic variations of chemical composition and that major changes in rupture characteristics at 1200° F accompany certain variations in composition. A summary of the influence of alloy modification on the 100-hour rupture strength at 1200° F is shown in figure 44 for the elements (Si, Cr, Ni, Co, Mo, W, and Cb) producing significant changes. There were also marked changes with alloy modification in such other metallurgical properties as microstructure, hardness, and melting and forging characteristics which indicate reasons for the observed influence of composition on rupture characteristics.

FIGURE 44.—Summary of influences of alloy modification on 100-hour rupture strength at 1200° F. Horizontal dashed lines indicate property range for three basic heats.

The range in 100-hour rupture properties associated with the composition variables studied was 26,000 to 52,000 psi for the rupture strength and 5 to 40 percent for the rupture elongation. These ranges compare with properties of other heat-resisting alloys as shown in table XI. It is seen that the rupture properties of the basic alloy can be varied over just as large a strength range, but at a higher level, as a result of variations in prior processing as was obtained by composition modifications for a single processing condition. The strength of the modification (0Mo-0W-0Cb) at the low end of the composition strength range is similar in magnitude to strengths of the standard heat-resisting alloys of the 18Cr-8Ni type. Wide property ranges are also shown for seven superalloys studied in a research program on a large number of alloys in which it was found that no accurate comparison could be made between alloys on the basis of chemical composition because prior processing conditions were not controlled. The present investigation has shown that certain variables in melting and hot-working procedures definitely result in major variations in high-temperature properties and that these variations probably cannot be completely removed by subsequent heat treatment.

LIMITATIONS OF DATA

Interpretation of the results can be made only subject to the limitations initially placed on the investigation and those which developed as a result of the investigation. The major limitations which appear to be of significance are listed below:

(1) A limited number of composition variables were studied. Simultaneous variations of elements were made only for Mo, W, and Cb. While certain of the composition variables studied showed significant influences on properties there was only limited indication of what to expect from simultaneous variation of other combinations of the elements in the alloy.

(2) Comparisons between alloys were limited to properties in one condition of prior processing. It was shown that the control exercised over processing was sufficient to obtain reliable reproducibility of properties between heats of the basic alloy. But it was also shown that, unless all the processing procedures, including both melting and hot-working conditions, are controlled, variability in properties may result. Reasons for this variability were not evident from this investigation. The relative influences of processing on alloys other than the basic are not known. Because only one processing condition and heat treatment were used for all the alloys no indication could be obtained of the optimum properties which would be expected for the alloys by variation of treatment.

(3) Limitations are also imposed in the interpretation of the influence of composition on high-temperature characteristics in general by the fact that only one type of test was used to evaluate properties and this at only one temperature. Testing time was also usually limited to that necessary to establish the 100-hour rupture strength.

In the discussion of the results of this investigation cognizance is made of these limitations.

COMPARATIVE RUPTURE AND CREEP CHARACTERISTICS

The main reason for consideration of the creep data from time-elongation curves of the rupture tests was to determine if creep resistance or elongation best correlated with the rupture strengths. It was observed that in general the stresses to cause a creep rate of 0.1 percent per hour were of the same order of magnitude and followed the same trends with composition variation as the 100-hour rupture strengths. The main exception to this observation was in the alloys in which Cb was systematically varied from 0 to 4 percent in which case the stresses for constant creep rates remained constant or decreased with increasing rupture strength (see fig. 36). It seemed apparent, therefore, that the marked influence of Cb additions from 0 to 1 or 2 percent on increasing inherent ductility was responsible for the unusual relation between creep and rupture properties. While stresses at a constant creep rate of 0.1 percent per hour were of the same order of magnitude as the 100-hour rupture strength, these stresses were higher for the 0-percent-Cb alloys (low elongation) and equal to or less than the rupture strength for the 1- and 2-percent-Cb alloys (high elongation). Apparently, therefore, the influence of Cb on changing the rupture strength was less dependent on the resistance to creep, as measured by stress at constant creep rate, than on the relative ability of the alloys to deform before fracture.

Figure 45 shows, for all the alloys studied, the variation of the 100-hour rupture strength with stress to cause a creep rate of 0.1 percent per hour. Average curves are drawn representing the points indicating the low (5 to 10 percent), intermediate (11 to 19 percent), and high (20 to 40 percent) 100-hour rupture-elongation levels encountered. While there are ranges for the rupture-creep property relations it is noted that the range representing high elongations is definitely at a higher level than that representing low elongations. The range for intermediate elongations overlaps both those for high and low elongations. These ranges, while partially the result of variation in actual elongation within the range, particularly at the lower elongations, are believed to be mainly caused by the limitation of the reproducibility of properties from heat to heat of a given analysis and by the fact that the creep properties in many cases were estimated from only a small amount of time-elongation data. Another possible cause of the ranges could be that for certain alloys the stress at constant creep rate is not an accurate representation of the creep resistance.

In general it appears, however, that the stress to cause a creep rate of 0.1 percent per hour is a measure of creep resistance which does control the 100-hour rupture strength, that the relation is linear and represented by a line with a slope of approximately 45°, but that the level of rupture properties at a given creep resistance is dependent upon inherent ability to deform before fracture. Specific examples of the relative dependence of rupture strength on stress at constant creep rate are as follows (see fig. 45):

(1) At a constant 0.1-percent-per-hour creep strength of 45,000 psi (which means all alloys on this vertical 45,000-psi line have constant creep resistance) alloys having high elongation

FIGURE 45.—Influence of creep resistance and 100-hour rupture elongation on 100-hour rupture strength at 1200° F of modified alloys.

will take longer to fracture than those having low elongation. The 100-hour rupture strength will be approximately 5000 psi higher for an alloy with 20-percent or more total elongation than for an alloy with 5- to 10-percent elongation.

(2) The 100-hour rupture strength must remain the same, for example at 45,000 psi, even though the stress at constant creep rate, or creep resistance, decreases by approximately 5000 psi because the ability to deform prior to fracture increases at the same time.

It is noted in figure 45 that the level of the relation between rupture strength and creep resistance is dependent on total elongation only at the lower elongations. The reason for this is the difference between the time-elongation curves for ductile and brittle materials. For ductile materials toward the end of the period of increasing creep rate (third-stage creep) there is a large amount of deformation in a very short time period. In this case the total elongation has a relatively small time dependence, the elongation having little influence on the rupture time. For brittle materials, on the other hand, the elongation change with time is more gradual near the end of the test. Thus with the same creep resistance the rupture time is more dependent on the relative inherent ability of the materials to deform before fracture.

The points in figure 45 that indicate elongations between 5 and 10 percent represent the alloys which did not contain Cb. One point at the highest stress represents the high-Cr alloy which had low ductility. It is evident that the unusual relation between creep and rupture properties observed for alloys in which Cb was varied systematically was the result of the added influence of total elongation on rupture strength.

It can be concluded that the rupture-strength variations with chemical composition observed in this investigation were the result of the changes in inherent creep resistance caused by alloy additions except for composition variations for which total elongation to fracture changed from low (5 to 10 percent) to high (above 20 percent) in which case the greater ability to deform before fracture also improved the rupture strength.

INTERPRETATION OF INFLUENCE OF CHEMICAL-COMPOSITION VARIABLES ON RUPTURE PROPERTIES AT 1200° F OF MODIFIED ALLOYS

Interpretation of the manner in which the composition variations influence the high-temperature properties of these alloys by controlling the inherent creep resistance and the ability to deform before fracture can be made in view of simultaneous effects noted in other metallurgical characteristics. The following observations of such effects were made:

(1) Only the following nine alloys of the 63 different compositions studied developed a pronounced amount of visible microstructural precipitate during aging:

Alloy	Composition variable (percent)
15	0.40C
16	0.60C
52	30Cr
29	0Co
49	3Mo-2W-4Cb
50	3Mo-2W-6Cb
82	2Mo-4W-4Cb
83	4Mo-2W-4Cb
67	4Mo-4W-4Cb

Except for the 30-percent-Cr alloy, the additional precipitate, resulting from either increased C or Cb or decreased Co, did not have any apparent beneficial effect on strength. The matrix precipitate which occurred during aging of the 30-percent-Cr alloy was of a different type from that of other alloys with heavy precipitation, being preferred rather than random. The hardness increase during aging of the 30-percent-Cr alloy was exceptionally large. Thus the substantial strength increase with the addition of Cr from 20 to 30 percent appeared to result, at least in part, from the aging characteristics caused by higher Cr.

(2) Neither Mo nor W, when varied from 0 to 7 percent in the basic alloy containing 1 percent Cb, showed the least effect upon the relative amounts of visible precipitate occurring during aging. However, accompanying the increases in these elements were improvements in creep resistance and rupture strength over the entire composition range. Likewise Mo and W, when varied simultaneously from 0 to 4 percent, produced no increase in amount of visible aging precipitate in alloys containing 2 percent or less of Cb. Creep-resistance and rupture-strength improvements were considerable and continuous in the 20 series of alloys in which either Mo or W was increased systematically. In 16 series of alloys, there was no appreciable change in the effect of these elements on aging precipitate present. The remaining four series were those containing 4 percent Cb, and in these the presence of at least 6 percent total of Mo plus W was necessary to increase the amount of visible aging precipitate. The

elements Mo and W were similar in effect on properties in these systems as in the systems containing lower Cb. However, these high-Cb alloys did not develop an appreciable relative increase in hardness during aging and had a random rather than the preferred matrix precipitate of the high-Cr alloy which apparently derived its superior strength from the aging reaction.

(3) The Cb produced its major improvement in rupture strength in additions of 1 percent to the 0-percent-Cb alloys. This increase in rupture strength appeared to be the result of the higher ductility caused by Cb rather than an improvement in creep resistance, which Cb additions either did not change or reduced. Additions of more than 2 percent Cb did not add anything to rupture strength because creep resistance was not increased and the rupture elongations were all at a high level where changes in total elongation did not appreciably affect fracture time. Microstructural examinations indicated that Cb, or the compound it caused to form, was at most only partially soluble at temperatures up to 2200° F. Limited solubility appeared to be the reason that there was no improvement in creep resistance when Cb was added. The major changes in microstructure caused by Cb—increasing the amount of insoluble constituent, changing the mode of aging precipitation from preferred to random, and refining the grain size—appeared to be associated with the marked increase in rupture elongation resulting from Cb additions. It is noted that low rupture elongation was also associated with the preferred type of aging precipitate in the 30-percent-Cr alloy. Rupture-strength improvements with Cr additions, however, were the result of increased creep resistance which was not the case for the Cb-modified alloys.

Additions of 4 percent or more of Cb in the presence of 6 percent or more of Mo plus W caused a marked increase in the amount of random matrix precipitation during aging. This additional precipitate added nothing to strength and did not appreciably increase the relative hardening during aging. However, the strength increases accompanying additions of Mo and W in this region continued to be consistent with those which appeared to be the result of solid-solution effects for the lower-Cb alloys.

(4) There were certain similarities between the effects of C and Cb on the amount of excess constituents present in the microstructures. While the excess constituents resulting from C and Cb additions were not necessarily the same phases, the appearance of large amounts of excess constituents, both in the solution-treated condition and during aging of the higher-C modifications, had little effect on properties. Apparently C combines with elements normally present in the solid solution to form certain of the observed excess constituents. In view of this the inherent matrix strength of the material should be reduced. This effect appeared to be the case for the 0.60-percent-C alloy which did show a tendency toward lower strength. However, balancing factors, which could hold strength up to a certain extent, could be that some strengthening resulted from the very heavy aging precipitation, or that C did not combine with the major elements causing the strength.

(5) Additions of Co from 0 to 20 percent which tended to raise creep resistance, and thus rupture strength of the alloy, decreased the amount of visible aging precipitate, apparently increasing the solubility of the strengthening elements. Further addition to 32 percent Co increased creep resistance but did not appreciably improve rupture strength because of the lower rupture elongation.

(6) The major strengthening effect of Ni was between 0 and 10 percent. The addition of 10 percent Ni changed the alloy from an unbalanced ferrite-austenite composition of the 0-percent-Ni alloy to the austenitic-matrix-type alloy typical of all the other alloys studied. By preventing the formation of the weak ferrite-sigma-type phase 10 percent Ni caused the elements in this phase to enter the solid solution of the matrix, thus increasing the creep resistance and rupture strength.

Each of the above observations of relations of metallurgical characteristics and high-temperature properties points to the conclusion that the major strengthening effects produced by alloy variations in this investigation were the result of the elements entering into solid solution in the alloys. The two outstanding examples of solid-solution strengthening were for Mo and W. These elements would enter the solid solution by substitution, as also would Cr, Ni, and Co, for atoms of Fe, which they replaced in the alloys. The atoms of Cr, Ni, and Co are all about the same size as Fe atoms and could substitutionally enter the crystal lattice of the solid solution with ease. Substitution of the larger or incongruous atoms of Mo and W into the lattice, however, would necessarily set up a strained condition. Such strains in the lattice would interfere with the flow conditions during creep, thus giving the material higher creep resistance. The role of Cb, which also has relatively large atoms, is complicated by the high affinity of Cb for C and by the apparent low limit of solubility of Cb, or the phase which it forms, in the basic alloy system studied. The substitution of the similarly sized elements, Cr, Ni, or Co, into the lattice would not set up particularly strained conditions and thus strengthening from solid-solution effects would not result. This has also been demonstrated by a recent investigation of Fe-Cr-Ni alloys (reference 2). The effects of Ni and Co on properties and microstructure appeared to be the result of these elements influencing the matrix solubility of other elements, the two most probable other elements being Mo and W. As noted, Cr apparently increased strength, at least in part, by aging effects.

It would appear therefore that as the number of incongruous atoms entering solid solution increased the strength should increase proportionately. The composition modifications studied most thoroughly in this investigation were those involving the simultaneous variation of Mo, W, and Cb. The modifications in which Mo and W additions caused strength increases were pointed out as examples of strengthening as a result of solution effects. Figure 46 shows the influence on the 100-hour rupture strength of total atomic additions of Mo and W to alloys containing four levels of Cb. This figure is similar to the presentation in figure 42 of the

same data on a weight percent basis. The solid-line curves drawn represent the data even better, however, when presented on an atomic percent basis. Trends in the summary curves, with Cb content as a parameter, are the same in both presentations, Cb above 1 percent being of no benefit to strength. In general, the curves in figure 46 show a continuous and approximately proportionate increase in strength with atomic additions of Mo and W. This is consistent with what would be expected if solid-solution effects are responsible for the strength increase.

The points in the graphs of figure 46 have been connected so as to show the comparative effects of Mo and W, the short-dashed lines showing the Mo effects and the long-dashed lines the W effects. There is a general trend indicated by these curves for W to cause a relatively greater strengthening than does Mo. This means that, although the average solid-line curves drawn do represent quite well the data in the graphs for the composition ranges studied, additions of atoms of W to the solid solution had a greater strengthening effect than equivalent atomic additions of Mo.

Exceptions to the solid-solution strengthening effect, particularly that of the 30-percent-Cr alloy, were noted previously. One other major exception, which does not agree with the conclusion that strengthening resulted from solid-solution effects, was that encountered in the influence of Si variations. The effect of Si, varied from 0.5 to 1.6 percent, was to lower strength properties markedly and to increase total deformation to fracture. There was no apparent change in microstructure produced by Si. It was also observed that the high-Si alloy was the only alloy of all those studied which did not show any increase in hardness during aging.

A clue to the apparently anomalous effect of Si is to be found in the results of the effect of deoxidation practice during melting on the properties of the basic alloy. Table VI shows a 100-hour rupture strength of 52,000 psi for alloy 74 which was not deoxidized before pouring. This strength of 52,000 psi is to be compared with the strength range of 48,000 to 50,000 psi for the basic alloy deoxidized in the normal manner with calcium-silicon deoxidant and with the 55,000-psi rupture strength of alloy 75 which was deoxidized with a zirconium-silicon-iron deoxidant. These results indicate that a marked influence may occur on properties of a given alloy as a result of variation of melting procedure. The element Si definitely plays an important role in melting, particularly in deoxidation practice. One heat (alloy 27) in which the charge was aimed at yielding 0.25 percent Si in the basic analysis and which was deoxidized in the normal way with 15 grams of calcium-silicon alloy resulted in 0.58 percent Si and gave properties typical of the basic alloy. Another heat (alloy 79) aimed at 0.25 percent Si, but in which only 5 grams of calcium-silicon deoxidant were used, resulted in a blow hole at the ingot center. It thus appears that inherent characteristics, imparted to the material during melting, not removed by subsequent processing, and not evident in microstructure, could be responsible for the unusually low strengths of the high-Si alloys.

FIGURE 46 —Influence of molybdenum and tungsten additions on a total atomic percent basis on 100-hour rupture strength at 1200° F of columbium modifications.

The basic alloy has been shown by previous investigations to be an alloy which does not develop appreciable strengthening at high temperatures as a result of visible precipitation reactions during aging after solution treatment (references 1 and 3). Evidence presented in this discussion indicates that the major strengthening effects accounting for the good strength of the basic alloy result from additions of incongruous atoms of elements to the solid-solution lattice of the austenite-type matrix.

Another characteristic evaluated for the alloys was the relative forgeability. Although this evaluation was only qualitative the indications were that high-temperature characteristics as measured by rupture tests at 1200° F were in general reflected at temperatures of 1800° to 2200° F in the relative forgeability of the alloys. Alloys which had higher rupture strengths as a result of greater resistance to creep also tended to be less plastic in the forging range. The main exception to this was for Mo additions which apparently did not affect forgeability. The alloys not containing Cb, which had quite low rupture elongation, tended to crack during forging.

OPTIMUM ALLOY CONTENT AND COMPOSITION RANGES

In addition to the main objective of determining the influence of chemical-composition variations on rupture properties at 1200° F, the present investigation was also intended as an initial step toward establishment of optimum compositions for alloys of the basic-alloy type. Interpretation of the results for this purpose, however, is subject to the limitations of the number of compositions studied and the single preparation condition placed on the investigation.

While the over-all property range obtained was quite wide and information was obtained concerning the influence of each element on properties, no alloy was obtained which had properties which were outstanding compared with those of the basic analysis.

It was shown that most of the elements present in this analysis are necessary to yield the best properties, but that variations over relatively wide ranges can be made of one element at a time in the basic analysis without appreciably altering properties. Indications are that Ni can be varied from 10 to 20 percent, C from 0.08 to 0.60 percent, Co from 20 to 32 percent, Cb from 1 to 4 percent, Mn from 0 to 2.5 percent, and N from 0.08 to 0.18 percent in the basic analysis without appreciably affecting properties. It was also shown that Cr, Mo, and W are necessary for maintenance of properties and that Cb in additions not beyond 1 percent is necessary for high ductility characteristics. It is possible, however, to obtain strengths as high or higher than that of the basic alloy without the use of Cb but this involves increasing Mo and W.

Seemingly the only major reduction in required alloy content in the basic alloy, which could be made without appreciably lowering properties, is that Ni could be lowered to 10

percent. Possibly Cb could be decreased a few tenths of a percent below 1.

NATURE OF PHASES PRESENT IN EXPERIMENTAL ALLOYS

As yet little is known concerning the nature of the phases present in alloys of the type investigated. It is generally accepted that the austenite-type matrix is a solid solution which is saturated with respect to certain unidentified constituents at both the solution and aging temperatures. It is also known that Cb, Cr, Mo, and W are prone to form carbides or nitrides under certain conditions and that intermetallic compounds, such as the Fe-Cr sigma phase, and also a ferrite-type phase, are possibilities of microconstituents.

There was a limited amount of evidence gained from the microstructural studies of this investigation concerning the nature of the phases encountered. There is evidence that C entered into the reaction forming the phase which was at least partially insoluble at the solution-treatment temperature and that Cb was the other significant element in the formation of this phase. It also appeared that C was an important constituent of the precipitate which occurred during aging.

Evidently Cr contributed to the formation of the phase which precipitated during aging of the 0Mo-0W-0Cb alloy. It appeared that Cr was also quite important in the aging reaction in the 0-percent-Cb alloys since additions of Mo and W to these alloys did not change the appearance or appreciably affect the amount of aging precipitate.

Additions of Cb from 2 to 4 percent in alloys containing high Mo plus W appreciably increased the amount of aging precipitate. Evidently this occurred as a result of exceeding the solubility limit of the solution which caused the rejection during aging of the excess phase from supersaturated solution. The constituents of this phase were not evident from the data, although there was some indication that Mo and W, which apparently increased strength by substitutional entrance into solid solution, probably were not present in the precipitate. The two examples of this were:

(1) Additions of C to the basic alloy increased aging precipitate but did not appreciably lower strength which would be expected if Mo or W were forced out of solution.

(2) Additions of Cb from 2 to 4 percent in alloys also containing at least 6 percent total of Mo plus W did not affect strength appreciably while increasing the amount of aging precipitate. On the other hand, when Mo or W was raised from 2 to 4 percent in alloys containing 4 percent Cb, producing alloys with more aging precipitate, the strength was improved, indicating that Mo and W went into solution.

In the event Mo and W did maintain strength by remaining in or entering into solid solution, it is probable that Cr or some of the other elements with atoms of similar size to Cr were forced out of solution as carbides or intermetallic compounds.

On the basis of the composition range studied for N, it did not appear that this element appreciably affected the microconstituents.

CONCLUSIONS

By the use of careful control over processing conditions this investigation has shown that for forged alloys containing chromium, nickel, cobalt, iron, molybdenum, tungsten, and columbium it is possible to correlate the stress-rupture properties at 1200° F with systematic variations in chemical composition and that a wide range in properties can be obtained by such variations. However, no alloy was obtained which had properties which were outstanding compared with those of the basic analysis.

Subject to the limitations placed on this investigation of the limited number of composition variables studied, the use of only one condition of processing, the evaluation of high-temperature characteristics by only relatively short-time rupture tests at 1200° F, and the use of only microstructural and hardness data to provide interpretation of results, the findings lead to the following conclusions:

1. Carbon (varied from 0.08 to 0.60 percent), manganese (0 to 2.5 percent), nitrogen (0.08 to 0.18 percent), nickel (10 to 20 percent), cobalt (20 to 32 percent), and columbium (2 to 4 percent) do not appreciably influence 1200° F rupture properties. Nitrogen (0.004 to 0.08 percent), chromium (10 to 30 percent), nickel (0 to 10 percent), cobalt (0 to 20 percent), molybdenum (0 to 4 percent), tungsten (0 to 4 percent), and columbium (0 to 1 percent) improve the rupture strength. Silicon (0.5 to 1.6 percent) and nickel (20 to 30 percent) lower rupture strength.

2. The rupture-strength variations with chemical composition observed in this investigation were the result of changes in inherent creep resistance, caused by alloy additions, except for composition variations for which total elongation to fracture changed from low (5 to 10 percent) to high (above 20 percent), in which case the greater ability to deform before fracture also improved the rupture strength.

3. The rupture-strength improvements accompanying the increased creep resistance with additions of molybdenum and tungsten apparently are the result of the strengthening influence of these incongruous atoms entering substitutionally into the matrix solid solution. Increased creep resist-

ance with nickel and cobalt additions apparently results from the manner in which these elements improve the solubility of molybdenum and tungsten. The increased creep resistance produced by chromium additions apparently results, at least, in part, from an aging reaction. The creep resistance is not influenced by columbium which enters solid solution to only a very limited extent. Improvements in rupture strength with small additions of columbium result from the greater ability to deform before fracture of alloys containing columbium. The detrimental effect of silicon on strength properties is possibly connected with melting phenomena which are not yet understood.

4. Columbium, chromium, and carbon produce major changes in microstructure. There is limited evidence to indicate that these are the major elements in the present excess constituents in the structure of the alloys.

5. Melting and hot-working conditions have an important influence on the inherent high-temperature properties of alloys of the type studied.

(b) Melt data

Time (min)	Operation
0.....	Fe, Cr, Ni, and Co melting stock placed in hot crucible (fifth heat in crucible).
0.....	Power on, 400 volts, 10 kw.
15.....	Charge melted.
17.....	Slag skimmed.
18.....	Mn added.
20.....	Ferrotungsten and ferrocolumbium added.
22.....	Power down to 300 volts, 6 kw.
23.....	15 grams of 30-percent-Ca and 65-percent-Si alloy added to deoxidize.
24.....	Slag skimmed.
25.....	Power off. Bath temperature: Leeds and Northrup optical pyrometer—2860° F. Pt, Pt-Rh immersion thermocouple—2840° F.
27.....	Heat poured.
Cooling-curve data taken on hot-top metal. Temperature halt in curve at 2495° F.

° Blow hole in ingot of low-Mn (18) and low-Si (79) heats.

TABLE IV.—TYPICAL FORGING RECORD

[Alloy 65, 4Mo-0W-2Cb]

(a) Forging operations

Time	Operation
8:25 a. m.	Ingot moved to center of furnace at 2200° F after a preheat near door of furnace.
8:30	Ingot on temperature, 2200° F.
9:05	60 hammer blows between flat dies on square faces of ingot; forging only top half of ingot.
9:20	55 blows between flat dies on square faces; 10 blows between flat dies on corners.
9:32	60 blows between flat dies on square faces; 10 blows between flat dies on corners.
9:45	55 blows between flat dies on square faces; 10 blows between flat dies on corners to approximately 1.10-in.-square bar.
9:54	70 blows in first swage.
10:04	21 blows in first swage to approximately 0.95 in. round; 46 blows in second swage.
10:12	64 blows in second swage.
10:18	65 blows in second swage.
10:27	40 blows in second swage to approximately 0.75 in. round; forged piece cut off from unformed half of ingot; forged piece recharged to furnace.
10:40	65 blows in third swage.
10:45	47 blows in third swage.
10:54	55 blows in third swage.
11:02	55 blows in third swage.
11:10	48 blows in third swage.
11:16	55 blows in third swage to approximately 0.58 in. round; this piece cut in two, both pieces recharged to furnace for forging in the last swage.
11:24	54 blows on bar C, 59 blows on bar D in last swage.
11:30	53 blows on bar C, 55 blows on bar D in last swage.
11:36	45 blows on bar C, 52 blows on bar D in last swage.
11:41	45 blows on bar C, 48 blows on bar D in last swage.
11:47	55 blows on bar C, 56 blows on bar D in last swage.
11:52	60 blows on bar C, 62 blows on bar D in last swage.
11:57	45 blows on bar C, 46 blows on bar D in last swage.
12:02	40 blows on bar C, 35 blows on bar D in last swage, finishing to 0.40 in. round. Finishing temperatures for all forging operations were 1800° F or above as judged by color.

(b) Forging summary

Die	Heatings	Blows
Flat.....	4	260
First swage.....	2	91
Second swage.....	4	215
Third swage.....	6	325
Last swage.....	8	Bar C—397 Bar D—413
Total heatings: 16.		
Total blows:		
Bar C—797.		
Bar D—813.		
Forging range: 2200° to 1800° F.		
Initial size of ingot:		
1.42 in. square tapered to 1.04 in. square.		
8.60 in. long.		
Final size of forged bars:		
Bar C: 0.40 in. round by 19.3 in.		
Bar D: 0.40 in. round by 21.0 in.		
Reduction during forging: 63 percent.		

TABLE V.—FORGING DATA FOR EXPERIMENTAL ALLOYS

Alloy	Bar ^a	Modification from basic alloy (percent)	Total heatings	Approximate total blows	Bar size		Estimated forgeability compared with that of basic alloy

^a Letter designates location of bar in ingot as follows:

Bar A was from bottom quarter of ingot in all cases except 16A, which was from lower middle quarter of ingot

Bar B was from lower middle quarter except 16B, which was from bottom of ingot

Bar D was from upper quarter of ingot

^b All bars were rounds except where squares (sq) are indicated.

TABLE VI.—INFLUENCE OF FORGING AND MELTING VARIABLES ON RUPTURE TEST CHARACTERISTICS AT 1200° F OF BASIC ALLOY ^a

[Heat treatment: 2200° F, 1 hr, water-quenched; 1400° F, 24 hr, air-cooled]

Alloy	Rupture strength (psi)		Estimated 100-hr rupture elongation (percent in 1 in.)	Stress (psi) to cause creep rates of—		Minimum creep rate at 40,000 psi (percent/hr)
	100 hr	1000 hr		0.01 percent/hr	0.1 percent/hr	
Final adopted forging procedure—round bar stock

* Classification key:

Solution-treated structure	Aged structure			
	A. S. T. M. grain size number (GS)	Amount of grain boundary precipitate (GB)	Aging precipitate in matrix (MP): Type *	Amount
Amount of insoluble constituent (IC)				
I—small. II—medium. III—large. IV—very large.	1 (up to 1½ grains/sq in.) 2 to 8 (86 grains or more/sq in.)	x—small. y—medium. z—large.	C—precipitate tends to follow crystallographic planes. R—random precipitate.	a—small. b—medium. c—large. d—very large.

* Ferrite-sigma-type phase in 0-percent-Ni alloy 23. A large amount of precipitate occurred in sigma phase during aging but only a small amount in austenite matrix.

TABLE VIII.—SUMMARY OF INFLUENCE OF ALLOYING ELEMENTS ON INCREASING TENDENCY FOR MICROSTRUCTURAL CHANGES

Alloying element varied	Composition range (percent)	In soluble constituent increase	Grain size decrease	Grain boundary precipitation increase	Mode of matrix precipitation	Amount of matrix precipitation increase
C.....	0.08-0.60	Strong.....	Mild.....	None.....	Random.....	Very strong.
Mn.....	0-2.5	None.....	None.....	None.....	Random.....	None.

Co.....	0-32	None.....	Negative mild.....	None.....	Random.....	Negative mild.
Mo.....	0-4	None.....	Weak.....	None.....	Random ^b	Weak.
W.....	0-4	None.....	Weak.....	None.....	Random ^b	Weak.
Cb.....	0-1	Strong.....	Strong.....	Negative mild.....	Preferred to random.....	Negative mild.
Cb.....	1-4	Strong.....	Mild.....	None.....	Random.....	Mild.
N.....	0.004-0.18	None.....	None.....	None.....	Random.....	None.

^a Ferrite-sigma phase in 0-percent-Ni alloy in air conditions. A large amount of aging precipitate occurred in sigma phase, but only a small amount in austenite matrix.

^b Mode of precipitation not affected by Mo and W. In alloys containing Cb precipitate was random; without Cb precipitate followed a preferred orientation.
